6. A graph G is connected if and only if G cannot be expressed as the union of two or more mutually disjoint connected graphs.

Examples:

1. Consider the complete bipartite graph $K_{3,3} = (V_1 \cup V_2, E)$ with parts $V_1 = \{v_1, v_2, v_3\}$ and $V_2 = \{v_4, v_5, v_6\}$. Then

$$v_1, \{v_1, v_5\}, v_5, \{v_5, v_2\}, v_2, \{v_2, v_6\}, v_6, \{v_6, v_3\}, v_3$$

is a path of length 4 between v_1 and v_3,

$$v_1, \{v_1, v_5\}, v_5, \{v_5, v_2\}, v_2, \{v_2, v_5\}, v_5, \{v_5, v_3\}, v_3$$

is a walk of length 4, which is not a path, and

$$v_1, \{v_1, v_5\}, v_5, \{v_5, v_2\}, v_2, \{v_2, v_6\}, v_6, \{v_6, v_1\}, v_1$$

is a cycle of length 4.

2. Graphs G_1 and G_2 in Figure 39.1 are simple, but G_3 is not.

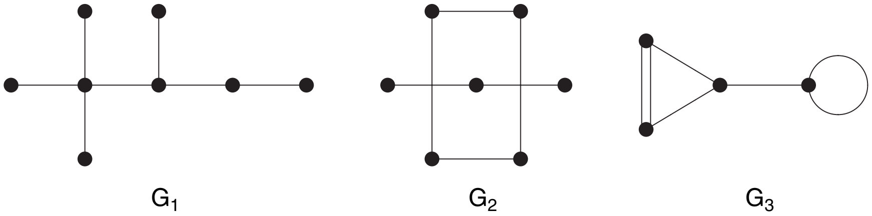

FIGURE 39.1 Three graphs. (Vertices are represented by points and an edge is represented by a line segment between the endpoints, or a loop.)

3. Graphs G_1 and G_2 are bipartite, but G_3 is not.
4. Graph G_1 is a tree. Its diameter equals 4.
5. Graph G_2 is not connected; it is the union of two disjoint graphs, a path P_3 and a cycle C_4. The complement $\overline{G_2}$ is connected and can be expressed as the join of $\overline{P_3}$ and $\overline{C_4}$.
6. Graph G_3 contains three kinds of cycles, cycles of length 3 (corresponding to the two triangles), cycles of length 2 (corresponding to the pair of multiple edges), and one of length 1 (corresponding to the loop).

39.2 Special Graphs

A graph G is **regular** (or **k-regular**) if every vertex of G has the same degree (equal to k).

A graph G is **walk-regular** if for every vertex v the number of walks from v to v of length ℓ depends only on ℓ (not on v).

A simple graph G is **strongly regular** with parameters (n, k, λ, μ) whenever G has n vertices and

- G is k-regular with $1 \leq k \leq n-2$.
- Every two adjacent vertices of G have exactly λ common neighbors.
- Every two distinct nonadjacent vertices of G have exactly μ common neighbors.

An **embedding** of a graph in $\mathbb{R}^n$ consists of a representation of the vertices by distinct points in $\mathbb{R}^n$, and a representation of the edges by curve segments between the endpoints, such that a curve segment intersects another segment or itself only in an endpoint. (A curve segment between $\mathbf{x}$ and $\mathbf{y}$ is the range of a continuous map ϕ from $[0, 1]$ to $\mathbb{R}^n$ with $\phi(0) = \mathbf{x}$ and $\phi(1) = \mathbf{y}$.)

A graph is **planar** if it admits an embedding in $\mathbb{R}^2$.

A graph is **outerplanar** if it admits an embedding in $\mathbb{R}^2$, such that the vertices are represented by points on the unit circle, and the representations of the edges are contained in the unit disc.

A graph G is **linklessly embeddable** if it admits an embedding in $\mathbb{R}^3$, such that no two disjoint cycles of G are linked. (Two disjoint Jordan curves in $\mathbb{R}^3$ are linked if there is no topological 2-sphere in $\mathbb{R}^3$ separating them.)

Deletion of an edge e from a graph $G = (V, E)$ is the operation that deletes e from E and results in the subgraph $G - e = (V, E \setminus \{e\})$ of G.

Deletion of a vertex v from a graph $G = (V, E)$ is the operation that deletes v from V and all edges with endpoint v from E. The resulting subgraph of G is denoted by $G - v$.

Contraction of an edge e of a graph (V, E) is the operation that merges the endpoints of e in V, and deletes e from E.

A **minor** of a graph G is any graph that can be obtained from G by a sequence of edge deletions, vertex deletions, and contractions.

Let G be a simple graph. The **line graph** $L(G)$ of G has the edges of G as vertices, and vertices of $L(G)$ are adjacent if the corresponding edges of G have an endpoint in common.

The **cocktail party graph** $CP(a)$ is the graph obtained by deleting a disjoint edges from the complete graph K_{2a}. (Note that $CP(0)$ is the null graph.)

Let G be a simple graph with vertex set $\{v_1, \ldots, v_n\}$, and let $a_1, \ldots, a_n$ be nonnegative integers. The **generalized line graph** $L(G; a_1, \ldots, a_n)$ consists of the disjoint union of the line graph $L(G)$ and the cocktail party graphs $CP(a_1), \ldots, CP(a_n)$, together with all edges joining a vertex $\{v_i, v_j\}$ of $L(G)$ with each vertex of $CP(a_i)$ and $CP(a_j)$.

Facts:

If no reference is given, the fact is trivial or a classical result that can be found in almost every introduction to graph theory, such as [Har69] or [Wes01].

1. [God93, p. 81] A strongly regular graph is walk-regular.
2. A walk-regular graph is regular.
3. The complement of a strongly regular graph with parameters (n, k, λ, μ) is strongly regular with parameters $(n, n - k - 1, n - 2k + \mu - 2, n - 2k + \lambda)$.
4. Every graph can be embedded in $\mathbb{R}^3$.
5. [RS04] (Robertson, Seymour) For every graph property $\mathcal{P}$ that is closed under taking minors, there exists a finite list of graphs such that a graph G has property $\mathcal{P}$ if and only if no graph from the list is a minor of G.
6. The graph properties planar, outerplanar, and linklessly embeddable are closed under taking minors.
7. (Kuratowski, Wagner) A graph G is planar if and only if no minor of G is isomorphic to K_5 or $K_{3,3}$.
8. [CRS04, p. 8] A regular generalized line graph is a line graph or a cocktail party graph.
9. (Whitney) The line graphs of two connected nonisomorphic graphs G and G' are nonisomorphic, unless $\{G, G'\} = \{K_3, K_{1,3}\}$.

Examples:

1. Graph G_3 of Figure 39.1 is regular of degree 3.

2. The complete graph K_n is walk-regular and regular of degree $n-1$.
3. The complete bipartite graph $K_{k,k}$ is regular of degree k, walk-regular and strongly regular with parameters $(2k, k, 0, k)$.
4. Examples of outerplanar graphs are all trees, C_n, and $\overline{P_5}$.
5. Examples of graphs that are planar, but not outerplanar are: K_4, $CP(3)$, $\overline{C_6}$, and $K_{2,n-2}$ for $n \geq 5$. Examples of graphs that are not planar, but linklessly embeddable are: K_5 and $K_{3,n-3}$ for $n \geq 6$.

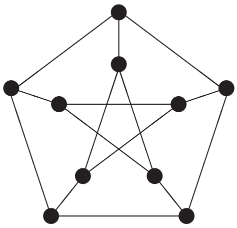

FIGURE 39.2 The Petersen graph.

6. The Petersen graph (Figure 39.2) and K_n for $n \geq 6$ are not linklessly embeddable.
7. The complete graph K_5 can be obtained from the Petersen graph by contraction with respect to five mutually disjoint edges. Therefore, K_5 is a minor of the Petersen graph.
8. The cycle C_9 is a subgraph of the Petersen graph and, therefore, the Petersen graph has every cycle C_ℓ with $\ell \leq 9$ as a minor.
9. Figure 39.3 gives a simple graph G, the line graph $L(G)$, and the generalized line graph $L(G; 2, 1, 0, 0, 0)$ (the vertices of G are ordered from left to right).
10. For $n \geq 4$ and $k \geq 2$ the line graphs $L(K_n)$ and $L(K_{k,k})$ and their complements are strongly regular. The complement of $L(K_5)$ is the Petersen graph.

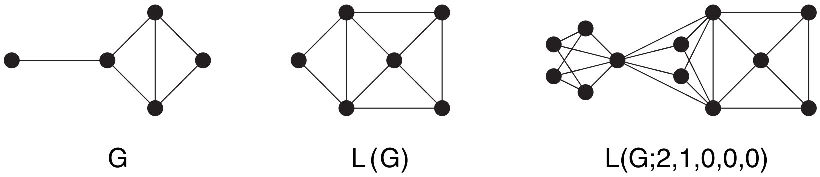

FIGURE 39.3 A graph with its line graph and a generalized line graph.

39.3 The Adjacency Matrix and Its Eigenvalues

Definitions:

The **adjacency matrix** $\mathcal{A}_G$ of a graph G with vertex set $\{v_1, \ldots, v_n\}$ is the symmetric $n \times n$ matrix, whose (i, j)th entry is equal to the number of edges between v_i and v_j.

The **eigenvalues** of a graph G are the eigenvalues of its adjacency matrix.

The **spectrum** $\sigma(G)$ of a graph G is the multiset of eigenvalues (that is, the eigenvalues with their multiplicities).

Two graphs are **cospectral** whenever they have the same spectrum.

A graph G is **determined by its spectrum** if every graph cospectral with G is isomorphic to G.

The **characteristic polynomial** $p_G(x)$ of a graph G is the characteristic polynomial of its adjacency matrix $\mathcal{A}_G$, that is, $p_G(x) = \det(xI - \mathcal{A}_G)$.

A **Hoffman polynomial** of a graph G is a polynomial $h(x)$ of minimum degree such that $h(\mathcal{A}_G) = J$.

The **main angles** of a graph G are the cosines of the angles between the eigenspaces of $\mathcal{A}_G$ and the all-ones vector $\mathbf{1}$.

Facts:

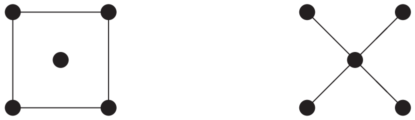
If no reference is given, the fact is trivial or a standard result in algebraic graph theory that can be found in the classical books [Big74] and [CDS80].

1. If $\mathcal{A}_G$ is the adjacency matrix of a simple graph G, then $J - I - \mathcal{A}_G$ is the adjacency matrix of the complement of G.
2. If $\mathcal{A}_G$ and $\mathcal{A}_{G'}$ are adjacency matrices of simple graphs G and G', respectively, then $((\mathcal{A}_G + I) \otimes (\mathcal{A}_{G'} + I)) - I$ is the adjacency matrix of the strong product $G \cdot G'$.
3. Isomorphic graphs are cospectral.
4. Let G be a graph with vertex set $\{v_1, \ldots, v_n\}$ and adjacency matrix $\mathcal{A}_G$. The number of walks of length ℓ from v_i to v_j equals $(\mathcal{A}_G^\ell)_{ij}$, i.e., the i, j-entry of $\mathcal{A}_G^\ell$.
5. The eigenvalues of a graph are real numbers.
6. The adjacency matrix of a graph is diagonalizable.
7. If $\lambda_1 \geq \ldots \geq \lambda_n$ are the eigenvalues of a graph G, then $|\lambda_i| \leq \lambda_1$. If $\lambda_1 = \lambda_2$, then G is disconnected. If $\lambda_1 = -\lambda_n$ and G is not empty, then at least one connected component of G is nonempty and bipartite.
8. [CDS80, p. 87] If $\lambda_1 \geq \ldots \geq \lambda_n$ are the eigenvalues of a graph G, then G is bipartite if and only if $\lambda_i = -\lambda_{n+1-i}$ for $i = 1, \ldots, n$. For more information on bipartite graphs, see Chapter 41.
9. If G is a simple k-regular graph, then the largest eigenvalue of G equals k, and the multiplicity of k equals the number of connected components of G.
10. [CDS80, p. 94] If $\lambda_1 \geq \ldots \geq \lambda_n$ are the eigenvalues of a simple graph G with n vertices and m edges, then $\sum_i \lambda_i^2 = 2m \leq n\lambda_1$. Equality holds if and only if G is regular.
11. [CDS80, p. 95] A simple graph G has a Hoffman polynomial if and only if G is regular and connected.
12. [CRS97, p. 99] Suppose G is a simple graph with n vertices, r distinct eigenvalues $\nu_1, \ldots, \nu_r$, and main angles $\beta_1, \ldots, \beta_r$. Then the complement $\overline{G}$ of G has characteristic polynomial
$$p_{\overline{G}}(x) = (-1)^n p_G(-x-1)\left(1 - n\sum_{i=1}^{r} \beta_i^2/(x+1+\nu_i)\right).$$
13. [CDS80, p. 103], [God93, p. 179] A connected simple regular graph is strongly regular if and only if it has exactly three distinct eigenvalues. The eigenvalues $(\nu_1 > \nu_2 > \nu_3)$ and parameters (n, k, λ, μ) are related by $\nu_1 = k$ and
$$\nu_2, \nu_3 = \frac{1}{2}\left(\lambda - \mu \pm \sqrt{(\mu-\lambda)^2 + 4(k-\mu)}\right).$$
14. [BR91, p. 150], [God93, p. 180] The multiplicities of the eigenvalues ν_1, ν_2, and ν_3 of a connected strongly regular graph with parameters (n, k, λ, μ) are 1 and
$$\frac{1}{2}\left(n - 1 \pm \frac{(n-1)(\mu-\lambda) - 2k}{\sqrt{(\mu-\lambda)^2 + 4(k-\mu)}}\right) \quad \text{(respectively).}$$
15. [GR01, p. 190] A regular connected simple graph with at most four distinct eigenvalues is walk-regular.
16. [CRS97, p. 79] Cospectral walk-regular simple graphs have the same main angles.
17. [Sch73] Almost all trees are cospectral with another tree.

18. [DH03] The number of nonisomorphic simple graphs on n vertices, not determined by the spectrum, is asymptotically bounded from below by $n^3 g_{n-1}(\frac{1}{24} - o(1))$, where g_{n-1} denotes the number of nonisomorphic simple graphs on $n-1$ vertices.
19. [DH03] The complete graph, the cycle, the path, the regular complete bipartite graph, and their complements are determined by their spectrum.
20. [DH03] Suppose G is a regular connected simple graph on n vertices, which is determined by its spectrum. Then also the complement $\overline{G}$ of G is determined by its spectrum, and if $n+1$ is not a square, also the line graph $L(G)$ of G is determined by its spectrum.
21. [CRS04, p. 7] A simple graph G is a generalized line graph if and only if the adjacency matrix $\mathcal{A}_G$ can be expressed as $\mathcal{A}_G = C^T C - 2I$, where C is an integral matrix with exactly two nonzero entries in each column. (It follows that the nonzero entries are ± 1.)
22. [CRS04, p. 7] A generalized line graph has smallest eigenvalue at least -2.
23. [CRS04, p. 85] A connected simple graph with more than 36 vertices and smallest eigenvalue at least -2 is a generalized line graph.
24. [CRS04, p. 90] There are precisely 187 connected regular simple graphs with smallest eigenvalue at least -2 that are not a line graph or a cocktail party graph. Each of these graphs has smallest eigenvalue equal to -2, at most 28 vertices, and degree at most 16.

Examples:

1. Figure 39.4 gives a pair of nonisomorphic bipartite graphs with their adjacency matrices. Both matrices have spectrum $\{2,\ 0^3,\ -2\}$ (exponents indicate multiplicities), so the graphs are cospectral.



$$\begin{bmatrix} 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 \end{bmatrix} \qquad \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix}$$

FIGURE 39.4 Two cospectral graphs with their adjacency matrices.

2. The main angles of the two graphs of Figure 39.4 (with the given ordering of the eigenvalues) are $2/\sqrt{5},\ 1/\sqrt{5},\ 0$ and $3/\sqrt{10},\ 0, 1/\sqrt{10}$, respectively.
3. The spectrum of K_{n_1,n_2} is $\{\sqrt{n_1 n_2},\ 0^{n-2},\ -\sqrt{n_1 n_2}\}$.
4. By Fact 14, the multiplicities of the eigenvalues of any strongly regular graph with parameters $(n, k, 1, 1)$ would be nonintegral, so no such graph can exist (this result is known as the Friendship theorem).
5. The Petersen graph has spectrum $\{3,\ 1^5,\ -2^4\}$ and Hoffman polynomial $(x-1)(x+2)$. It is one of the 187 connected regular graphs with least eigenvalue -2 that is neither a line graph nor a cocktail party graph.

6. The eigenvalues of the path P_n are $2\cos\frac{i\pi}{n+1}$ $(i = 1, \ldots, n)$.
7. The eigenvalues of the cycle C_n are $2\cos\frac{2i\pi}{n}$ $(i = 1, \ldots, n)$.

39.4 Other Matrix Representations

Definitions:

Let G be a simple graph with adjacency matrix $\mathcal{A}_G$. Suppose D is the diagonal matrix with the degrees of G on the diagonal (with the same vertex ordering as in $\mathcal{A}_G$). Then $L_G = D - \mathcal{A}_G$ is the **Laplacian matrix** of G (often abbreviated to the **Laplacian**, and also known as **admittance matrix**), and the matrix $|L_G| = D + \mathcal{A}_G$ is called the **signless Laplacian matrix**.

The **Laplacian eigenvalues** of a simple graph G are the eigenvalues of the Laplacian matrix L_G.

If $\mu_1 \leq \mu_2 \leq \ldots \leq \mu_n$ are the Laplacian eigenvalues of G, then μ_2 is called the **algebraic connectivity** of G. (See Section 39.6.)

Let G be simple graph with vertex set $\{v_1, \ldots, v_n\}$. A symmetric real matrix $M = [m_{ij}]$ is called a **generalized Laplacian** of G, whenever $m_{ij} < 0$ if v_i and v_j are adjacent, and $m_{ij} = 0$ if v_i and v_j are nonadjacent and distinct (nothing is required for the diagonal entries of M).

Let G be a graph without loops with vertex set $\{v_1, \ldots, v_n\}$ and edge set $\{e_1, \ldots, e_m\}$. The **(vertex-edge) incidence matrix** of G is the $n \times m$ matrix N_G defined by $(N_G)_{ij} = 1$ if vertex v_i is an endpoint of edge e_j and $(N_G)_{ij} = 0$ otherwise.

An **oriented (vertex-edge) incidence matrix** of G is a matrix N'_G obtained from N_G by replacing a 1 in each column by a -1, and thereby orienting each edge of G.

If $\mathcal{A}_G$ is the adjacency matrix of a simple graph G, then $S_G = J - I - 2\mathcal{A}_G$ is the **Seidel matrix** of G.

Let G be a simple graph with Seidel matrix S_G, and let I' be a diagonal matrix with ± 1 on the diagonal. Then the simple graph G' with Seidel matrix $S_{G'} = I' S_G I'$ is **switching equivalent** to G. The graph operation that changes G into G' is called **Seidel switching**.

Facts:

In all facts below, G is a simple graph. If no reference is given, the fact is trivial or a classical result that can be found in [BR91].

1. Let G be a simple graph. The Laplacian matrix L_G and the signless Laplacian $|L_G|$ are positive semidefinite.
2. The nullity of L_G is equal to the number of connected components of G.
3. The nullity of $|L_G|$ is equal to the number of connected components of G that are bipartite.
4. [DH03] The Laplacian and the signless Laplacian of a graph G have the same spectrum if and only if G is bipartite.
5. (Matrix-tree theorem) Let G be a graph with Laplacian matrix L_G, and let c_G denote the number of spanning trees of G. Then $\mathrm{adj}(L_G) = c_G J$.
6. Suppose N_G is the incidence matrix of G. Then $N_G N_G^T = |L_G|$ and $N_G^T N_G - 2I = \mathcal{A}_{L(G)}$.
7. Suppose N'_G is an oriented incidence matrix of G. Then $N'_G N'^T_G = L_G$.
8. If $\mu_1 \leq \ldots \leq \mu_n$ are the Laplacian eigenvalues of G, and $\overline{\mu}_1 \leq \ldots \leq \overline{\mu}_n$ are the Laplacian eigenvalues of $\overline{G}$, then $\mu_1 = \overline{\mu}_1 = 0$ and $\overline{\mu}_i = n - \mu_{n+2-i}$ for $i = 2, \ldots, n$.
9. [DH03] If $\mu_1 \leq \ldots \leq \mu_n$ are the Laplacian eigenvalues of a graph G with n vertices and m edges, then $\sum_i \mu_i = 2m \leq \sqrt{n \sum_i \mu_i(\mu_i - 1)}$ with equality if and only if G is regular.

10. [DH98] A connected graph G has at most three distinct Laplacian eigenvalues if and only if there exist integers μ and $\overline{\mu}$, such that any two distinct nonadjacent vertices have exactly μ common neighbors, and any two adjacent vertices have exactly $\overline{\mu}$ common non-neighbors.
11. If G is k-regular and $\mathbf{v} \notin \operatorname{span}\{\mathbf{1}\}$, then the following are equivalent:
    (a) λ is an eigenvalue of $\mathcal{A}_G$ with eigenvector $\mathbf{v}$.
    (b) $k - \lambda$ is an eigenvalue of L_G with eigenvector $\mathbf{v}$.
    (c) $k + \lambda$ is an eigenvalue of $|L_G|$ with eigenvector $\mathbf{v}$.
    (d) $-1 - 2\lambda$ is an eigenvalue of S_G with eigenvector $\mathbf{v}$.
12. [DH03] Consider a simple graph G with n vertices and m edges. Let $\nu_1 \leq \ldots \leq \nu_n$ be the eigenvalues of $|L_G|$, the signless Laplacian of G. Let $\lambda_1 \geq \ldots \geq \lambda_m$ be the eigenvalues of $L(G)$, the line graph of G. Then $\lambda_i = \nu_{n-i+1} - 2$ if $1 \leq i \leq \min\{m, n\}$, and $\lambda_i = -2$ if $\min\{m, n\} < i \leq m$.
13. [GR01, p. 298] Let G be a connected graph, let M be a generalized Laplacian of G, and let $\mathbf{v}$ be an eigenvector for M corresponding to the second smallest eigenvalue of M. Then the subgraph of G induced by the vertices corresponding to the positive entries of $\mathbf{v}$ is connected.
14. The Seidel matrices of switching equivalent graphs have the same spectrum.

Examples:

1. The Laplacian eigenvalues of the Petersen graph are $\{0,\ 2^5,\ 5^4\}$.
2. The two graphs of Figure 39.5 are nonisomorphic, but the Laplacian matrices have the same spectrum. Both Laplacian matrices have $12J$ as adjugate, so both have 12 spanning trees. They are not cospectral with respect to the adjacency matrix because one is bipartite and the other one is not.

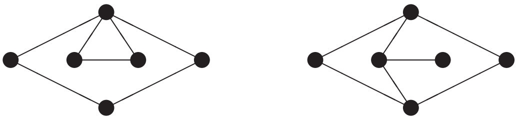


FIGURE 39.5 Graphs with cospectral Laplacian matrices.

3. Figure 39.6 gives two graphs with cospectral signless Laplacian matrices. They are not cospectral with respect to the adjacency matrix because one is bipartite and the other one is not. They also do not have cospectral Laplacian matrices because the numbers of components differ.

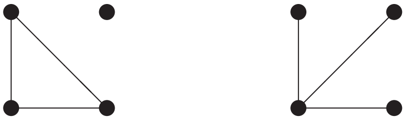

FIGURE 39.6 Graphs with cospectral signless Laplacian matrices.

4. The eigenvalues of the Laplacian and the signless Laplacian matrix of the path P_n are $2 + 2\cos\frac{i\pi}{n}$ $(i = 1, \ldots, n)$.
5. The complete bipartite graph K_{n_1,n_2} is Seidel switching equivalent to the empty graph on $n = n_1 + n_2$ vertices. The Seidel matrices have the same spectrum, being $\{n-1, -1^{n-1}\}$.

39.5 Graph Parameters

Definitions:

A subgraph G' on n' vertices of a simple graph G is a **clique** if G' is isomorphic to the complete graph $K_{n'}$. The largest value of n' for which a clique with n' vertices exists is called the **clique number** of G and is denoted by $\omega(G)$.

An induced subgraph G' on n' vertices of a graph G is a **coclique** or **independent set of vertices** if G' has no edges. The largest value of n' for which a coclique with n' vertices exists is called the **vertex independence number** of G and is denoted by $\iota(G)$. Note that the standard notation for the vertex independence number of G is $\alpha(G)$, but $\iota(G)$ is used here due to conflict with the use of $\alpha(G)$ to denote the algebraic connectivity of G in Chapter 48.

The **Shannon capacity** $\Theta(G)$ of a simple graph G is defined by $\Theta(G) = \sup_\ell \sqrt[\ell]{\iota(G^\ell)}$

A **vertex coloring** of a graph is a partition of the vertex set into cocliques. A coclique in such a partition is called a **color class**.

The **chromatic number** $\chi(G)$ of a graph G is the smallest number of color classes of any vertex coloring of G. (The chromatic number is not defined if G has loops.)

For a simple graph $G = (V, E)$, the **conductance** or **isoperimetric number** $\Phi(G)$ is defined to be the minimum value of $|\partial(V')|/|V'|$ over any subset $V' \subset V$ with $|V'| \leq |V|/2$, where $\partial(V')$ equals the set of edges in E with one endpoint in V' and one endpoint outside V'.

An infinite family of graphs with constant degree and isoperimetric number bounded from below is called a family of **expanders**.

A symmetric real matrix M is said to satisfy the **Strong Arnold Hypothesis** provided there does not exist a symmetric nonzero matrix X with zero diagonal, such that $MX = \mathbf{0}$, $M \circ X = \mathbf{0}$.

The **Colin de Verdière parameter** $\mu(G)$ of a simple graph G is the largest nullity of any generalized Laplacian M of G satisfying the following:

- M has exactly one negative eigenvalue of multiplicity 1.
- The Strong Arnold Hypothesis.

Consider a simple graph G with vertex set $\{v_1, \ldots, v_n\}$. The **Lovász parameter** $\vartheta(G)$ is the minimum value of the largest eigenvalue $\lambda_1(M)$ of any real symmetric $n \times n$ matrix $M = [m_{ij}]$, which satisfies $m_{ij} = 1$ if v_i and v_j are nonadjacent (including the diagonal).

Consider a simple graph G with vertex set $\{v_1, \ldots, v_n\}$. The integer $\eta(G)$ is defined to be the smallest rank of any $n \times n$ matrix M (over any field), which satisfies $m_{ii} \neq 0$ for $i = 1, \ldots, n$ and $m_{ij} = 0$, if v_i and v_j are distinct nonadjacent vertices.

Facts:

In the facts below, all graphs are simple.

1. [Big74, p. 13] A connected graph with r distinct eigenvalues (for the adjacency, the Laplacian or the signless Laplacian matrix) has diameter at most $r - 1$.
2. [CDS80, pp. 90–91], [God93, p. 83] The chromatic number $\chi(G)$ of a graph G with adjacency eigenvalues $\lambda_1 \geq \ldots \geq \lambda_n$ satisfies: $1 - \lambda_1/\lambda_n \leq \chi(G) \leq 1 + \lambda_1$.
3. [CDS80, p. 88] For a graph G, let m_+ and m_- denote the number of nonnegative and nonpositive adjacency eigenvalues, respectively. Then $\iota(G) \leq \min\{m_+, m_-\}$.
4. [GR01, p. 204] If G is a k-regular graph with adjacency eigenvalues $\lambda_1 \geq \ldots \geq \lambda_n$, then $\omega(G) \leq \frac{n(\lambda_2+1)}{n-k+\lambda_2}$ and $\iota(G) \leq \frac{-n\lambda_n}{k-\lambda_n}$.
5. [Moh97] Suppose G is a graph with maximum degree Δ and algebraic connectivity μ_2. Then the isoperimetric number $\Phi(G)$ satisfies $\mu_2/2 \leq \Phi(G) \leq \sqrt{\mu_2(2\Delta - \mu_2)}$.
6. [HLS99] The Colin de Verdière parameter $\mu(G)$ is minor monotonic, that is, if H is a minor of G, then $\mu(H) \leq \mu(G)$.
7. [HLS99] If G has at least one edge, then $\mu(G) = \max\{\mu(H) \mid H \text{ is a component of } G\}$.

8. [HLS99] The Colin de Verdière parameter $\mu(G)$ satisfies the following:
    (a) $\mu(G) \leq 1$ if and only if G is the disjoint union of paths.
    (b) $\mu(G) \leq 2$ if and only if G is outerplanar.
    (c) $\mu(G) \leq 3$ if and only if G is planar.
    (d) $\mu(G) \leq 4$ if and only if G is linklessly embeddable.
9. (Sandwich theorems)[Lov79], [Hae81] The parameters $\vartheta(G)$ and $\eta(G)$ satisfy: $\iota(G) \leq \vartheta(G) \leq \chi(\overline{G})$ and $\iota(G) \leq \eta(G) \leq \chi(\overline{G})$. In all cases strict inequality is possible.
10. [Lov79], [Hae81] The parameters $\vartheta(G)$ and $\eta(G)$ satisfy: $\vartheta(G \cdot H) = \vartheta(G)\vartheta(H)$ and $\eta(G \cdot H) \leq \eta(G)\eta(H)$.
11. [Lov79], [Hae81] The Shannon capacity $\Theta(G)$ of a graph G satisfies: $\iota(G) \leq \Theta(G)$, $\Theta(G) \leq \vartheta(G)$, and $\Theta(G) \leq \eta(G)$. In all cases strict inequality is possible.
12. [Lov79], [Hae81] If G is a k-regular graph with eigenvalues $k = \lambda_1 \geq \ldots \geq \lambda_n$, then $\vartheta(G) \leq -n\lambda_n/(k - \lambda_n)$. Equality holds if G is strongly regular.
13. [Lov79] The Lovász parameter $\vartheta(G)$ can also be defined as the maximum value of $\text{tr}(MJ_n)$, where M is any positive semidefinite $n \times n$ matrix, satisfying $\text{tr}(M) = 1$ and $m_{ij} = 0$ if v_i and v_j are adjacent vertices in G.

Examples:

1. Suppose G is the Petersen graph. Then $\iota(G) = 4$, $\vartheta(G) = 4$ (by Facts 9 and 12). Thus, $\Theta(G) = 4$ (by Fact 11). Moreover, $\chi(G) = 3$, $\chi(\overline{G}) = 5$, and $\mu(G) = 5$ (take $M = L_G - 2I$).
2. The isoperimetric number $\Phi(G)$ of the Petersen graph equals 1. Indeed, $\Phi(G) \geq 1$, by Fact 5, and any pentagon gives $\Phi(G) \leq 1$.
3. $\mu(K_n) = n - 1$ (take $M = -J$).
4. If G is the empty graph with at least two vertices, then $\mu(G) = 1$. (M must be a diagonal matrix with exactly one negative entry, and the Strong Arnold Hypothesis forbids two or more diagonal entries to be 0.)
5. By Fact 12, $\vartheta(C_5) = \sqrt{5}$. If $(v_1, \ldots, v_5)$ are the vertices of C_5, cyclically ordered, then (v_1, v_1), (v_2, v_3), (v_3, v_5), (v_4, v_2), (v_5, v_4) is a coclique of size 5 in $C_5 \cdot C_5$. Thus, $\iota(C_5 \cdot C_5) \geq 5$ and, therefore, $\Theta(C_5) = \sqrt{5}$.

39.6 Association Schemes

Definitions:

A set of graphs $G_0, \ldots, G_d$ on a common vertex set $V = \{v_1, \ldots, v_n\}$ is an **association scheme** if the adjacency matrices $A_0, \ldots, A_d$ satisfy:

- $A_0 = I$.
- $\sum_{i=0}^{d} A_i = J$.
- $\text{span}\{A_0, \ldots, A_d\}$ is closed under matrix multiplication.

The numbers $p_{i,j}^k$ defined by $A_i A_j = \sum_{i=0}^{d} p_{i,j}^k A_k$ are called the **intersection numbers** of the association scheme.

The (associative) algebra spanned by $A_0, \ldots, A_d$ is the **Bose–Mesner algebra** of the association scheme.

Consider a connected graph $G_1 = (V, E_1)$ with diameter d. Define $G_i = (V, E_i)$ to be the graph wherein two vertices are adjacent if their distance in G_1 equals i. If $G_0, \ldots, G_d$ is an association scheme, then G_1 is a **distance-regular graph**.

Let V' be a subset of the vertex set V of an association scheme. The **inner distribution** $\mathbf{a} = [a_0, \ldots, a_d]^T$ of V' is defined by $a_i|V'| = \mathbf{c}^T A_i \mathbf{c}$, where $\mathbf{c}$ is the characteristic vector of V' (that is, $c_i = 1$ if $v_i \in V$ and $c_i = 0$ otherwise).

Facts:

Facts 1 to 7 below are standard results on association schemes that can be found in any of the following references: [BI84], [BCN89], [God93].

1. Suppose $G_0, \ldots, G_d$ is an association scheme. For any three integers $i, j, k \in \{0, \ldots, d\}$ and for any two vertices x and y adjacent in G_k, the number of vertices z adjacent to x in G_i and to y in G_j equals the intersection number p_{ij}^k. In particular, G_i is regular of degree $k_i = p_{ii}^0$ $(i \neq 0)$.
2. The matrices of a Bose–Mesner algebra $\mathcal{A}$ can be diagonalized simultaneously. In other words, there exists a nonsingular matrix S such that SAS^{-1} is a diagonal matrix for every $A \in \mathcal{A}$.
3. A Bose–Mesner algebra has a basis $\{E_0 = \frac{1}{n}J, E_1, \ldots, E_d\}$ of idempotents, that is, $E_i E_j = \delta_{i,j} E_i$ ($\delta_{i,j}$ is the Kronecker symbol).
4. The change-of-coordinates matrix $P = [p_{ij}]$ defined by $A_j = \sum_i p_{ij} E_i$ satisfies:
   (a) p_{ij} is an eigenvalue of A_j with eigenspace range(E_i).
   (b) $p_{i0} = 1$, $p_{0i} = k_i$ (the degree of G_i $(i \neq 0)$).
   (c) $nk_j(P^{-1})_{ji} = m_i p_{ij}$, where $m_i = \text{rank}(E_i)$ (the multiplicity of eigenvalue p_{ij}).
5. (Krein condition) The Bose–Mesner algebra of an association scheme is closed under Hadamard multiplication. The numbers $q_{i,j}^k$, defined by $E_i \circ E_j = \sum_k q_{i,j}^k E_k$, are nonnegative.
6. (Absolute bound) The multiplicities $m_0 = 1, m_1, \ldots, m_d$ of an association scheme satisfy
$$\sum_{k: q_{i,j}^k > 0} m_k \leq m_i m_j \quad \text{and} \quad \sum_{k: q_{i,i}^k > 0} m_k \leq m_i(m_i + 1)/2.$$
7. A connected strongly regular graph is distance-regular with diameter two.
8. [BCN89, p. 55] Let V' be a subset of the vertex set V of an association scheme with change-of-coordinates matrix P. The inner distribution $\mathbf{a}$ of V' satisfies $\mathbf{a}^T P^{-1} \geq \mathbf{0}$.

Examples:

1. The change-of-coordinates matrix P of a strongly regular graph with eigenvalues k, ν_2, and ν_3 is equal to
$$\begin{bmatrix} 1 & k & n-k-1 \\ 1 & \nu_2 & -\nu_2 - 1 \\ 1 & \nu_3 & -\nu_3 - 1 \end{bmatrix}.$$
2. A strongly regular graph with parameters $(28, 9, 0, 4)$ cannot exist because it violates Facts 5 and 6.
3. The Hamming association scheme $H(d, q)$ has vertex set $V = Q^d$, the set of all vectors with d entries from a finite set Q of size q. Two such vectors are adjacent in G_i if they differ in exactly i coordinate places. The graph G_1 is distance-regular. The matrix P of a Hamming association scheme can be expressed in terms of Kravčuk polynomials, which gives
$$p_{ij} = \sum_{k=0}^{j} (-\mathbf{1})^k (q-1)^{j-k} \binom{i}{k} \binom{d-i}{j-k}.$$

4. An error correcting code with minimum distance δ is a subset V' of the vertex set V of a Hamming association scheme, such that V' induces a coclique in $G_1, \ldots, G_{\delta-1}$. If $\mathbf{a}$ is the inner distribution of V', then $a_0 = 1$, $a_1 = \cdots = a_{\delta-1} = 0$, and $|V'| = \sum_i a_i$. Therefore, by Fact 8, the linear programming problem "Maximize $\sum_{i \geq \delta} a_i$, subject to $\mathbf{a}^T P^{-1} \geq 0$ (with $a_0 = 1$ and $a_1 = \cdots = a_{\delta-1} = 0$)" leads to an upper bound for the size of an error correcting code with given minimum distance. This bound is known as Delsarte's Linear Programming Bound.
5. The Johnson association scheme $J(d, \ell)$ has as vertex set V all subsets of size d of a set of size ℓ ($\ell \geq 2d$). Two vertices are adjacent in G_i if the intersection of the corresponding subsets has size $d - i$. The graph G_1 is distance-regular. The matrix P of a Johnson association scheme can be expressed in terms of Eberlein polynomials, which gives:

$$p_{ij} = \sum_{k=0}^{j} (-1)^k \binom{i}{k} \binom{d-i}{j-k} \binom{\ell-d-i}{j-k}.$$

Directed graphs, often called digraphs, have much in common with graphs, which were the subject of the previous chapter. While digraphs are of interest in their own right, and have been the subject of much research, this chapter focuses on those aspects of digraphs that are most useful to matrix theory. In particular, it will be seen that digraphs can be used to understand how the zero-nonzero structure of square matrices affects matrix products, determinants, inverses, and eigenstructure. Basic material on digraphs and their adjacency matrices can be found in many texts on graph theory, nonnegative matrix theory, or combinatorial matrix theory. For all aspects of digraphs, except their spectra, see [BG00]. Perhaps the most comprehensive single source for results, proofs, and references to original papers on the interplay between digraphs and matrices is [BR91, Chaps. 3 and 9]. Readers preferring a matrix analytic rather than combinatorial approach to irreducibility, primitivity, and their consequences, should consult [BP94, Chap. 2].

Digraphs are important tools in many areas of linear algebra both within combinatorial matrix theory (see especially Chapter 47 on spectral graph theory and Chapter 45 on tournaments) and beyond, in areas as diverse as abstract algebra (see Chapter 34 on representations of quivers and mixed graphs) and numerical analysis (see, for example, Chapter 53 on sparse matrix methods).

40.1 Digraphs

Definitions:

A **directed graph** $\Gamma = \Gamma(V, E)$ consists of a finite, nonempty set V of **vertices** (sometimes called **nodes**), together with a subset E of $V \times V$, whose elements are called **arcs** (sometimes called **edges**, **directed edges,** or **directed arcs**).

A **loop** is an arc of the form (v, v) for some vertex v.

If there is more than one arc (u, v) for some u and v in V, then Γ is called a **directed multigraph**.

If there is at most one arc (u, v) for each u and v in V, then Γ is called a **digraph**.

If the digraph Γ contains no loops, then Γ is called a **simple** digraph.

A **weighted digraph** is a digraph Γ with a **weight function** $w : E \to \mathbf{F}$, where the set $\mathbf{F}$ is often the real or complex numbers.

A **subdigraph** Γ' of a digraph Γ is a digraph $\Gamma' = \Gamma'(V', E')$ such that $V' \subseteq V$ and $E' \subseteq E$.

A **proper** subgraph Γ' of a digraph Γ is a subdigraph of Γ such that $V' \subset V$ or $E' \subset E$.

If V' is a nonempty subset of V, then the **vertex induced subdigraph of** Γ **induced by** V' is the digraph with vertex set V' whose arcs are those arcs in E that lie in $V' \times V'$.

A **walk** is a sequence of arcs $(v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$, where one or more vertices may be repeated. If $v_0 = v_k$, the walk is **closed**.

The **length** of a walk is the number of arcs in the walk. (Note that some authors define the length to be the number of vertices rather than the number of arcs.)

A **simple walk** is a walk in which all vertices, except possibly v_0 and v_k, are distinct. (Note that some authors use **path** to mean what we call a simple walk.)

A **cycle** is a simple walk for which $v_0 = v_k$. A cycle of length k, is called a k**-cycle**.

A **generalized cycle** is either a cycle passing through all vertices in V or else a union of cycles such that every vertex in V lies on exactly one cycle.

Let $\Gamma = \Gamma(V, E)$ be a digraph. The **undirected graph** G **associated with the digraph** Γ is the undirected graph with vertex set V, whose edge set is determined as follows: There is an edge between vertices u and v in G if and only if at least one of the arcs (u, v) and (v, u) is present in Γ.

The digraph Γ is **connected** if the associated undirected graph G is connected.

The digraph Γ is a **tree** if the associated undirected graph G is a tree.

The digraph Γ is a **doubly directed tree** if the associated undirected graph is a tree and if whenever (i, j) is an edge in Γ, (j, i) is also an edge in Γ.

Examples:

1. The key distinction between a graph on a vertex set V and a digraph on the same set is that for a graph we refer to the *edge between vertices u and v*, whereas for a digraph, we have two arcs, the *arc from u to v*, and the *arc from v to u*. Thus, there is one connected, simple graph on two vertices, K_2 (see Figure 40.1(a)), but there are three possible connected, simple digraphs on two vertices (see Figure 40.1(b)). Note that all graphs in Figure 40.1 are trees, and that the graph in Figure 40.1(a) is the undirected graph associated with each of the digraphs in Figure 40.1(b). The third graph in Figure 40.1(b) is a doubly directed tree.

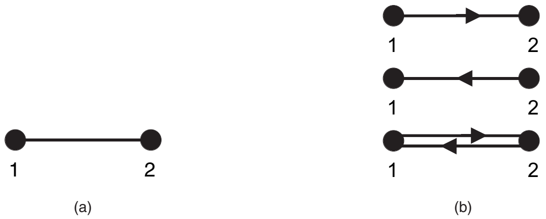

FIGURE 40.1 (a) The unique simple connected graph on two vertices, and (b) three simple connected digraphs on two vertices.

2. Let Γ be the digraph in Figure 40.2. Then $(1,1), (1,1), (1,3), (3,1), (1,2)$ is a walk of length 5 from vertex 1 to vertex 2. $(1,2), (2,3)$ is a simple walk of length 2. $(1,1)$ is a 1-cycle; $(1,3), (3,1)$ is a 2-cycle; and $(1,2), (2,3), (3,1)$ is a 3-cycle. $(1,1), (2,3), (3,2)$ and $(1,2), (2,3), (3,1)$ are two generalized cycles. Not all digraphs contain generalized cycles; consider the digraph obtained by deleting the arc $(2,3)$ from Γ, for example. Unless we are emphasizing a particular vertex on a cycle, such as all cycles starting (and ending) at

vertex v, we view cyclic permutations of a cycle as equivalent. That is, in Figure 40.2, we would speak of *the* 3-cycle, although technically $(1, 2), (2, 3), (3, 1)$; $(2, 3), (3, 1), (1, 2)$; and $(3, 1), (1, 2), (2, 3)$ are distinct cycles.

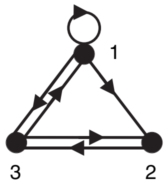

FIGURE 40.2 The digraph in Example 2.

40.2 The Adjacency Matrix of a Directed Graph and the Digraph of a Matrix

If Γ is a directed graph on n vertices, then there is a natural way that we can record the arc information for Γ in an $n \times n$ matrix. Conversely, if A is an $n \times n$ matrix, we can naturally associate a digraph Γ on n vertices with A.

Definitions:

Let Γ be a digraph with vertex set V. Label the vertices in V as $v_1, v_2, \ldots, v_n$. Once the vertices have been ordered, the **adjacency matrix** for Γ, denoted $\mathcal{A}_\Gamma$, is the $0, 1$-matrix whose entries a_{ij} satisfy: $a_{ij} = 1$ if (v_i, v_j) is an arc in Γ, and $a_{ij} = 0$ otherwise. When the set of vertex labels is $\{1, 2, \ldots, n\}$, the default labeling of the vertices is $v_i = i$ for $1 \leq i \leq n$.

Let A be an $n \times n$ matrix. Let V be the set $\{1, 2, \ldots, n\}$. Construct a digraph denoted $\Gamma(A)$ on V as follows. For each i and j in V, let (i, j) be an arc in Γ exactly when $a_{ij} \neq 0$. $\Gamma(A)$ is called the **digraph of the matrix** A. Commonly Γ is viewed as a weighted digraph with weight function $w((i, j)) = a_{ij}$ for all (i, j) with $a_{ij} \neq 0$.

Let A be a square matrix with entries in $\{0, 1, -1\}$ with all entries above the diagonal nonnegative. Suppose $a_{ij} = 1$ if and only if $a_{ji} = -1$ for each pair of indices i and j. Then A is called the **skew adjacency matrix** of the simple, undirected graph G associated with the digraph $\Gamma(A)$.

Facts: [BR91, Chap. 3]

1. If a digraph H is obtained from a digraph Γ by adding or removing an arc, then $\mathcal{A}_H$ is obtained by changing the corresponding entry of $\mathcal{A}_\Gamma$ to a 1 or a 0, respectively. If a digraph H is obtained from a digraph Γ by deleting the i^{th} vertex in the ordered set V and by deleting all arcs in E containing the i^{th} vertex, then $\mathcal{A}_H = \mathcal{A}_\Gamma(i)$. That is, $\mathcal{A}_H$ is obtained by deleting row i and column i of $\mathcal{A}_\Gamma$.
2. Given one ordering of the vertices in V, any other ordering of those vertices is simply a permutation of the original ordering. Since the rows and columns of $A = \mathcal{A}_\Gamma$ are labeled by the ordered vertices, reordering the vertices in Γ corresponds to simultaneously permuting the rows and columns of A. That is, if P is the permutation matrix corresponding to a permutation of the vertices of V, then the new adjacency matrix is PAP^T. Since $P^T = P^{-1}$ for a permutation matrix, all algebraic properties preserved by similarity transformations are invariant under changes of the ordering of the vertices.
3. Let Γ be a digraph with vertex set V. The Jordan canonical form of an adjacency matrix for Γ is independent of the ordering applied to the vertices in V. Consequently, all adjacency matrices for Γ have the same rank, trace, determinant, minimum polynomial, characteristic polynomial, and spectrum.

4. If A is an $n \times n$ matrix and if $v_i = i$ for $1 \leq i \leq n$, then A and $\mathcal{A}_{\Gamma(A)}$ have the same zero-nonzero pattern, and hence, $\Gamma(A) = \Gamma(\mathcal{A}_{\Gamma(A)})$.
5. [CCF12] The spectrum of the skew adjacency matrix can be used to distinguish between members of certain families of cospectral simple graphs.

Examples:

1. For the digraph Γ given in Figure 40.3, if we order the vertices as $v_i = i$ for $i = 1, 2, \ldots, 7$, then

$$A = \mathcal{A}_\Gamma = \begin{bmatrix} 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

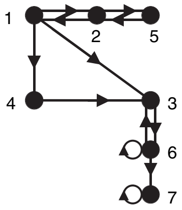

FIGURE 40.3 The digraph Γ for Example 1.

If we reorder the vertices in the graph Γ given in Figure 40.3 so that $v_1, v_2, \cdots, v_7$ is the sequence $1, 2, 5, 4, 3, 6, 7$, then the new adjacency matrix is

$$B = \mathcal{A}_\Gamma = \left[\begin{array}{ccc|c|cc|c} 0 & 1 & 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ \hline 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{array}\right].$$

2. If A is the 3×3 matrix

$$A = \begin{bmatrix} 3 & -2 & 5 \\ 0 & 0 & -11 \\ 9 & -6 & 0 \end{bmatrix},$$

then $\Gamma(A)$ is the digraph given in Figure 40.2. Up to permutation similarity,

$$\mathcal{A}_\Gamma = \begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 0 \end{bmatrix}.$$

3. If A is any symmetric matrix, then the directed graph $\Gamma(A)$ and the undirected graph $G(A)$ coincide under the identification of all pairs of arcs (i, j) and (j, i) in the arc set of $\Gamma(A)$ with the edge (i, j) in the edge set of $G(A)$. Further, since the weights associated with the arcs (i, j) and (j, i) are equal by the symmetry of A, this arc to edge identification transforms

the weighted digraph associated with A to the weighted undirected graph associated with A. Note that when A has a nonzero diagonal entry, both $\Gamma(A)$ and $G(A)$ will have a loop at the corresponding vertex.

40.3 Walk Products and Cycle Products

For a square matrix A, $a_{12}a_{23}$ is nonzero exactly when both a_{12} and a_{23} are nonzero. That is, exactly when both $(1,2)$ and $(2,3)$ are arcs in $\Gamma(A)$. Note also that $a_{12}a_{23}$ is one summand in $(A^2)_{13}$. Consequently, there is a close connection between powers of a matrix A and walks in its digraph $\Gamma(A)$. In fact, the signs (complex arguments) of walk products play a fundamental role in the study of the matrix sign patterns for real matrices (matrix ray patterns for complex matrices). See Chapter 42, [LHE94], or [Stu03].

Definitions:

Let A be an $n \times n$ matrix. Let W given by $(v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$ be a walk in $\Gamma(A)$. The **walk product** for the walk W is

$$\prod_{j=1}^{k} a_{v_{j-1},v_j},$$

and is often denoted by $\prod_W a_{ij}$. This product is a generic summand of the (v_0, v_k)-entry of A^k. If $s_1, s_2 \ldots, s_n$ are scalars, $\prod_W s_i$ denotes the ordinary product of the s_i over the index set $v_0, v_1, v_2, \ldots, v_{k-1}, v_k$.

If W is a cycle in the directed graph $\Gamma(A)$, then the walk product for W is called a **cycle product**.

Let A be an $n \times n$ real or complex matrix. Define $|A|$ to be the matrix obtained from A by replacing a_{ij} with $\left|a_{ij}\right|$ for all i and j.

Facts:

1. Let A be a square matrix. The walk W given by $(v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$ occurs in $\Gamma(A)$ exactly when $a_{v_0 v_1} a_{v_1 v_2} \cdots a_{v_{k-1} v_k}$ is nonzero.
2. [BR91, Sect. 3.4], [LHE94] Let A be a square matrix. For each positive integer k, and for all i and j, the (i,j)-entry of A^k is the sum of the walk products for all length k walks in $\Gamma(A)$ from i to j. Further, there is a walk of length k from i to j in $\Gamma(A)$ exactly when the (i,j)-entry of $|A|^k$ is nonzero.
3. Let A be a square $0,1$-matrix. For each positive integer k, and for each index i, the (i,i)-entry of A^k counts the number of closed walks of length k that originate at vertex i. Consequently, for each positive integer k, the trace of A^k, $tr(A^k)$ counts the number of closed walks of length k in $\Gamma(A)$. When $A = A^T$, $tr(A^k)$ counts the number of undirected, closed walks of length k in the undirected graph $G(A)$.
4. [Cio06], [Dk13] Let A be a square $0,1$-matrix. Since for each positive integer k, the trace of the k^{th} power of a square matrix equals the sum of the k^{th} powers of the eigenvalues of the matrix, it follows that the sum of the k^{th} powers of the eigenvalues of A equals the total number of closed walks of length k in $\Gamma(A)$. The **combinatorial trace method** exploits this relationship to develop results connecting spectral and graphical properties of graphs and digraphs.
5. [BR91, Sect. 3.4], [LHE94] Let A be a square, real or complex matrix. For all positive integers k, $\Gamma(A^k)$ is a subdigraph of $\Gamma(|A|^k)$. Further, $\Gamma(A^k)$ is a proper subgraph of $\Gamma(|A|^k)$ exactly when additive cancellation occurs in summing products for length k walks from some i and j.

6. [LHE94] Let A be a square, real matrix. The sign pattern of the k^{th} power of A is determined solely by the sign pattern of A when the signs of the entries in A are assigned so that for each ordered pair of vertices, all products of length k walks from the first vertex to the second have the same sign.
7. [FP69] Let A and B be square, real matrices with $\Gamma(A) = \Gamma(B)$. There exists a nonsingular, real diagonal matrix D such that $B = DAD^{-1}$ if and only if the cycle product for every cycle in $\Gamma(A)$ equals the cycle product for the corresponding cycle in $\Gamma(B)$.
8. Let A be a real, square matrix. There exists a nonsingular, real diagonal matrix D such that DAD^{-1} is nonnegative if and only if the cycle product for every cycle in $\Gamma(A)$ is positive.

Examples:

1. If $A = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$, then $\left(A^2\right)_{12} = a_{11}a_{12} + a_{12}a_{22} = (1)(1) + (1)(-1) = 0$, whereas $\left(|A|^2\right)_{12} = 2$.
2. If A is the matrix in Example 2 of the previous section, then $\Gamma(A)$ contains four cycles: the loop $(1, 1)$; the two 2-cycles $(1, 3), (3, 1)$ and $(2, 3), (3, 2)$; and the 3-cycle $(1, 2), (2, 3), (3, 1)$. Each of these cycles has a positive cycle product, and using $D = diag(1, -1, 1)$, DAD^{-1} is nonnegative.

40.4 Generalized Cycle Products

If the matrix A is 2×2, then $\det(A) = a_{11}a_{22} - a_{12}a_{22}$. Assuming that the entries of A are nonzero, the two summands $a_{11}a_{22}$ and $a_{12}a_{21}$ are exactly the walk products for the two generalized cycles of $\Gamma(A)$. From Section 4.1, the determinant of an $n \times n$ matrix A is the sum of all terms of the form $(-1)^{sign(\sigma)} a_{1j_1} a_{2j_2} \cdots a_{nj_n}$ where $\sigma = (j_1, j_2, \ldots, j_n)$ is a permutation of the ordered set $\{1, 2, \ldots, n\}$. Such a summand is nonzero precisely when $(1, j_1), (2, j_2), \cdots, (n, j_n)$ are all arcs in $\Gamma(A)$. For this set of arcs, there is exactly one arc originating at each of the n vertices and exactly one arc terminating at each of the n vertices. Hence, the arcs correspond to a generalized cycle in $\Gamma(A)$. See [BR91, Sect. 9.1]. Since the eigenvalues of A are the roots of $\det(\lambda I - A)$, it follows that results connecting the cycle structure of a matrix to its determinant should play a key role in determining the spectrum of the matrix. For further results connecting determinants and generalized cycles, see [MOD89] or [BJ86]. Generalized cycles play a crucial role in the study of the nonsingularity of sign patterns, see Chapter 42 or [Stu91]. In general, there are fewer results for the spectra of digraphs than for the spectra of graphs. There are generalizations of Gerŝgorin's Theorem for spectral inclusion regions for complex matrices that depend on directed cycles. See Section 16.2, [Bru82] or [BR91, Sect. 3.6], or especially, [Var04].

Definitions:

Let A be an $n \times n$ matrix. Let $\sigma = (j_1, j_2, \ldots, j_n)$ be a permutation of the ordered set $\{1, 2, \ldots, n\}$. When (i, j_i) is an arc in $\Gamma(A)$ for each i the cycle or vertex-disjoint union of cycles $(1, j_1), (2, j_2), \ldots, (n, j_n)$ is called the **generalized cycle induced by** σ.

The cycle product or product of cycle products for the cycle(s) comprising the generalized cycle induced by σ is called the **generalized cycle product** corresponding to σ, and the **signed generalized cycle product** is obtained by multiplying this by $(-1)^{n-k}$ where k is the number of disjoint cycles in the generalized cycle induced by σ.

Facts:

1. The entries in A that correspond to a generalized cycle constitute a diagonal of the matrix and vice versa.
2. If σ is a permutation of the ordered set $\{1, 2, \ldots, n\}$, then the nonzero entries of the $n \times n$ permutation matrix P corresponding to σ are precisely the diagonal of P corresponding to the generalized cycle induced by σ.
3. [BR91, Sect. 9.1] Let A be an $n \times n$ real or complex matrix. Then $\det(A)$ is the sum over all permutations of the ordered set $\{1, 2, \ldots, n\}$ of all of the signed generalized cycle products for $\Gamma(A)$. If $\Gamma(A)$ contains no generalized cycle, then A is singular. If $\Gamma(A)$ contains at least one generalized cycle, then A is nonsingular unless additive cancellation occurs in the sum of the signed generalized cycle products.
4. [Cve75] [Har62] Let A be an $n \times n$ real or complex matrix. The coefficient of x^{n-k} in $\det(xI - A)$ is $(-1)^k$ times the sum over all vertex-induced subdigraphs H of $\Gamma(A)$ on k vertices of the signed generalized cycle products for H.
5. [BP94, Chap. 3], [BR97, Sect. 1.8] Let A be an $n \times n$ real or complex matrix. Let g be the greatest common divisor of the lengths of all cycles in $\Gamma(A)$. Then $\det(xI - A) = x^k p\left(x^g\right)$ for some nonnegative integer k and some polynomial $p(z)$ with $p(0) \neq 0$. Consequently, the spectrum of A is invariant under $\frac{2\pi}{g}$ rotations of the complex plane. Further, if A is nonsingular, then g divides n, and $\det(xI - A) = p\left(x^g\right)$ for some polynomial $p(z)$ with $p(0) = (-1)^n \det(A)$.

Examples:

1. If A is the matrix in Example 2 of the previous section, then $\Gamma(A)$ contains two generalized cycles — the loop $(1, 1)$ together with the two 2-cycle $(2, 3), (3, 2)$; and the 3-cycle $(1, 2), (2, 3), (3, 1)$. The corresponding generalized cycle products are $(3)(-11)(-6) = 198$ and $(-2)(-11)(9) = 198$, with corresponding signs -1 and 1, respectively. Thus, $\det(A) = 0$ is a consequence of additive cancellation.
2. If $A = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$, then the only cycles in $\Gamma(A)$ are loops, so $g = 1$. The spectrum of A is clearly invariant under $\frac{2\pi}{g}$ rotations, but it is also invariant under rotations through the smaller angle of π.

40.5 Strongly Connected Digraphs and Irreducible Matrices

Irreducibility of a matrix, which can be defined in terms of permutation similarity (see Section 38.3), and which Frobenius defined as an algebraic property in his extension of Perron's work on the spectra of positive matrices, is equivalent to the digraph property of being strongly connected, defined in this section. Today, most discussions of the celebrated Perron-Frobenius Theorem (see Chapter 10) use digraph theoretic terminology.

Definitions:

Vertex u **has access to** vertex v in a digraph Γ if there exists a walk in Γ from u to v. By convention, every vertex has access to itself even if there is no walk from that vertex to itself.

If u and v are vertices in a digraph Γ such that u has access to v, and such that v has access to u, then u and v are **access equivalent (or** u and v **communicate**).

Access equivalence is an equivalence relation on the vertex set V of Γ that partitions V into **access equivalence classes**.

If V_1 and V_2 are nonempty, disjoint subsets of V, then V_1 **has access to** V_2 if some vertex in v_1 in V_1 has access in Γ to some vertex v_2 in V_2.

For a digraph Γ, the subdigraphs induced by each of the access equivalence classes of V are the **strongly connected components** *of* Γ.

When all of the vertices of Γ lie in a single access equivalence class, Γ is **strongly connected**.

Let $V_1, V_2, \ldots, V_k$ be the access equivalence classes for some digraph Γ. Define a new digraph, $R(\Gamma)$, called the **reduced digraph** (also called the **condensation graph**) for Γ as follows. Let $W = \{1, 2, \ldots, k\}$ be the vertex set for $R(\Gamma)$. If $i, j \in W$ with $i \neq j$, then (i, j) is an arc in $R(\Gamma)$ precisely when V_i has access to V_j.

Facts: [BR91, Chap. 3]

1. [BR91, Sect. 3.1] A digraph Γ is strongly connected if and only if there is a walk from each vertex in Γ to every other vertex in Γ.
2. The square matrix A is irreducible if and only if $\Gamma(A)$ is strongly connected. A reducible matrix A is completely reducible if $\Gamma(A)$ is a disjoint union of two or more strongly connected digraphs. Some authors declare the 1×1 zero matrix to be reducible; in this chapter, we will declare it to be irreducible but restrict many results to $n \times n$ matrices with $n \geq 2$.
3. [BR91, Sect. 3.1] Suppose that V_1 and V_2 are distinct access equivalence classes for some digraph Γ. If any vertex in V_1 has access to any vertex in V_2, then every vertex in V_1 has access to every vertex in V_2. Further, exactly one of the following holds: V_1 has access to V_2, V_2 has access to V_1, or neither has access to the other. Consequently, access induces a partial order on the access equivalence classes of vertices.
4. [BR91, Lemma 3.2.3] For some positive integer k, the access equivalence classes for a digraph Γ can be labeled as $V_1, V_2, \ldots, V_k$ so that whenever there is an arc from a vertex in V_i to a vertex in V_j, $i \leq j$.
5. [Sch86] If Γ is a digraph, then $R(\Gamma)$ is a simple digraph that contains no cycles. Further, the vertices in $R(\Gamma)$ can always be labeled so that if (i, j) is an arc in $R(\Gamma)$, then $i < j$.
6. [BR91, Theorem 3.2.4] Suppose that Γ is not strongly connected. Then there exists at least one ordering of the vertices in V so that $\mathcal{A}_\Gamma$ is block upper triangular where the diagonal blocks of $\mathcal{A}_\Gamma$ are the adjacency matrices of the strongly connected components of Γ.
7. [BR91, Theorem 3.2.4] Let A be a square matrix. Then A has a Frobenius normal form. (See Section 38.3.)
8. The Frobenius normal form of a square matrix A is not necessarily unique. The set of Frobenius normal forms for A is preserved by permutation similarities that correspond to permutations that reorder the vertices within the access equivalence classes of $\Gamma(A)$. If B is a Frobenius normal form for A, then the all edges in $R(\Gamma(B))$ satisfy (i, j) is an edge implies $i < j$. Let σ be any permutation of the vertices of $R(\Gamma(B))$ such that $(\sigma(i), \sigma(j))$ is an edge in $R(\Gamma(B))$ implies $\sigma(i) < \sigma(j)$. Let B be block partitioned by the access equivalence classes of $\Gamma(B)$. Applying the permutation similarity corresponding to σ to the blocks of B produces a Frobenius normal form for A. All Frobenius normal forms for A are produced using combinations of the above two types of permutations.
9. [BR91, Sect. 3.1] [BP94, Chap. 3] Let A be an $n \times n$ matrix for $n \geq 2$. The following are equivalent:
   - (a) A is irreducible.
   - (b) $\Gamma(A)$ is strongly connected.
   - (c) For each i and j, there is a positive integer k such that $(|A|^k)_{ij} > 0$.

(d) There does not exist a permutation matrix P such that

$$PAP^T = \left[\begin{array}{c|c} A_{11} & A_{12} \\ \hline \mathbf{0} & A_{22} \end{array}\right],$$

where A_{11} and A_{22} are square matrices.

10. Let A be a square matrix. A is completely reducible if and only if there exists a permutation matrix P such that PAP^T is a direct sum of at least two irreducible matrices.
11. All combinations of the following transformations preserve irreducibility, reducibility, and complete reducibility: Scalar multiplication by a nonzero scalar; transposition; permutation similarity; left or right multiplication by a nonsingular, diagonal matrix.
12. Complex conjugation preserves irreducibility, reducibility, and complete reducibility for square, complex matrices.

Examples:

1. For the digraph Γ shown in Figure 40.3, vertex 4 has access to itself and to vertices 3, 6, and 7, but not to any of vertices 1, 2, or 5. For this Γ, the access equivalence classes are: $V_1 = \{1, 2, 5\}, V_2 = \{3, 6\}, V_3 = \{4\}$, and $V_4 = \{7\}$. The strongly connected components of Γ are given in Figure 40.4(a) and $R(\Gamma)$ is given in Figure 40.3(b). If the access equivalence classes for Γ are relabeled so that $V_2 = \{4\}$ and $V_3 = \{3, 6\}$, then the labels on vertices 2 and 3 switch in the reduced digraph given in Figure 40.4(b). With this labeling, if (i, j) is an arc in the reduced digraph, then $i \leq j$.

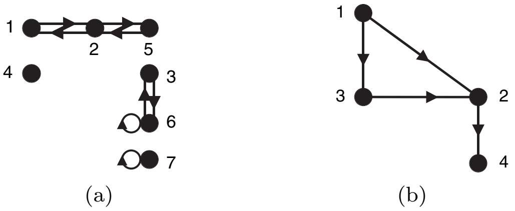

FIGURE 40.4 (a) The strongly connected components of Γ and (b) the reduced digraph $R(\Gamma)$.

2. If A and B are the adjacency matrices of Example 40.2.1, then $A(3, 4, 6, 7) = A[1, 2, 5]$ is the adjacency matrix for the largest strongly connected component of the digraph Γ in Figure 40.3 using the first ordering of V; and using the second ordering of V, B is block-triangular and the irreducible, diagonal blocks of B are the adjacency matrices for each of the four strongly connected components of Γ. B is a Frobenius normal form for A.
3. The matrix A in Example 40.2.2 is irreducible; hence, it is its own Frobenius normal form.

40.6 Primitive Digraphs and Primitive Matrices

Primitive matrices, defined in this section, are necessarily irreducible. Unlike irreducibility, primitivity depends not just on the matrix A but also its powers, and hence, on the signs of the entries of the original matrix. Consequently, most authors restrict discussions of primitivity to nonnegative matrices. Much work has been done on bounding the exponent of a primitive matrix; see [BR91, Sect. 3.5] or [BP94, Sect. 2.4]. One consequence of the fifth fact stated next is that powers of sparse matrices and inverses of sparse matrices can experience substantial fill-in.

Definitions:

A digraph Γ with at least two vertices is **primitive** if there is a positive integer k such that for every pair of vertices u and v (not necessarily distinct), there exists at least one walk of length k from u to v. A digraph on a single vertex is **primitive** if there is a loop on that vertex.

The **exponent** of a digraph Γ (sometimes called **the index of primitivity**) is the smallest value of k that works in the definition of primitivity.

A digraph Γ is **imprimitive** if it is not primitive. This includes the simple digraph on one vertex.

If A is a square, nonnegative matrix such that $\Gamma(A)$ is primitive with exponent k, then A is called a **primitive matrix** *with* **exponent** k.

Facts:

1. A primitive digraph must be strongly connected, but not conversely.
2. A strongly connected digraph with at least one loop is primitive.
3. [BP94, Chap. 3] [BR91, Sects. 3.2 and 3.4] Let Γ be a strongly connected digraph with at least two vertices. The following are equivalent:
   (a) Γ is primitive.
   (b) The greatest common divisor of the cycle lengths for Γ is 1 (i.e., Γ is aperiodic, cf. Section 10.2).
   (c) There is a smallest positive integer k such that for each $t \geq k$ and each pair of vertices u and v in Γ, there is a walk of length t from u to v.
4. [BR91, Sect. 3.5] Let Γ be a primitive digraph with $n \geq 2$ vertices and exponent k. Then
   (a) $k \leq (n-1)^2 + 1$.
   (b) If s is the length of the shortest cycle in Γ, then $k \leq n + s(n-2)$.
   (c) If Γ has $p \geq 1$ loops, then $k \leq 2n - p - 1$.
5. [BR91, Theorem 3.4.4] Let A be an $n \times n$ nonnegative matrix with $n \geq 2$. The matrix A is primitive if and only if there exists a smallest positive integer k such that A^k is positive. When such a positive integer k exists, the smallest such k is the exponent of A. Further, if A^k is positive, then A^h is positive for all integers $h \geq k$. A nonnegative matrix A with the property that some power of A is positive is also called **regular**. See Chapter 10 and Chapter 72 for more information about primitive matrices and their uses.
6. [BP94, Chap. 3] If A is an irreducible, nonnegative matrix with positive trace, then A is primitive.
7. [BP94, Chap. 6] Let A be a nonnegative, tridiagonal matrix with all entries on the first superdiagonal and on the first subdiagonal positive, and at least one entry on the main diagonal positive. Then A is primitive, and hence, some power of A is positive. Further, if $s > \rho(A)$ where $\rho(A)$ is the spectral radius of A, then the tridiagonal matrix $sI - A$ is a nonsingular M-matrix with a positive inverse.

Examples:

1. The digraph Γ in Figure 40.2 is primitive with exponent 3; the strongly connected digraph in Figure 40.1*b* is not primitive.
2. Let $A_1 = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ and let $A_2 = \begin{bmatrix} 1 & -1 \\ 1 & -1 \end{bmatrix}$. Note that $A_1 = |A_2|$. Clearly, $\Gamma(A_1) = \Gamma(A_2)$ is an irreducible, primitive digraph with exponent 1. For all positive integers k, A_1^k is positive, so it makes sense to call A_1 a primitive matrix. In contrast, $A_2^k = \mathbf{0}$ for all integers $k \geq 2$.

40.7 Irreducible, Imprimitive Matrices and Cyclic Normal Form

While most authors restrict discussions of matrices with primitive digraphs to nonnegative matrices, many authors have exploited results for imprimitive digraphs to understand the structure of real and complex matrices with imprimitive digraphs.

Definitions:

Let A be an irreducible $n \times n$ matrix with $n \geq 2$ such that $\Gamma(A)$ is imprimitive. The greatest common divisor $g > 1$ of the lengths of all cycles in $\Gamma(A)$ is called the **index of imprimitivity of** A (or **period** of A).

If there is a permutation matrix P such that

$$PAP^T = \begin{bmatrix} \mathbf{0} & A_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & A_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots & A_{g-1} \\ A_g & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \end{bmatrix},$$

where each of the diagonal blocks is a square zero matrix, then the matrix PAP^T is called a **cyclic normal form** for A.

By convention, when A is primitive, A is said to have index of imprimitivity 1, and A is said to be its own cyclic normal form.

Facts:

1. [BP94, Sect. 2.2] [BR91, Sect. 3.4] [Min88, Sects. 3.3 and 3.4] Let A be an irreducible matrix with index of imprimitivity $g > 1$. Then there exists a permutation matrix P such that PAP^T is a cyclic normal form for A. Further, the cyclic normal form is unique up to cyclic permutation of the blocks A_j and permutations within the partition sets of V of $\Gamma(A)$ induced by the partitioning of PAP^T. Finally, if A is real or complex, then $|A_1|\,|A_2| \cdots |A_g|$ is irreducible and nonzero.
2. [BP94, Sect. 3.3] [BR91, Sect. 3.4] If A is an irreducible matrix with index of imprimitivity $g > 1$, and if there exists a permutation matrix P and a positive integer k such that

$$PAP^T = \begin{bmatrix} \mathbf{0} & A_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & A_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots & A_{k-1} \\ A_k & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \end{bmatrix},$$

   where each diagonal block is square zero matrix, then k divides g. Conversely, if A is real or complex, if PAP^T has the specified form for some positive integer k, if PAP^T has no zero rows and no zero columns, and if $|A_1|\,|A_2| \cdots |A_k|$ is irreducible, then A is irreducible, and k divides g.
3. [BR91, Sect. 3.4] Let A be an irreducible, nonnegative matrix with index of imprimitivity $g > 1$. Let m be a positive integer. Then A^m is irreducible if and only if m and g are relatively prime. If A^m is reducible, then it is completely reducible, and it is permutation similar to a direct sum of r irreducible matrices for some positive

integer r. Further, either each of these summands is primitive (when $g/r = 1$), or each of these summands has index of imprimitivity $g/r > 1$.

4. [Min88, Sect. 3.4] Let A be an irreducible, nonnegative matrix in cyclic normal form with index of imprimitivity $g > 1$. Suppose that for $1 \leq i \leq k-1$, A_i is $n_i \times n_{i+1}$ and that A_g is $n_g \times n_1$. Let $k = \min(n_1, n_2, \ldots, n_g)$. Then 0 is an eigenvalue for A with multiplicity at least $n - gk$; and if A is nonsingular, then each $n_i = n/g$.
5. [Min88, Sect. 3.4] If A is an irreducible, nonnegative matrix in cyclic normal form with index of imprimitivity g, then for $j = 1, 2, \ldots, g$, reading the indices modulo g, $B_j = \prod_{i=j}^{j+g-1} A_i$ is irreducible. Further, all of the matrices B_j have the same nonzero eigenvalues. If the nonzero eigenvalues (not necessarily distinct) of B_1 are $\omega_1, \omega_2, \ldots, \omega_m$ for some positive integer m, then the spectrum of A consists of 0 with multiplicity $n - gm$ together with the complete set of g^{th} roots of each of the ω_i.
6. Let A be a square matrix. Then A has a Frobenius normal form for which each irreducible, diagonal block is in cyclic normal form.
7. Let A be a square matrix. If A is reducible, then the spectrum of A (which is a multiset) is the union of the spectra of the irreducible, diagonal blocks of any Frobenius normal form for A.
8. Explicit, efficient algorithms for computing the index of imprimitivity and the cyclic normal form for an imprimitive matrix and for computing the Frobenius normal form for a matrix can be found in [BR91, Sect. 3.7].
9. All results stated here for block upper triangular forms have analogs for block lower triangular forms.

Examples:

1. If A is the 4×4 matrix $A = \begin{bmatrix} \mathbf{0} & A_1 \\ A_2 & \mathbf{0} \end{bmatrix}$, where $A_1 = I_2$ and $A_2 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$, then A and $A_1A_2 = A_2$ are irreducible but $g \neq 2$. In fact, $g = 4$ since A is actually a permutation matrix corresponding to the permutation (1324). Also note that when $A_1 = A_2 = I_2$, A is completely reducible since $\Gamma(A)$ consists of two disjoint cycles.
2. If M is the irreducible matrix $M = \begin{bmatrix} 0 & -1 & 0 & -1 \\ 6 & 0 & 3 & 0 \\ 0 & 2 & 0 & 2 \\ 6 & 0 & 3 & 0 \end{bmatrix}$, then $g = 2$, and using the permutation matrix $Q = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}$, $N = QMQ^T = \left[\begin{array}{cc|cc} 0 & 0 & 3 & 6 \\ 0 & 0 & 3 & 6 \\ \hline 2 & 2 & 0 & 0 \\ -1 & -1 & 0 & 0 \end{array}\right]$ is a cyclic normal form for M. Note that $|N_1|\,|N_2| = \begin{bmatrix} 3 & 6 \\ 3 & 6 \end{bmatrix} \begin{bmatrix} 2 & 2 \\ 1 & 1 \end{bmatrix} = \begin{bmatrix} 12 & 12 \\ 12 & 12 \end{bmatrix}$ is irreducible even though $N_1N_2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$ is not irreducible.
3. The matrix B in Example 40.2.1 is a Frobenius normal form for the matrix A in that example. Observe that B_{11} is imprimitive with $g = 2$, but B_{11} is not in cyclic normal form. The remaining diagonal blocks, B_{22} and B_{33}, have primitive digraphs; hence, they are in cyclic normal form. Let $Q = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}$. Then $QB_{11}Q^T = \left[\begin{array}{c|cc} 0 & 3 & 6 \\ \hline 2 & 0 & 0 \\ -1 & 0 & 0 \end{array}\right]$ is a cyclic normal form for B_{11}. Using the permutation matrix $P = Q \bigoplus I_1 \bigoplus I_2 \bigoplus I_1$, PBP^T is a Frobenius normal form for A with each irreducible, diagonal block in cyclic normal form.

4. Let $A = \begin{bmatrix} 2 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 3 \end{bmatrix}$ and let $B = \begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 0 \\ 0 & 0 & 3 \end{bmatrix}$. Observe that A and B are each in Frobenius normal form, each with two irreducible, diagonal blocks, and that $A_{11} = B_{11}$ and $A_{22} = B_{22}$. Consequently, $\sigma(A) = \sigma(B) = \sigma(A_{11}) \cup \sigma(A_{22}) = \{1, 3, 3\}$. However, B has only one independent eigenvector for eigenvalue 3, whereas A has two independent eigenvectors for eigenvalue 3. The underlying cause for this difference is the difference in the access relations as captured in the reduced digraphs $R(\Gamma(A))$ (two isolated vertices) and $R(\Gamma(B))$ (two vertices joined by a single arc). The role that the reduced digraph of a matrix plays in connections between the eigenspaces for each of the irreducible, diagonal blocks of a matrix and those of the entire matrix is discussed in [Sch86] and in [BP94, Theorem 2.3.20]. For connections between $R(\Gamma(A))$ and the structure of the generalized eigenspaces for A, see also [Rot75].

40.8 Minimally Connected Digraphs and Nearly Reducible Matrices

Replacing zero entries in an irreducible matrix with nonzero entries preserves irreducibility, and equivalently, adding arcs to a strongly connected digraph preserves strong connectedness. Consequently, it is of interest to understand how few nonzero entries are needed in a matrix and in what locations to guarantee irreducibility; or equivalently, how few arcs are needed in a digraph and between which vertices to guarantee strong connectedness. Except as noted, all of the results in this section can be found in both [BR91, Sect. 3.3] and [Min88, Sect. 4.5]. Further results on nearly irreducible matrices and on their connections to nearly decomposable matrices can be found in [BH79].

Definitions:

A digraph is **minimally connected** if it is strongly connected and if the deletion of any arc in the digraph produces a subdigraph that is not strongly connected.

A matrix is **nearly reducible** if it is irreducible and if the replacement of any nonzero entry in the matrix with zero produces a reducible matrix.

Facts:

1. A digraph Γ is minimally connected if and only if $\mathcal{A}_\Gamma$ is nearly reducible.
2. A matrix A is nearly reducible if and only if $\Gamma(A)$ is minimally connected.
3. The only minimally connected digraph on one vertex is the simple digraph on one vertex.
4. The only nearly reducible 1×1 matrix is the zero matrix.
5. [BR91, Theorem 3.3.5] Let Γ be a minimally connected digraph on n vertices with $n \geq 2$. Then Γ has no loops, at least n arcs, and at most $2(n-1)$ arcs. When Γ has exactly n arcs, Γ is an n-cycle. When Γ has exactly $2(n-1)$ arcs, Γ is a doubly directed tree.
6. Let A be an $n \times n$ nearly reducible matrix with $n \geq 2$. Then A has no nonzeros on its main diagonal, A has at least n nonzero entries, and A has at most $2(n-1)$ nonzero entries. When A has exactly n nonzero entries, $\Gamma(A)$ is an n-cycle. When A has exactly $2(n-1)$ nonzero entries, $\Gamma(A)$ is a doubly directed tree.
7. [Min88, Theorem 4.5.1] Let A be an $n \times n$ nearly reducible matrix with $n \geq 2$. Then there exists a positive integer m and a permutation matrix P such that

$$PAP^T = \left[\begin{array}{ccccc|c} 0 & 1 & 0 & \cdots & 0 & \mathbf{0}^T \\ 0 & 0 & 1 & \cdots & 0 & \mathbf{0}^T \\ \vdots & \vdots & \ddots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 0 & 1 & \mathbf{0}^T \\ 0 & 0 & \cdots & 0 & 0 & \mathbf{v}^T \\ \hline \mathbf{u} & \mathbf{0} & \cdots & \mathbf{0} & \mathbf{0} & B \end{array}\right],$$

where the upper left matrix is $m \times m$, B is nearly reducible, $\mathbf{0}$ is an $(n-m) \times 1$ vector, both of the vectors $\mathbf{u}$ and $\mathbf{v}$ are $(n-m) \times 1$, and each of $\mathbf{u}$ and $\mathbf{v}$ contains a single nonzero entry.

Examples:

1. Let Γ be the third digraph in Figure 40.1*b*. Then Γ is minimally connected. The subdigraph Γ' obtained by deleting arc $(1,2)$ from Γ is no longer strongly connected. However, it is still connected since its associated undirected graph is the graph in Figure 40.1*a*.
2. For $n \geq 1$, let $A^{(n)}$ be the $(n+1) \times (n+1)$ matrix be given by

$$A^{(n)} = \left[\begin{array}{c|cccc} 0 & 1 & 1 & \cdots & 1 \\ \hline 1 & & & & \\ 1 & & & & \\ \vdots & & & \mathbf{0}_{n\times n} & \\ 1 & & & & \end{array}\right].$$

Then $A^{(n)}$ is nearly reducible. The digraph $\Gamma(A^{(n)})$ is called a *rosette*, and has the most arcs possible for a minimally connected digraph on $n+1$ vertices. Suppose that $n \geq 2$, and let $P = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \bigoplus I_{n-2}$. Then

$$PA^{(n)}P^T = \left[\begin{array}{c|cccc} 0 & 1 & 0 & \cdots & 0 \\ \hline 1 & & & & \\ 0 & & & & \\ \vdots & & & A^{(n-1)} & \\ 0 & & & & \end{array}\right]$$

is the decomposition for $A^{(n)}$ given in Fact 7 with $m = 1$.

University of Wyoming

41.1 Basics of Bipartite Graphs 41-1
41.2 Bipartite Graphs Associated with Matrices 41-4
41.3 Factorizations and Bipartite Graphs 41-8
References 41-11

An $m \times n$ matrix is naturally associated with a bipartite graph, and the structure of the matrix is reflected by the combinatorial properties of the associated bipartite graph. This chapter discusses the fundamental structural theorems for matrices that arise from this association, and describes their implications for linear algebra.

41.1 Basics of Bipartite Graphs

This section introduces the various properties and families of bipartite graphs that have special significance for linear algebra.

Definitions:

A graph G is **bipartite** provided its vertices can be partitioned into disjoint subsets U and V such that each edge of G has the form $\{u, v\}$, where $u \in U$ and $v \in V$. The set $\{U, V\}$ is a **bipartition** of G.

A **complete bipartite graph** is a simple bipartite graph with bipartition $\{U, V\}$ such that each $\{u, v\}$ ($u \in U$, $v \in V$) is an edge. The complete bipartite graph with $|U| = m$ and $|V| = n$ is denoted by $K_{m,n}$.

A **chordal graph** is one in which every cycle of length 4 or more has a chord, that is, an edge joining two nonconsecutive vertices on the cycle.

A **chordal bipartite graph** is a bipartite graph in which every cycle of length 6 or more has a chord.

A bipartite graph is **quadrangular** provided it is simple and each pair of vertices with a common neighbor lies on a cycle of length 4.

A **weighted bipartite graph** consists of a simple bipartite graph G and a function $w : E \to X$, where E is the edge set of G and X is a set (usually $\mathbb{Z}$, $\mathbb{R}$, $\mathbb{C}$, $\{-1, 1\}$, or a set of indeterminates). A **signed bipartite graph** is a weighted bipartite graph with $X = \{-1, 1\}$. In a signed bipartite graph, the **sign** of a set α of edges, denoted $\operatorname{sgn}(\alpha)$, is the product of the weights of the edges in α. The set α is **positive** or **negative** depending on whether $\operatorname{sgn}(\alpha)$ is $+1$ or -1.

Let G be a bipartite graph with bipartition $\{U, V\}$ and let u_1, u_2, …, u_m and v_1, v_2, …, v_n be orderings of the distinct elements of U and V, respectively. The **biadjacency matrix** of G is the $m \times n$ matrix $\mathcal{B}_G = [b_{ij}]$, where b_{ij} is the multiplicity of the edge $\{u_i, v_j\}$. Note that if U, respectively, V, is empty, then $\mathcal{B}_G$ is a matrix with no rows, respectively, no columns. For a weighted bipartite graph, b_{ij} is defined to be the weight of the edge $\{u_i, v_j\}$ if present, and 0 otherwise. For a signed bipartite graph, b_{ij} is the sign of the edge $\{u_i, v_j\}$ if present, and 0 otherwise.

Let N'_G be an oriented incidence matrix of simple graph G. The **cut space** of G is the column space of ${N'_G}^T$, and the **cut lattice** of G is the set of integer vectors in the cut space of G. The **flow space** of G is $\{x \in \mathbb{R}^m : N'_G x = 0\}$, and the **flow lattice** of G is $\{x \in \mathbb{Z}^m : N'_G x = 0\}$.

A **matching** of G is a set M of mutually disjoint edges. If M has k edges, then M is a **k-matching**, and if each vertex of G is in some (and hence exactly one) edge of M, then M is a **perfect matching**.

Facts:

Unless otherwise noted, the following can be found in [BR91, Chap. 3] or [Big93]. In the references, the results are stated and proven for simple graphs, but still hold true for graphs.

1. A bipartite graph has no loops. It has more than one bipartition if and only if the graph is disconnected. Each forest (and, hence, each tree and each path) is bipartite. The cycle C_n is bipartite if and only if n is even.
2. The following statements are equivalent for a graph G:
   (a) G is bipartite.
   (b) The vertices of G can be labeled with the colors red and blue so that each edge of G has a red vertex and a blue vertex.
   (c) G has no cycles of odd length.
   (d) There exists a permutation matrix P such that $P^T \mathcal{A}_G P$ has the form
   $$\begin{bmatrix} O & B \\ B^T & O \end{bmatrix}.$$
   (e) G is loopless and every minor of the vertex-edge incidence matrix N_G of G is 0, 1, or -1.
   (f) The characteristic polynomial $p_{\mathcal{A}_G}(x) = \sum_{i=0}^{n} c_i x^{n-i}$ of $\mathcal{A}_G$ satisfies $c_k = 0$ for each odd integer k.
   (g) $\sigma(G) = -\sigma(G)$ (as multisets), where $\sigma(G)$ is the spectrum of $\mathcal{A}_G$.
3. The connected graph G is bipartite if and only if $-\rho(\mathcal{A}_G)$ is an eigenvalue of $\mathcal{A}_G$.
4. The bipartite graph G is disconnected if and only if there exist permutation matrices P and Q such that $P\mathcal{B}_G Q$ has the form
   $$\begin{bmatrix} B_1 & O \\ O & B_2 \end{bmatrix},$$
   where both B_1 and B_2 have at least one column or at least one row. More generally, if G is bipartite and has k connected components, then there exist permutation matrices P and Q such that
   $$P\mathcal{B}_G Q = \begin{bmatrix} B_1 & O & \cdots & O \\ O & B_2 & \cdots & O \\ \vdots & \vdots & \ddots & \vdots \\ O & O & \cdots & B_k \end{bmatrix},$$
   where the B_i are the biadjacency matrices of the connected components of G.

5. [GR01] If G is a simple graph with n vertices, m edges, and c components, then its cut space has dimension $n-c$, and its flow space has dimension $m-n+c$. If G is a plane graph, then the edges of G can be oriented and ordered so that the flow space of G equals the cut space of its dual graph. The norm, $\mathbf{x}^T\mathbf{x}$, is even for each vector $\mathbf{x}$ in the cut lattice of G if and only if each vertex has even degree. The norm of each vector in the flow lattice of G is even if and only if G is bipartite.
6. [Bru66], [God85], [Sim89] Let G be a bipartite graph with a unique perfect matching. Then there exist permutation matrices P and Q such that $P\mathcal{B}_G Q$ is a square, lower triangular matrix with all 1s on its main diagonal. If G is a tree, then the inverse of $P\mathcal{B}_G Q$ is a $(0,1,-1)$-matrix. Let n be the order of $\mathcal{B}_G$, and let H be the simple graph with vertices $1,2,\ldots,n$ and $\{i,j\}$ an edge if and only if $i\neq j$ and either the (i,j)- or (j,i)-entry of $P\mathcal{B}_G Q$ is nonzero. If H is bipartite, then $(P\mathcal{B}_G Q)^{-1}$ is diagonally similar to a nonnegative matrix, which equals $P\mathcal{B}_G Q$ if and only if G can be obtained by appending a pendant edge to each vertex of a bipartite graph.

Examples:

1. Up to matrix transposition and permutations of rows and columns, the biadjacency matrix of the path P_{2n}, the path P_{2n+1}, and the cycle C_{2n} are

$$\begin{bmatrix} 1 & 1 & 0 & \cdots & 0 \\ 0 & 1 & 1 & \cdots & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 1 \\ 0 & 0 & \cdots & 0 & 1 \end{bmatrix}_{n\times n}, \quad \begin{bmatrix} 1 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & 1 & \cdots & 0 & 0 \\ \vdots & & \ddots & \ddots & \vdots & 0 \\ 0 & 0 & \cdots & 1 & 1 & 0 \\ 0 & 0 & \cdots & 0 & 1 & 1 \end{bmatrix}_{n\times(n+1)}, \quad \begin{bmatrix} 1 & 1 & 0 & \cdots & 0 \\ 0 & 1 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 1 \\ 1 & 0 & \cdots & 0 & 1 \end{bmatrix}_{n\times n}.$$

2. The biadjacency matrix of the complete bipartite graph $K_{m,n}$ is $J_{m,n}$, the $m\times n$ matrix of all ones.
3. Up to row and column permutations, the biadjacency matrix of the graph obtained from $K_{n,n}$ by removing the edges of a perfect matching is $J_n - I_n$.

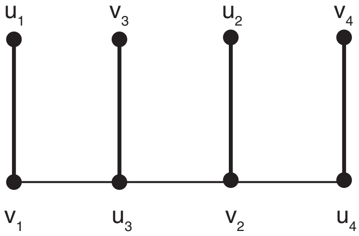

FIGURE 41.1 The graph for Example 4.

4. Let G be the bipartite graph shown in Figure 41.1.
Then

$$\mathcal{B}_G = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}$$

G has a unique perfect matching, and the graph H defined in Fact 6 is the path 1–3–2–4. Hence, $\mathcal{B}_G$ is diagonally similar to a nonnegative matrix. Also, since G is obtained from the bipartite graph v_1—u_3—v_2—u_4 by appending pendant vertices to each vertex, $\mathcal{B}_G^{-1}$ is diagonally similar to $\mathcal{B}_G$. Indeed,

$$S\mathcal{B}_G^{-1}S = S \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ -1 & -1 & 1 & 0 \\ 0 & -1 & 0 & 1 \end{bmatrix} S^{-1} = \mathcal{B}_G,$$

where S is the diagonal matrix with main diagonal $(1, 1, -1, -1)$.

41.2 Bipartite Graphs Associated with Matrices

This section presents some of the ways that matrices have been associated with bipartite graphs and surveys resulting consequences.

Definitions:

The **bigraph** of the $m \times n$ matrix $A = [a_{ij}]$ is the simple graph with vertex set $U \cup V$, where $U = \{1, 2, \ldots, m\}$ and $V = \{1', 2', \ldots, n'\}$, and edge set $\{\{i, j'\} : a_{ij} \neq 0\}$. If A is a nonnegative integer matrix, then the **multi-bigraph** of A has vertex set $U \cup V$ and edge $\{i, j'\}$ of multiplicity a_{ij}. If A is a general matrix, then the **weighted bigraph** of A has vertex set $U \cup V$ and edge $\{i, j'\}$ of weight a_{ij}. If A is a real matrix, then the **signed bigraph** of A is obtained by weighting the edge $\{i, j'\}$ of the bigraph by $+1$ if $a_{ij} > 0$, and by -1 if $a_{ij} < 0$.

The **(zero) pattern** of the $m \times n$ matrix $A = [a_{ij}]$ is the $m \times n$ $(0, 1)$-matrix whose (i, j)-entry is 1 if and only if $a_{ij} \neq 0$.

The **sign pattern** of the real $m \times n$ matrix $A = [a_{ij}]$ is the $m \times n$ matrix whose (i, j)-entry is $+$, 0, or $-$, depending on whether a_{ij} is positive, zero, or negative. (See Chapter 42 for more information on sign patterns.)

A $(0, 1)$-matrix is a **Petrie matrix** provided the 1s in each of its columns occur in consecutive rows. A $(0, 1)$-matrix A has the **consecutive ones property** if there exists a permutation P such that PA is a Petrie matrix.

The **directed bigraph** of the real $m \times n$ matrix $A = [a_{ij}]$ is the directed graph with vertices $1, 2, \ldots, m$, $1', 2', \ldots, n'$, the arc (i, j') if and only if $a_{ij} > 0$, and the arc (j', i) if and only if $a_{ij} < 0$.

An $m \times n$ matrix A is a **generic matrix** with respect to the field F provided its nonzero elements are independent indeterminates over the field F. The matrix A can be viewed as a matrix whose elements are in the ring of polynomials in these indeterminates with coefficients in F.

Let A be an $n \times n$ matrix with each diagonal entry nonzero. The **bipartite fill-graph** of A, denoted $G^+(A)$, is the simple bipartite graph with vertex set $\{1, 2, \ldots, n\} \cup \{1', 2', \ldots, n'\}$ with an edge joining i and j' if and only if there exists a path from i to j in the digraph, $\Gamma(A)$, of A each of whose intermediate vertices has label less than $\min\{i, j\}$. If A is symmetric, then (by identifying vertices i and i' for $i = 1, 2, \ldots, n$ and deleting loops), $G^+(A)$ can be viewed as a simple graph, and is called the **fill-graph** of A.

The square matrix B has a **perfect elimination ordering** provided there exist permutation matrices P and Q such that the bipartite fill-graph, $G^+(PBQ)$, and the bigraph of PBQ are the same.

Associated with the $n \times n$ matrix $A = [a_{ij}]$ is the sequence H_0, H_1, $\ldots$, H_{n-1} of bipartite graphs defined by:

1. H_0 consists of vertices $1, 2, \ldots, n$, and $1', 2', \ldots, n'$, and edges of the form $\{i, j'\}$, where $a_{ij} \neq 0$.
2. For $k = 1, \ldots, n-1$, H_k is the graph obtained from H_{k-1} by deleting vertices k and k' and inserting each edge of the form $\{r, c'\}$, where $r > k$, $c > k$, and both $\{r, k'\}$ and $\{k, c'\}$ are edges of H_{k-1}.

The **4-cockades** are the bipartite graphs recursively defined by the following: A 4-cycle is a 4-cockade, and if G is a 4-cockade and e is an edge of G, then the graph obtained from G by identifying e with an edge of a 4-cycle disjoint from G is a 4-cockade. A **signed 4-cockade** is a 4-cockade whose edges are weighted by ± 1 in such a way that every 4-cycle is negative.

Facts:

General references for bipartite graphs associated with matrices are [BR91, Chap. 3] and [BS04].

1. [Rys69] (See also [BR91, p. 18].) If A is an $m \times n$ $(0,1)$-matrix such that each entry of AA^T is positive, then either A has a column with no zeros or the bigraph of A has a chordless cycle of length 6. The converse is not true.
2. [RT76], [GZ98] If $G = (V, E)$ is a connected quadrangular graph, then $|E| \leq 2|V| - 4$. The connected quadrangular graphs with $|E| = 2|V| - 4$ are characterized in the first reference.
3. [RT76], If A is an $m \times n$ $(0,1)$-matrix such that no entry of AA^T or $A^T A$ is 1, and the bigraph of A is connected, then A has at most $2(m+n) - 4$ nonzero entries.
4. [Tuc70] The $(0,1)$-matrix A has the consecutive ones property if and only if it does not have a submatrix whose rows and columns can be permuted to have one of the following forms for $k \geq 1$.

$$\begin{bmatrix} 1 & 1 & 0 & \cdots & 0 \\ 0 & 1 & 1 & & 0 \\ \vdots & & \ddots & \ddots & \vdots \\ 0 & 0 & & 1 & 1 \\ 1 & 0 & \cdots & 0 & 1 \end{bmatrix}_{(k+2)\times(k+2)}, \qquad \begin{bmatrix} 1 & 0 & \cdots & 0 & 0 \\ 1 & 1 & & 0 & 1 \\ 0 & 1 & \ddots & \vdots & \vdots \\ \vdots & & \ddots & 1 & 1 \\ 0 & 0 & \cdots & 1 & 0 \\ 0 & 0 & \cdots & 0 & 1 \end{bmatrix}_{(k+3)\times(k+2)},$$

$$\begin{bmatrix} 1 & 0 & \cdots & 0 & 0 & 1 \\ 1 & 1 & & 0 & 1 & 1 \\ 0 & 1 & \ddots & \vdots & \vdots & \vdots \\ \vdots & & \ddots & 1 & 1 & 1 \\ 0 & 0 & \cdots & 1 & 1 & 0 \\ 0 & 0 & \cdots & 0 & 1 & 1 \end{bmatrix}_{(k+3)\times(k+3)}, \qquad \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix}_{4\times 6}, \qquad \begin{bmatrix} 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 1 \end{bmatrix}_{4\times 5}.$$

5. [ABH99] Let A be a $(0,1)$-matrix and let $L = D - AA^T$, where D is the diagonal matrix whose ith diagonal entry is the ith row sum of AA^T. Then L is a symmetric, singular matrix each of whose eigenvalues is nonnegative. Let $\mathbf{v}$ be an eigenvector of L corresponding to the second smallest eigenvalue of L. If A has the consecutive ones property and the entries of $\mathbf{v}$ are distinct, then PA is a Petrie matrix, where P is the permutation matrix such that the entries of $P\mathbf{v}$ are in increasing order. In addition, the reference gives a recursive method for finding a P such that PA is a Petrie matrix when the elements of $\mathbf{v}$ are not distinct.
6. The directed bigraph of the real matrix A contains at most one of the arcs (i, j') or (j', i).
7. [FG81] The directed bigraph of the real matrix A is strongly connected if and only if there do not exist subsets α and β such that $A[\alpha, \beta] \geq 0$ and $A(\alpha, \beta) \leq 0$. Here,

either α or β may be the empty set, and a vacuous matrix M satisfies both $M \geq 0$ and $M \leq 0$.

8. [FG81] If $A = [a_{ij}]$ is a fully indecomposable, $n \times n$ sign pattern, then the following are equivalent:
   (a) There is a matrix $\widehat{A}$ with sign pattern A such that $\widehat{A}$ is invertible and its inverse is a positive matrix.
   (b) There do not exist subsets α and β such that $A[\alpha, \beta] \geq O$ and $A(\alpha, \beta) \leq O$.
   (c) The bipartite directed graph of A is strongly connected.
   (d) There exists a matrix with sign pattern A each of whose line sums is 0.
   (e) There exists a rank $n-1$ matrix with sign pattern A each of whose line sums is 0.
9. [Gol80] Up to relabeling of vertices, G is the fill-graph of some $n \times n$ symmetric matrix if and only if G is chordal.
10. [GN93] Let A be an $n \times n$ $(0,1)$-matrix with each diagonal entry equal to 1. Suppose that B is a matrix with zero pattern A, and that B can be factored as $B = LU$, where $L = [\ell_{ij}]$ is a lower triangular matrix and $U = [u_{ij}]$ is an upper triangular matrix. If $i \neq j$ and either $\ell_{ij} \neq 0$ or $u_{ij} \neq 0$, then $\{i, j'\}$ is an edge of $G^+(A)$. Moreover, if B is a generic matrix with zero pattern A, then such a factorization $B = LU$ exists, and for each edge $\{i, j'\}$ of $G^+(A)$ either $\ell_{ij} \neq 0$ or $u_{ij} \neq 0$.
11. [GG78] If the bigraph of the generic, square matrix A is chordal bipartite, then A has a perfect elimination ordering and, hence, there exist permutation matrices P and Q such that performing Gaussian elimination on PAQ has no fill-in. The converse is not true; see Example 3.
12. [GN93] If A is a generic $n \times n$ matrix with each diagonal entry nonzero, and $\alpha = \{1, 2, \ldots, r\}$, then the bigraph of the Schur complement of $A[\alpha]$ in A is the bigraph H_r defined above.
13. [DG93] For each matrix with a given pattern, small relative perturbations in the nonzero entries cause only small relative perturbations in the singular values (independent of the values of the matrix entries) if and only if the bigraph of the pattern is a forest. The singular values of such a matrix can be computed to high relative accuracy.
14. [DES99] If the signed bipartite graph of the real matrix is a signed 4-cockade, then small relative perturbations in the nonzero entries cause only small relative perturbations in the singular values (independent of the values of the matrix entries). The singular values of such a matrix can be computed to high relative accuracy.

Examples:

1. Let

$$A = \begin{bmatrix} - & + & 0 \\ + & - & + \\ + & 0 & - \end{bmatrix}.$$

The directed bigraph of A is shown in Figure 41.2.

Since this is strongly connected, Fact 7 implies that there do not exist subsets α and β such that $A[\alpha, \beta] \geq O$ and $A(\alpha, \beta) \leq O$. Also, there is a matrix with sign pattern A whose inverse is positive. One such matrix is

$$\begin{bmatrix} -3/2 & 2 & 0 \\ 1 & -2 & 1 \\ 1 & 0 & -1 \end{bmatrix}.$$

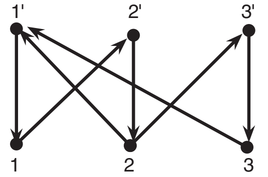

FIGURE 41.2 The directed bigraph for Example 1.

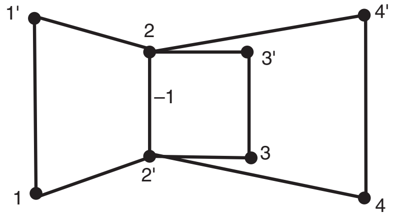

FIGURE 41.3 The signed 4-cockade in Example 2.

2. The biadjacency matrix of the signed 4-cockade on 8 vertices (unlabeled edges have sign +1) shown in Figure 41.3 is

$$\begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & -1 & 1 & 1 \\ 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix}.$$

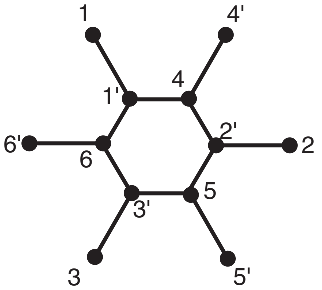

FIGURE 41.4 Bigraph ad bipartite fill-graph for the matrix in Example 3.

3. Both the bipartite fill-graph and the bigraph of the matrix

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 \\ 1 & 0 & 1 & 0 & 0 & 1 \end{bmatrix}$$

are the graph shown in Figure 41.4. Since its bigraph has a chordless 6-cycle, this example shows that the converse to Fact 11 is false.

4. Let

$$A = \begin{bmatrix} x_1 & x_2 & x_3 & x_4 \\ x_5 & x_6 & 0 & 0 \\ x_7 & 0 & x_8 & 0 \\ x_9 & 0 & 0 & x_{10} \end{bmatrix},$$

where $x_1, \ldots, x_{10}$ are independent indeterminates. The bigraph of A is chordal bipartite. The biadjacency matrix of H_1 is J_3. Thus, by Fact 12, the pattern of the Schur complement of $A[\{1\}]$ in A is J_3. The bipartite fill-graph of A has biadjacency matrix J_4. If

$$P = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix},$$

then the bipartite fill-graph of PAP^T and the bigraph of PAP^T are the same. Hence, it is possible to perform Gaussian elimination (without pivoting) on PAP^T without any fill-in.

Applications:

1. [Ken69], [ABH99] Petrie matrices are named after the archaeologist Flinders Petrie and were first introduced in the study of seriation, that is, the chronological ordering of archaeological sites. If the rows of the matrix A represent archaeological sites ordered by their historical time period, the columns of A represent artifacts, and $a_{ij} = 1$ if and only if artifact j is present at site i, then one would expect A to be a Petrie matrix. More recently, matrices with the consecutive ones property have arisen in genome sequencing (see [ABH99]).
2. [BBS91], [Sha97] If U is a unitary matrix and A is the pattern of U, then the bigraph of A is quadrangular. If U is fully indecomposable, then U has at most $4n - 4$ nonzero entries. The matrices achieving equality are characterized in the first reference. (See Fact 2 for more on quadrangular graphs.)

41.3 Factorizations and Bipartite Graphs

This section discusses the combinatorial interpretations and applications of certain matrix factorizations.

Definitions:

A **biclique** of a graph G is a subgraph that is a complete bipartite graph. For disjoint subsets X and Y of vertices, $B(X, Y)$ denotes the biclique consisting of all edges of the form $\{x, y\}$ such that $x \in X$ and $y \in Y$ (each of multiplicity 1). If G is bipartite with bipartition $\{U, V\}$, then it is customary to take $X \subseteq U$ and $Y \subseteq V$.

A **biclique partition** of $G = (V, E)$ is a collection $B(X_1, Y_1), \ldots, B(X_k, Y_k)$ of bicliques of G whose edges partition E.

A **biclique cover** of $G = (V, E)$ is a collection of bicliques such that each edge of E is in at least one biclique.

The **biclique partition number of** G, denoted $\mathrm{bp}(G)$, is the smallest k such that there is a partition of G into k bicliques. The **biclique cover number of** G, denoted $\mathrm{bc}(G)$, is the smallest k such that there is a cover of G by k bicliques. If G does not have a biclique partition, respectively, cover, then $\mathrm{bp}(G)$, respectively, $\mathrm{bc}(G)$, is defined to be infinite.

If G is a graph, then $n_+(G)$, respectively, $n_-(G)$, denotes the number of positive, respectively, negative, eigenvalues of $\mathcal{A}_G$ (including multiplicity).

If $X \subseteq \{1, 2, \ldots, n\}$, then the **characteristic vector** of X is the $n \times 1$ vector $\vec{\mathbf{X}} = [\mathbf{x_i}]$, where $x_i = 1$ if $i \in X$, and $x_i = 0$ otherwise.

The **nonnegative integer rank** of the nonnegative integer matrix A is the minimum k such that there exist an $m \times k$ nonnegative integer matrix B and a $k \times n$ nonnegative integer matrix C with $A = BC$.

The **(0,1)-Boolean algebra** consists of the elements 0 and 1, endowed with the operations defined by $0 + 0 = 0$, $0 + 1 = 1 = 1 + 0$, $1 + 1 = 1$, $0 * 1 = 0 = 1 * 0$, $0 * 0 = 0$, and $1 * 1 = 1$. A **Boolean matrix** is a matrix whose entries belong to the (0,1)-Boolean algebra. Addition and multiplication of Boolean matrices is defined as usual, except Boolean arithmetic is used.

The **Boolean rank** of the $m \times n$ Boolean matrix A is the minimum k such that there exists an $m \times k$ Boolean matrix B and a $k \times n$ Boolean matrix C such that $A = BC$.

Let G be a bipartite graph with bipartition $\{\{1, 2, \ldots, m\}, \{1', 2', \ldots, n'\}\}$. Then $\mathcal{M}(G)$ denotes the set of all $m \times n$ matrices $A = [a_{ij}]$ such that if $a_{ij} \neq 0$, then $\{i, j'\}$ is an edge of G, that is, the bigraph of A is a subgraph of G. The graph G **supports rank decompositions** provided each matrix $A \in \mathcal{M}(G)$ is the sum of rank(A) elements of $\mathcal{M}(G)$ each having rank 1.

If G is a signed bipartite graph, then $\mathcal{M}(G)$ denotes the set of all matrices $A = [a_{ij}]$ such that if $a_{ij} > 0$, then $\{i, j'\}$ is a positive edge of G, and if $a_{ij} < 0$, then $\{i, j'\}$ is a negative edge of G. The signed bigraph G **supports rank decompositions** provided each matrix $A \in \mathcal{M}(G)$ is the sum of rank(A) elements of $\mathcal{M}(G)$ each having rank 1.

Facts:

1. [GP71]
   (a) A graph has a biclique partition (and, hence, cover) if and only if it has no loops.
   (b) For every graph G, $\text{bc}(G) \leq \text{bp}(G)$.
   (c) Every simple graph G with n vertices has a biclique partition with at most $n - 1$ bicliques, namely, $B(\{i\}, \{j : \{i, j\} \text{ is an edge of } G \text{ and } j > i\})$ $(i = 1, 2, \ldots, n - 1)$.
2. [CG87] Let G be a bipartite graph with bipartition (U, V), where $|U| = m$ and $|V| = n$. Let $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ be bicliques with $X_i \subseteq U$ and $Y_i \subseteq V$ for all i. The following are equivalent:
   (a) $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ is a biclique partition of G.
   (b) $\sum_{i=1}^{k} \vec{\mathbf{X}}_\mathbf{i} \vec{\mathbf{Y}}_\mathbf{i}^T = \mathcal{B}_G$.
   (c) $XY^T = \mathcal{B}_G$, where X is the $n \times k$ matrix whose ith column is $\vec{\mathbf{X}}_\mathbf{i}$, and Y is the $n \times k$ matrix whose ith column is $\vec{\mathbf{Y}}_\mathbf{i}$.
3. [CG87] For a simple bipartite graph G, bp(G) equals the nonnegative integer rank of $\mathcal{B}_G$.
4. [CG87]
   (a) Let G be the bipartite graph obtained from $K_{n,n}$ by removing a perfect matching. Then $\text{bp}(G) = n$. Furthermore, if $B(X_i, Y_i)$ $(i = 1, 2, \ldots, n)$ is a biclique partition of G, then there exist positive integers r and s such that $rs = n - 1$, $|X_i| = r$ and $|Y_i| = s$ $(i = 1, 2, \ldots, n)$, k is in exactly r of the X_i's and exactly s of the Y_i's $(k = 1, 2, \ldots, n)$, and $X_i \cap Y_j = 1$ for $i \neq j$.
   (b) In matrix terminology, if X and Y are $n \times n$ $(0, 1)$-matrices such that $XY^T = J_n - I_n$, then there exist integers r and s such that $rs = n - 1$, X has constant line sums r, Y has constant line sums s, and $Y^T X = J_n - I_n$.

   (c) In particular, if $n-1$ is prime, then either X is a permutation matrix and $Y = (J_n - I_n)X$, or Y is a permutation matrix and $X = (J_n - I_n)Y$.

5. [BS04, see p. 67] Let G be a graph on n vertices with adjacency matrix $\mathcal{A}_G$, and let $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ be bicliques of G. Then the following are equivalent:
   (a) $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ is a biclique partition of G.
   (b) $\sum_{i=1}^{k} \overrightarrow{\mathbf{X_i}}\,\overrightarrow{\mathbf{Y_i}}^{T} + \sum_{i=1}^{k} \overrightarrow{\mathbf{Y_i}}\,\overrightarrow{\mathbf{X_i}}^{\mathbf{T}} = \mathcal{A}_G$.
   (c) $XY^T + YX^T = \mathcal{A}_G$, where X is the $n \times k$ matrix whose ith column is $\overrightarrow{\mathbf{X_i}}$, and Y is the $n \times k$ matrix whose ith column is $\overrightarrow{\mathbf{Y_i}}$.
   (d) $\mathcal{A}_G = M \begin{bmatrix} O & I_m \\ I_m & O \end{bmatrix} M^T$, where M is the $n \times 2k$ matrix $\begin{bmatrix} X & Y \end{bmatrix}$ formed from the matrices X and Y defined in (c).
6. [CH89] The bicliques $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ partition K_n if and only if XY^T is an $n \times n$ tournament matrix, where X is the $n \times k$ matrix whose ith column is $\overrightarrow{\mathbf{X_i}}$, and Y is the $n \times k$ matrix whose ith column is $\overrightarrow{\mathbf{Y_i}}$. Thus, $\text{bp}(K_n)$ is the minimum nonnegative integer rank among all the $n \times n$ tournament matrices.
7. [CH89] The rank of an $n \times n$ tournament matrix is at least $n-1$.
8. (Attributed to Witsenhausen in [GP71])
$$\text{bp}(K_n) = n - 1;$$
   that is, it is impossible to partition the complete graph into $n-2$ or fewer bicliques.
9. [GP71] *The Graham–Pollak Theorem*: If G is a loopless graph, then
$$\text{bp}(G) \geq \max\{n_+(G), n_-(G)\}. \tag{41.1}$$
   The graph G is **eigensharp** if equality holds in Eq. (41.1). It is conjectured in [CGP86] that for all λ, and n sufficiently large, the complete graph λK_n with each edge of multiplicity k is eigensharp.
10. [ABS91] If $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ is a biclique partition of G, then there exists an acyclic subgraph of G with $\max\{(n_+(G), n_-(G)\}$ edges no two in the same $B(X_i, Y_i)$.
   In particular, for each biclique partition of K_n there exists a spanning tree no two of whose edges belong to the same biclique of the partition.
11. [CH89] For all positive integers r and s with $2 \leq r < s$, the edges of the complete graph K_{2rs} cannot be partitioned into copies of the complete bipartite graph $K_{r,s}$.
12. [Hof01] If m and n are positive integers with $2m \leq n$, and $G_{m,n}$ is the graph obtained from the complete graph K_n by duplicating the edges of an m-matching, then $n_+(G) = n - m - 1$, $n_-(G) = m + 1$, and $\text{bp}(G) \geq n - m + \lfloor \sqrt{2m} \rfloor - 1$.
13. [CGP86] Let A be an $m \times n$ $(0,1)$-matrix with bigraph G and let $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ be bicliques. The following are equivalent:
   (a) $B(X_1, Y_1)$, $B(X_2, Y_2)$, …, $B(X_k, Y_k)$ is a biclique cover of G.
   (b) $\sum_{i=1}^{k} \overrightarrow{\mathbf{X_i}}\,\overrightarrow{\mathbf{Y_i}}^{\mathbf{T}} = A$ (using Boolean arithmetic).
   (c) $XY^T = B$ (using Boolean arithmetic), where X is the $m \times k$ matrix whose jth column is $\overrightarrow{\mathbf{X_j}}$, and Y is the $m \times k$ matrix whose j column is $\overrightarrow{\mathbf{Y_j}}$.
14. [CGP86] The Boolean rank of a $(0,1)$-matrix A equals the biclique cover number of its bigraph.

15. [CSS87] Let k be a positive integer and let $t(k)$ be the largest integer n such that there exists an $n \times n$ tournament matrix with Boolean rank k. Then for $k \geq 2$, $t(k) < k^{\log_2(2k)}$, and $n(n^2+n+1)+2 \leq t(n^2+n+1)$.
    It is still an open problem to determine the minimum Boolean rank among $n \times n$ tournament matrices.
16. [DHM95, JM97] The bipartite graph G supports rank decompositions if and only if G is chordal bipartite.
17. [GMS96] The signed bipartite graph G supports rank decompositions if and only if
    $$\operatorname{sgn}(\gamma) = (-1)^{(\ell(\gamma)/2)-1} \tag{41.2}$$
    for every cycle γ of G of length $\ell(\gamma) \geq 6$. Additionally, every matrix in $\mathcal{M}(G)$ has its rank equal to its term rank if and only if Eq. (41.2) holds for every cycle of G.

Examples:

1. A biclique partition of the graph $G_{2,4}$ obtained from K_4 by duplicating two disjoint edges is shown in Figure 41.5, with the edges of different textures forming the bicliques.

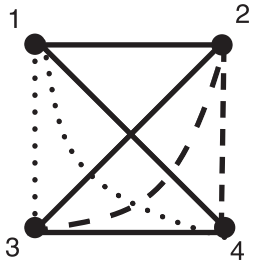

FIGURE 41.5 A biclique partition of the graph $G_{2,4}$ in Example 1.

2. Let n be an integer and r and s positive integers with $n-1 = rs$. Then $XY^T = J_n - I_n$, where $X = I + C^s + C^{2s} + \cdots + C^{s(r-1)}$, $Y = C + C^2 + C^3 + \cdots + C^s$, and C is the $n \times n$ permutation matrix with 1s in positions $(1,2)$, $(2,3)$, …, $(n-1,n)$, and $(n,1)$. This shows that for each pair of positive integers r and s with $rs = n-1$, there is a biclique partition of $J_n - I_n$ with X_i and Y_i satisfying the conditions in Fact 4.
3. For n odd, $B(\{i\},\{i+1, i+2, \ldots, i+\frac{n-1}{2}\})$ $(i = 1, 2, \ldots, n)$ is a partition of K_n into bicliques each isomorphic to $K_{1,\frac{n-1}{2}}$, where the indices are read mod n (see Fact 11).

The origins of sign pattern matrices are in the book [Sam47] by the Nobel Economics Prize winner P. Samuelson, who pointed to the need to solve certain problems in economics and other areas based only on the signs of the entries of the matrices. The study of sign pattern matrices has become somewhat synonymous with qualitative matrix analysis. The dissertation of C. Eschenbach [Esc87], directed by C.R. Johnson, studied sign pattern matrices that "require" or "allow" certain properties and summarized some of the work on sign patterns up to that point. In 1995, Richard Brualdi and Bryan Shader produced a thorough treatment [BS95] on sign pattern matrices from the sign-solvability vantage point. There is such a wealth of information contained in [BS95] that it is not possible to represent all of it here. Since 1995 there has been a remarkable number of papers on sign patterns and some generalized notions such as ray patterns. Sign pattern matrices have found new applications in a number of areas such as communication complexity [AFR85, PR94, LMS07, She08, RS10], neural networks [DK89], and chemistry [HKK10]. We remark that in this chapter we mostly use $\{+, -, 0\}$ notation for sign patterns, whereas in the literature $\{1, -1, 0\}$ notation is also commonly used, such as in [BS95]. We further note that because of the interplay between sign pattern matrices and graph theory, the study of sign patterns is regarded as a part of combinatorial matrix theory.

42.1 Basic Concepts

Definitions:

A **sign pattern matrix** (or **sign pattern**) is a matrix whose entries come from the set $\{+, -, 0\}$.

For a real matrix B, sgn(B) is the sign pattern whose entries are the signs of the corresponding entries in B.

If A is an $m \times n$ sign pattern matrix, the **sign pattern class** (or **qualitative class**) of A, denoted $Q(A)$, is the set of all $m \times n$ real matrices B with $\text{sgn}(B) = A$. If C is a real matrix, its qualitative class is given by $Q(C) = Q(\text{sgn}(C))$.

If P is a property referring to a real matrix, then a sign pattern A **requires** P if every real matrix in $Q(A)$ has property P, or **allows** P if some real matrix in $Q(A)$ has property P.

A square sign pattern that allows nilpotence is said to be **potentially nilpotent**.

A **generalized sign pattern** $\tilde{A}$ is a matrix whose entries are from the set $\{+, -, 0, \#\}$, where # indicates an ambiguous sum (the result of adding + with −). The qualitative class of $\tilde{A}$ is defined by allowing the # entries to be completely free. Two generalized sign patterns are **compatible** if there is a common real matrix in their qualitative classes.

A **subpattern** $\hat{A}$ of a sign pattern A is a sign pattern obtained by replacing some (possibly none) of the nonzero entries in A with 0; this fact is denoted by $\hat{A} \preceq A$. In this case, we say that A is a **superpattern** of $\hat{A}$.

A **diagonal pattern** is a square sign pattern all of whose off-diagonal entries are zero. Similarly, standard matrix terms such as "tridiagonal" and "upper triangular" can be applied to sign patterns having the required pattern of zero entries.

A **permutation pattern** is a square sign pattern matrix with entries 0 and +, where the entry + occurs precisely once in each row and in each column.

A **permutational similarity** of the (square) sign pattern A is a product of the form $P^T AP$, where P is a permutation pattern.

A **permutational equivalence** of the sign pattern A is a product of the form $P_1 AP_2$, where P_1 and P_2 are permutation patterns.

The **identity** pattern of order n, denoted I_n, is the $n \times n$ diagonal pattern with + diagonal entries.

A **signature pattern** is a diagonal sign pattern matrix, each of whose diagonal entries is + or −.

A **signature similarity** of the (square) sign pattern A is a product of the form SAS, where S is a signature pattern.

The **digraph** of an $n \times n$ sign pattern $A = [a_{ij}]$, denoted $\Gamma(A)$, is the digraph with vertex set $\{1, 2, \ldots, n\}$, where (i, j) is an arc if and only if $a_{ij} \neq 0$. (See Chapter 40 for more information on digraphs.)

The **signed digraph** of an $n \times n$ sign pattern $A = [a_{ij}]$, denoted $D(A)$, is the digraph with vertex set $\{1, 2, \ldots, n\}$, where (i, j) is an arc (bearing a_{ij} as its sign) if and only if $a_{ij} \neq 0$.

If $A = [a_{ij}]$ is an $n \times n$ sign pattern matrix, then a **(simple) cycle** of **length** k (or a k**-cycle**) in A is a formal product of the form $\gamma = a_{i_1 i_2} a_{i_2 i_3} \ldots a_{i_k i_1}$, where each of the elements is nonzero and the index set $\{i_1, i_2, \ldots, i_k\}$ consists of distinct indices. The **sign** (positive or negative) of a simple cycle in a sign pattern A is the actual product of the entries in the cycle, following the obvious rules that multiplication is commutative and associative, and $(+)(+) = +$, $(+)(-) = -$.

A **composite cycle** γ in A is a product of simple cycles, say $\gamma = \gamma_1 \gamma_2 \ldots \gamma_m$, where the index sets of the γ_i's are mutually disjoint. If the length of γ_i is l_i, then the length of γ is $\sum_{i=1}^{m} l_i$, and the **signature** of γ is $(-)^{\sum_{i=1}^{m}(l_i - 1)}$. A cycle γ is **odd** (**even**) when the length of the simple or composite cycle γ is odd (even).

If $A = [a_{ij}]$ is an $n \times n$ sign pattern matrix, then a **path** of length k in A is a formal product of the form $a_{i_1 i_2} a_{i_2 i_3} \ldots a_{i_k i_{k+1}}$, where each of the elements is nonzero and the indices $i_1, i_2, \ldots, i_{k+1}$ are distinct.

A **bipartite sign pattern matrix** is a sign pattern matrix whose digraph is bipartite.

A **combinatorially symmetric sign pattern matrix** is a square sign pattern A, where $a_{ij} \neq 0$ if and only if $a_{ji} \neq 0$.

The **graph of a combinatorially symmetric** $n \times n$ **sign pattern matrix** $A = [a_{ij}]$ is the graph with vertex set $\{1, 2, \ldots, n\}$, where $\{i, j\}$ is an edge if and only if $a_{ij} \neq 0$.

A **tree sign pattern** (t.s.p.) matrix is a combinatorially symmetric sign pattern matrix whose graph is a tree (possibly with loops).

A **star sign pattern** is a tree sign pattern whose graph is a star (i.e., a complete bipartite graph where one of the partition sets has exactly one element).

A **zero-nonzero pattern** is a $\{0, *\}$-matrix where $*$ indicates an entry that can take on any nonzero value in $\mathbb{R}$ (or another specified field).

Facts:

1. Simple cycles and paths in an $n \times n$ sign pattern matrix A correspond to simple cycles and paths in the digraph of A. In particular, the path $a_{i_1 i_2} a_{i_2 i_3} \ldots a_{i_k i_{k+1}}$ in A corresponds to the path $i_1 \to i_2 \to \ldots \to i_{k+1}$ in the digraph of A.
2. If A is an $n \times n$ sign pattern, then each nonzero term in $\det(A)$ is the product of the signature of a composite cycle γ of length n in A with the actual product of the entries in γ.
3. Two generalized sign patterns are compatible if and only if the signs of each position whose sign is specified in both are equal.

Examples:

1. The matrix $\begin{bmatrix} 0 & 5 & -4 \\ -2 & -1 & 7 \end{bmatrix}$ is in $Q(A)$, where $A = \begin{bmatrix} 0 & + & - \\ - & - & + \end{bmatrix}$.
2. If $A = [a_{ij}] = \begin{bmatrix} + & + & 0 & - & + \\ 0 & - & - & - & + \\ + & - & - & + & + \\ - & - & + & - & + \\ + & - & 0 & - & - \end{bmatrix}$,

   then the composite cycle $\gamma = (a_{12}a_{23}a_{31})(a_{45}a_{54})$ has length 5 and negative signature, and yields the term $-a_{12}a_{23}a_{31}a_{45}a_{54} = -$ in $\det(A)$.
3. If $A = \begin{bmatrix} + & + \\ + & - \end{bmatrix}$, then $A^2 = \begin{bmatrix} + & \# \\ \# & + \end{bmatrix}$, which is compatible with $\begin{bmatrix} + & - \\ 0 & \# \end{bmatrix}$.

42.2 Sign Nonsingularity

Definitions:

A square sign pattern A is **sign nonsingular** (SNS) if every matrix $B \in Q(A)$ is nonsingular.

A **strong sign nonsingular** sign pattern, abbreviated an S^{2}NS-pattern, is an SNS-pattern A such that the matrix B^{-1} is in the same sign pattern class for all $B \in Q(A)$.

A **self-inverse sign pattern** is an S^{2}NS-pattern A such that $B^{-1} \in Q(A)$ for every matrix $B \in Q(A)$.

A **maximal** sign nonsingular sign pattern matrix is an SNS-pattern A where no zero entry of A can be set nonzero so that the resulting pattern is SNS.

A **nearly sign nonsingular** (NSNS) sign pattern matrix is a square pattern A having at least two nonzero terms in the expansion of its determinant, with precisely one nonzero term having opposite sign to the others.

A square sign pattern A is **sign singular** if every matrix $B \in Q(A)$ is singular.

The **zero pattern** of a sign pattern A, denoted $|A|$, is the $(0, +)$-pattern obtained by replacing each $-$ entry in A by a $+$.

Since a sign pattern may be represented by any real matrix in its qualitative class, many concepts defined on sign patterns (such as SNS and S^2NS) may be applied to real matrices.

Facts:

Most of the following facts can be found in [BS95, Chaps. 1–4 and 6–8].

1. The $n \times n$ sign pattern A is sign nonsingular if and only if $\det(A) = +$ or $\det(A) = -$; that is, in the standard expansion of $\det(A)$ into $n!$ terms, there is at least one nonzero term, and all the nonzero terms have the same sign.
2. An $n \times n$ pattern A is an SNS-pattern if and only if for any $n \times n$ signature pattern D and any $n \times n$ permutation patterns P_1, P_2, DP_1AP_2 is an SNS-pattern.
3. [BMQ68] For any SNS-pattern A, there exist a signature pattern D and a permutation pattern P such that DPA has negative diagonal entries.
4. [BMQ68] An $n \times n$ sign pattern A with negative main diagonal is SNS if and only if the actual product of entries of every simple cycle in A is negative.
5. [Gib71] If an $n \times n$, $n \geq 3$, sign pattern A is SNS, then A has at least $\binom{n-1}{2}$ zero entries, with exactly this number if and only if there exist permutation patterns P_1 and P_2 such that P_1AP_2 has the same zero/nonzero pattern as the Hessenberg pattern given in Example 1 below.
6. The fully indecomposable maximal SNS-patterns of order ≤ 9 are given in [LMV96]. [GOD96] An $n \times n$ sign pattern A is a fully indecomposable maximal SNS-pattern with $\binom{n-1}{2}$ zero entries if and only if A is equivalent (namely, one can be be transformed into the other by any combination of transposition, multiplication by permutation patterns, and multiplication by signature patterns) to the pattern given in Example 1 below. For $n \geq 5$, there is precisely one equivalence class of fully indecomposable maximal SNS-patterns with $\binom{n-1}{2} + 1$ zero entries, and there are precisely two such equivalence classes having $\binom{n-1}{2} + 2$ zero entries.
7. [BS95, Corollary 1.2.8] If A is an $n \times n$ sign pattern, then A is an S^2NS-pattern if and only if
   (a) A is an SNS-pattern, and
   (b) For each i and j with $a_{ij} = 0$, the submatrix $A(i,j)$ of A of order $n-1$ obtained by deleting row i and column j is either an SNS-pattern or a sign singular pattern.
8. [BMQ68] If A is an $n \times n$ sign pattern with negative main diagonal, then A is an S^2NS-pattern if and only if
   (a) The actual product of entries of every simple cycle in A is negative, and
   (b) The actual product of entries of every simple path in A is the same, for any paths with the same initial row index and the same terminal column index.
9. [LLM95] An irreducible sign pattern A is NSNS if and only if there exists a permutation pattern P and a signature pattern S such that $B = APS$ satisfies:
   (a) $b_{ii} < 0$ for $i = 1, 2, \ldots, n$.
   (b) The actual product of entries of every cycle of length at least 2 of $D(B)$ is positive.
   (c) $D(B)$ is intercyclic (namely, any two cycles of lengths at least two have a common vertex).
10. [Bru88] An $n \times n$ sign pattern A is SNS if and only if $\mathrm{per}(|B|) = |\det(B)|$, where B is the $(1, -1, 0)$-matrix in $Q(A)$ and $|B|$ is obtained from B by replacing every -1 entry with 1.
11. [Tho86] The problem of determining whether a given sign pattern A is an SNS-pattern is equivalent to the problem of determining whether a certain digraph related to $D(A)$ has an even cycle.

For further reading, see [Kas63], [Bru88], [BS91], [Stu91], [BC92], [EHJ93], [BCS94a], [LMO96], [SS01], [SS02], [Fie05], [Fie08], and [FH10].

Examples:

1. For $n \geq 2$, the following Hessenberg pattern is SNS:

$$H_n = \begin{bmatrix} - & + & 0 & \dots & 0 \\ - & - & + & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & 0 \\ - & - & \dots & - & + \\ - & - & \dots & - & - \end{bmatrix}.$$

2. [BS95, p. 11] For $n \geq 2$, the following Hessenberg pattern is S^{2}NS:

$$G_n = \begin{bmatrix} + & - & 0 & \dots & 0 & 0 \\ 0 & + & - & \dots & 0 & 0 \\ 0 & 0 & + & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & + & - \\ + & 0 & 0 & \dots & 0 & + \end{bmatrix}.$$

3. $A = \begin{bmatrix} - & + & 0 & 0 \\ 0 & - & + & 0 \\ 0 & 0 & - & + \\ - & 0 & 0 & - \end{bmatrix}$ is S^{2}NS with inverse pattern $\begin{bmatrix} - & - & - & - \\ + & - & - & - \\ + & + & - & - \\ + & + & + & - \end{bmatrix}$.

4. [BS95, p. 114] The following patterns are maximal SNS-patterns:

$$\begin{bmatrix} - & + & 0 \\ - & - & + \\ - & - & - \end{bmatrix}, \quad \begin{bmatrix} - & + & 0 & + \\ - & - & + & 0 \\ 0 & - & - & + \\ - & 0 & - & - \end{bmatrix}.$$

Applications:

1. [HKK10] Sign patterns arise naturally in the study of chemical reaction networks.

42.3 Sign-Solvability, L-Matrices, and S^*-Matrices

Definitions:

A system of linear equations $Ax = b$ (where A and b are both sign patterns or both real matrices) is **sign-solvable** if for each $\tilde{A} \in Q(A)$ and for each $\tilde{b} \in Q(b)$, the system $\tilde{A}x = \tilde{b}$ is consistent and

$$\{\tilde{x} \ : \ \text{there exist } \tilde{A} \in Q(A) \text{ and } \tilde{b} \in Q(b) \text{ with } \tilde{A}\tilde{x} = \tilde{b}\}$$

is entirely contained in one qualitative class.

A sign pattern or real matrix A is an **L-matrix** if for every $B \in Q(A)$, the rows of B are linearly independent.

A **barely L-matrix** is an L-matrix that is not an L-matrix if any column is deleted.

An $n \times (n+1)$ matrix B is an S^***-matrix** provided that each of the $n+1$ matrices obtained by deleting a column of B is an SNS matrix.

An $n \times (n+1)$ matrix B is an S**-matrix** if it is an S^*-matrix and the kernel of every matrix in $Q(B)$ contains a vector all of whose coordinates are positive.

A **signing** of order k is a nonzero $(0, 1, -1)$- or $(0, +, -)$-diagonal matrix of order k.

A signing $D' = \text{diag}(d'_1, d'_2, \ldots, d'_k)$ is an **extension** of the signing D if $D' \neq D$ and $d'_i = d_i$ whenever $d_i \neq 0$.

A **strict signing** is a signing where all the diagonal entries are nonzero.

Let $D = \text{diag}(d_1, d_2, \ldots, d_k)$ be a signing of order k and let A be an $m \times n$ (real or sign pattern) matrix. If $k = m$, then DA is a **row signing** of the matrix A, and if D is strict, then DA is a **strict row signing** of the matrix A. If $k = n$, then AD is a **column signing** of the matrix A, and if D is strict, then AD is a **strict column signing** of the matrix A.

A real or sign pattern vector is **balanced** provided either it is a zero vector or it has both a positive entry and a negative entry. A vector v is **unisigned** if it is not balanced. A **balanced row signing** of the matrix A is a row signing of A in which all the columns are balanced. A **balanced column signing** of the matrix A is a column signing of A in which all the rows are balanced.

Facts:

Most of the following facts can be found in [BS95, Chaps. 1–3].

1. A square sign pattern A is an L-matrix if and only if A is an SNS matrix.
2. The linear system $Ax = 0$ is sign-solvable if and only if A^T is an L-matrix
3. If $Ax = b$ is sign-solvable, then A^T is an L-matrix.
4. $Ax = b$ is sign-solvable for all b if A is a square matrix and there exists a permutation matrix P such that PA is an invertible diagonal matrix.
5. Sign-solvability has been studied using signed digraphs; see [Man82], [Han83], [BS95, Chap. 3], and [Sha00].
6. [BS95] Let A be a matrix of order n and let b be an $n \times 1$ vector. Then $Ax = b$ is sign-solvable if and only if A is an SNS-matrix and for each i, $1 \leq i \leq n$, the matrix $A(i \leftarrow b)$, obtained from A by replacing the i-th column by b, is either an SNS matrix or has an identically zero determinant.
7. [BS95] If $AX = B$ is a sign-solvable linear system where A and B are square matrices of order n and B does not have an identically zero determinant, then A is an S^{2}NS matrix.
8. [BS95] Let $Ax = b$ be a linear system such that A has no zero rows. Then the linear system $Ax = b$ is sign-solvable and the vectors in its qualitative solution class have no zero coordinates if and only if the matrix $[A \mid -b]$ is an S^*-matrix.
9. An $n \times (n+1)$ matrix B is an S^*-matrix if and only if there exists a vector w with no zero coordinates such that the kernels of the matrices $\tilde{B} \in Q(B)$ are contained in $\{0\} \cup Q(w) \cup Q(-w)$.
10. [Man82] and [KLM84] Let $A = [a_{ij}]$ be an $m \times n$ matrix and let b be an $m \times 1$ vector. Assume that $z = (z_1, z_2, \ldots, z_n)^T$ is a solution of the linear system $Ax = b$. Let

    $$\beta = \{j \ : \ z_j \neq 0\} \text{ and } \alpha = \{i \ : \ a_{ij} \neq 0 \text{ for some } j \in \beta\}.$$

    Then $Ax = b$ is sign-solvable if and only if the matrix $[A[\alpha, \beta] \mid -b[\alpha]]$ is an S^*-matrix and the matrix $A(\alpha, \beta)^T$ is an L-matrix.
11. [KLM84] A matrix A is an L-matrix if and only if every row signing of A contains a unisigned column.
12. [BCS94a] An $m \times n$ matrix A is a barely L-matrix if and only if
    (a) A is an L-matrix.

   (b) For each $i = 1, 2, \ldots, n$, there is a row signing of A such that column i is the only unisigned column.

13. [BCS94a] An $m \times n$ matrix A is an S^*-matrix if and only if $n = m + 1$ and every row signing of A contains at least two unisigned columns.
14. [BCS94a] An $m \times n$ matrix A is an S^*-matrix if and only if $n = m+1$ and there exists a strict signing D such that AD and $A(-D)$ are the only balanced column signings of A.
15. [KLM84] A matrix A is an S-matrix if and only if A is an S^*-matrix and every row of A is balanced.
16. Let A be an $m \times n$ sign pattern that does not have a $p \times q$ zero submatrix for any positive integers p and q with $p + q \geq m$. Then A is an L-matrix if and only if every strict row signing of A has a unisigned column.

For further reading, see [Sha95], [Sha99], [KS00], and [SR04].

Examples:

1. $\begin{bmatrix} + & - & + & + \\ + & + & - & + \\ + & + & + & - \end{bmatrix}$ is an L-matrix by Fact 11, and is a barely L-matrix by Fact 42.2.5.
2. [BS95, p. 65] The $m \times (m + 1)$ matrix

$$H'_{m+1} = \begin{bmatrix} - & + & 0 & \ldots & 0 & 0 & 0 \\ - & - & + & \ldots & 0 & 0 & 0 \\ - & - & - & \ldots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ - & - & - & \ldots & - & + & 0 \\ - & - & - & \ldots & - & - & + \end{bmatrix}$$

   is an S-matrix. Every strict column signing $H'_{m+1}D$ of H'_{m+1} is an S^*-matrix, with only two such strict column signings yielding S-matrices (namely, when $D = \pm I$).

Applications:

1. [BS95, Sect. 1.1] In supply and demand analysis in economics, linear systems, where the coefficients as well as the constants have prescribed signs, arise naturally. For instance, the sign-solvable linear system

$$\begin{bmatrix} + & - \\ - & - \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 0 \\ - \end{bmatrix}$$

   arises from the study of a market with one product, where the price and quantity are determined by the intersection of its supply and demand curves.

42.4 Stability

Definitions:

A **negative stable** (respectively, **negative semistable**) real matrix is a square matrix B where each of the eigenvalues of B has negative (respectively, nonpositive) real part. In this section, the term *(semi)stable* will mean *negative (semi)stable.* More information on matrix stability can be found in Section 10.5 and Chapter 26.

A **sign stable** (respectively, **sign semistable**) sign pattern matrix is a square sign pattern A where every matrix $B \in Q(A)$ is stable (respectively, semistable).

A **potentially stable** sign pattern matrix is a square sign pattern A where some matrix $B \in Q(A)$ is stable.

An $n \times n$ sign pattern matrix A allows a **properly signed nest** if there exists $B \in Q(A)$ and a permutation matrix P such that $\operatorname{sgn}(\det(P^T BP[\{1, \ldots, k\}])) = (-1)^k$ for $k = 1, \ldots, n$.

A **minimally potentially stable** sign pattern matrix is a potentially stable, irreducible pattern such that replacing any nonzero entry by zero results in a pattern that is not potentially stable.

Facts:

Many of the following facts can be found in [BS95, Chap. 10].

1. A square sign pattern A is sign stable (respectively, sign semistable) if and only if each of the irreducible components of A is sign stable (respectively, sign semistable).
2. [QR65] If A is an $n \times n$ irreducible sign pattern, then A is sign semistable if and only if
   (a) A has nonpositive main diagonal entries.
   (b) If $i \neq j$, then $a_{ij}a_{ji} \leq 0$.
   (c) The digraph of A is a doubly directed tree.
3. If A is an $n \times n$ irreducible sign pattern, then A is sign stable if and only if
   (a) A has nonpositive main diagonal entries.
   (b) If $i \neq j$, then $a_{ij}a_{ji} \leq 0$.
   (c) The digraph of A is a doubly directed tree.
   (d) A does not have an identically zero determinant.
   (e) There does not exist a nonempty subset β of $[1, 2, \ldots, n]$ such that each diagonal element of $A[\beta]$ is zero, each row of $A[\beta]$ contains at least one nonzero entry, and no row of $A[\bar{\beta}, \beta]$ contains exactly one nonzero entry.

   The original version of this result was in terms of matchings and colorings in a graph [JKD77, Theorem 2]; the restatement given here comes from [BS95, Theorem 10.2.2].
4. An efficient algorithm for determining whether a pattern is sign stable is given in [KD77], and the sign stable patterns have been characterized in finitely computable terms in [JKD87].
5. The potentially stable tree sign patterns (see Section 42.5) for dimensions less than five are given in [JS89].
6. If an $n \times n$ sign pattern A allows a properly signed nest, then A is potentially stable.
7. In [JMO97], sufficient conditions are determined for an $n \times n$ zero–nonzero pattern to allow a nested sequence of nonzero principal minors, and a method is given to sign a pattern that meets these conditions so that it allows a properly signed nest. It is also shown that if A is a tree sign pattern that has exactly one nonzero diagonal entry, then A is potentially stable if and only if A allows a properly signed nest.
8. In [LOD02], a measure of the relative distance to the unstable matrices for a stable matrix is defined and extended to a potentially stable sign pattern, and the minimally potentially stable patterns are studied.

For further reading, see [GOD12] and [OTD12].

Conjectures and Open Problems

1. The characterization of potentially stable sign patterns is a very difficult open problem. Facts 5 through 7 above are related to this open question.

Examples:

1. [BS95] The pattern $\begin{bmatrix} - & + \\ - & - \end{bmatrix}$ is sign stable, while the pattern $\begin{bmatrix} 0 & + \\ - & 0 \end{bmatrix}$ is sign semistable, but not sign stable.
2. [JMO97] The matrix $\begin{bmatrix} -1 & 1 & 0 \\ -1 & -1 & 1 \\ 0 & -3 & 1 \end{bmatrix}$ has a (leading) properly signed nest, so that the pattern $\begin{bmatrix} - & + & 0 \\ - & - & + \\ 0 & - & + \end{bmatrix}$ is potentially stable.
3. [JMO97] The matrix $B = \begin{bmatrix} -3 & 1 & 0 \\ 0 & 0 & 1 \\ 8 & -3 & 0 \end{bmatrix}$ has -1 as a triple eigenvalue, and so is stable. Thus, the sign pattern $A = \text{sgn}(B)$ is potentially stable, but it does not allow a properly signed nest.
4. [LOD02] The $n \times n$ tridiagonal sign pattern A with $a_{11} = -, a_{i,i+1} = +, a_{i+1,i} = -$ for $i = 1, \ldots, n-1$, and all other entries 0, is minimally potentially stable.

Applications:

1. [BS95, Sect. 10.1] The theory of sign stability is very important in population biology [Log92]. For instance, a general ecosystem consisting of n different populations can be modeled by a linear system of differential equations. The entries of the coefficient matrix of this linear system reflect the effects on the ecosystem due to a small perturbation. The signs of the entries of the coefficient matrix can often be determined from general principles of ecology, while the actual magnitudes are difficult to determine and can only be approximated. The sign stability of the coefficient matrix determines the stability of an equilibrium state of the system.

42.5 Other Eigenvalue Characterizations and Allowing Properties

Definitions:

An n-**cycle pattern** is a sign pattern A where the digraph of A is an n-cycle.

A k-**consistent sign pattern matrix** is a sign pattern A where every matrix $B \in Q(A)$ has exactly k real eigenvalues.

For an $m \times n$ sign pattern matrix $A = [a_{ij}]$, the **directed bipartite digraph** of A, denoted $\text{BG}(A)$, is the digraph with bipartite vertex set $\{r_1, \ldots, r_m\} \cup \{c_1, \ldots, c_n\}$ such that (r_i, c_j) is an arc if and only if $a_{ij} = +$ and (c_j, r_i) is an arc if and only if $a_{ij} = -$.

Facts:

1. [EJ91] An $n \times n$ sign pattern A requires all real eigenvalues if and only if each irreducible component of A is a symmetric t.s.p. matrix.
2. [EJ91] An $n \times n$ sign pattern A requires all nonreal eigenvalues if and only if each irreducible component of A
   (a) Is bipartite.
   (b) Has all negative simple cycles.

   (c) Is SNS.

3. [EJ93] For an $n \times n$ sign pattern A, the following statements are equivalent for each positive integer $k \geq 2$:
   (a) The minimum algebraic multiplicity of the eigenvalue 0 occurring among matrices in $Q(A)$ is k.
   (b) A requires an eigenvalue with algebraic multiplicity k, with k maximal.
   (c) The maximum composite cycle length in A is $n - k$.
4. If an $n \times n$ sign pattern A does not require an eigenvalue with algebraic multiplicity 2 (namely, if A allows n distinct eigenvalues), then A allows diagonalizability.
5. Sign patterns that require all distinct eigenvalues have many nice properties, such as requiring diagonalizability. In [LH02], a number of sufficient or necessary conditions for a sign pattern to require all distinct eigenvalues are established.
6. [EHL94a] If a sign pattern A requires all distinct eigenvalues, then A is k-consistent for some k.
7. [EHL94a] Let A be an $n \times n$ sign pattern and let A_I denote the sign pattern obtained from A by replacing all the diagonal entries by $+$. Then A_I requires n distinct real eigenvalues if and only if A is permutation similar to a symmetric irreducible tridiagonal sign pattern.
8. [BS81] An $n \times n$ sign pattern A admits a matrix $B \in Q(A)$ with $Be = B^T e = 0$ (where $e = (1, \ldots, 1)^T$) and $\operatorname{rank}(B) = n - 1$ if and only if A is fully indecomposable and every arc of $\mathrm{BG}(A)$ lies on a cycle.
9. [LHZ97] A 3×3 nonnegative irreducible nonsymmetric sign pattern A allows normality if and only if $AA^T = A^T A$ and A is not permutation similar to $\begin{bmatrix} + & + & 0 \\ + & 0 & + \\ + & + & + \end{bmatrix}$.
10. [LHZ97] If $\begin{bmatrix} A_1 & A_2 \\ A_3 & A_4 \end{bmatrix}$ allows normality, where A_1 is square, then the square pattern
$$\begin{bmatrix} A_1 & A_2 & A_2 & \ldots & A_2 \\ A_3 & A_4 & A_4 & \ldots & A_4 \\ A_3 & A_4 & A_4 & \ldots & A_4 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ A_3 & A_4 & A_4 & \ldots & A_4 \end{bmatrix}$$
also allows normality. Parallel results hold for allowing idempotence and for allowing nilpotence of index 2. (See [HL99] and [EL99].)
11. [EL99] Suppose an $n \times n$ sign pattern A allows nilpotence. Then A^n is compatible with 0, and for $1 \leq k \leq n-1$, $\operatorname{tr}(A^k)$ is compatible with 0. Further, for each $m, 1 \leq m \leq n$, $E_m(A)$ (the sum of all principal minors of order m) is compatible with 0.
12. [HL99] Let A be a 5×5 irreducible symmetric sign pattern such that A^2 is compatible with A. Then A allows a symmetric idempotent matrix unless A can be obtained from the following by using permutation similarity and signature similarity:
$$\begin{bmatrix} + & + & + & + & 0 \\ + & + & - & 0 & - \\ + & - & + & + & + \\ + & 0 & + & + & - \\ 0 & - & + & - & + \end{bmatrix}.$$

13. [EJ93, SG03] Let A be an $n \times n$ sign pattern. If the maximum composite cycle length in A is equal to the maximum rank (see Section 42.6) of A, then A allows diagonalizability. In particular, if the maximum composite cycle length of A is at least $n-1$, then A allows diagonalizability.
14. [EJ93] If a sign pattern A allows diagonalizability, then the minimum rank of A (see Section 42.6) is less than or equal to the maximum composite cycle length of A. This necessary condition is not sufficient [SG03].
15. [SG03] Every combinatorially symmetric sign pattern allows diagonalizability.
16. A nonzero $n \times n \, (n \geq 2)$ sign pattern that requires nilpotence does not allow diagonalizability.
17. [GLS07] If a tree sign pattern A allows nilpotence of index 3, then A is a star sign pattern.
18. [EK10] If a full $n \times n$ sign pattern A allows nilpotence of index k, then A also allows nilpotence of index m for all m with $k \leq m \leq n$
19. [Kir11] A sign pattern A allows a diagonalizing matrix of some nonnegative irreducible matrix if and only if A is fully indecomposable and A contains a unique unisigned column, which contains no zero entries.

For further reading, see [Esc93a],[HLZ11], [Yeh96], [KMT96], [SG06], [COD09], and [LL09].

Conjectures and Open Problems

1. Characterization of patterns that require diagonalizability is still open. Facts 5 through 7 above are related to this open question.
2. Complete characterization of sign patterns that allow diagonalizability is still open. Facts 3, 4, 13, 14, 15, and 16 above are related to this open question.

Examples:

1. By Fact 1, the pattern
$$\begin{bmatrix} * & + & 0 & 0 \\ + & * & - & - \\ 0 & - & * & 0 \\ 0 & - & 0 & * \end{bmatrix},$$
where each $*$ entry could be $0, +$, or $-$, requires all real eigenvalues.
2. [LH02] Up to equivalence (negation, transposition, permutational similarity, and signature similarity), the 3×3 irreducible sign patterns that require three distinct eigenvalues are the irreducible tridiagonal symmetric sign patterns, irreducible tridiagonal skew-symmetric sign patterns, and 3-cycle sign patterns, together with the following:
$$\begin{bmatrix} + & + & 0 \\ 0 & 0 & + \\ + & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & + & 0 \\ - & 0 & + \\ + & - & 0 \end{bmatrix}, \begin{bmatrix} 0 & + & 0 \\ - & 0 & + \\ + & 0 & 0 \end{bmatrix}, \begin{bmatrix} 0 & + & - \\ - & 0 & + \\ + & - & 0 \end{bmatrix}, \begin{bmatrix} + & + & 0 \\ 0 & 0 & + \\ + & - & 0 \end{bmatrix}.$$
3. [EL99] The sign pattern $A = \begin{bmatrix} + & + & 0 \\ - & - & - \\ - & + & + \end{bmatrix}$ does not allow nilpotence, although it satisfies many "obvious" necessary conditions.
4. [LHZ97] The $n \times n$ sign pattern $\begin{bmatrix} + & + & + & \cdots & + \\ + & + & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ + & + & 0 & \cdots & 0 \end{bmatrix}$ allows normality.

42.6 Minimum Rank, Inertia

Definitions:

Let A be a sign pattern matrix.

The **minimum rank** of A, denoted $\operatorname{mr}(A)$, is defined by $\operatorname{mr}(A) = \min\{\text{ rank } B : B \in Q(A)\}$.

The **maximum rank** of A, $\operatorname{MR}(A)$, is given by $\operatorname{MR}(A) = \max\{\text{ rank } B : B \in Q(A)\}$.

The **term rank** of A is the maximum number of nonzero entries of A no two of which are in the same row or same column.

A sign pattern is said to be **row condensed** if it does not contain a zero row and no two rows are identical or are negatives of each other. **Column condensed** sign patterns are defined similarly. A sign pattern is said to be a **condensed sign pattern** if it is both row condensed and column condensed. Clearly, given any nonzero sign pattern A, we can delete zero, duplicate or oppositely signed rows and columns of A to get a condensed sign pattern matrix A_c (called the **condensed sign pattern of** A) with the same minimum rank. For the $m \times n$ zero sign pattern A, the condensed sign pattern $A_c = \emptyset$, the empty matrix, which has minimum rank 0.

For a symmetric sign pattern A, $\operatorname{smr}(A)$, the **symmetric minimum rank** of A is

$$\operatorname{smr}(A) = \min\{\text{ rank } B : B = B^T,\ B \in Q(A)\}.$$

The **symmetric maximum rank** of A, $\operatorname{SMR}(A)$, is given by

$$\operatorname{SMR}(A) = \max\{\text{ rank } B : B = B^T,\ B \in Q(A)\}.$$

For a symmetric sign pattern A, the **symmetric inertia set of** A is $\operatorname{si}(A) = \{\operatorname{in}(B) : B = B^T \in Q(A)\}$. $\operatorname{si}(A)$ is said to be **maximal** if it is not a proper subset of $\operatorname{si}(\tilde{A})$ for any symmetric sign pattern $\tilde{A}$.

A symmetric sign pattern A **requires unique symmetric inertia** if $\operatorname{in}(B_1) = \operatorname{in}(B_2)$ for all symmetric matrices $B_1, B_2 \in Q(A)$.

A sign pattern is said to be **full** or **entrywise nonzero** if it does not have any zero entry.

Facts:

1. $\operatorname{MR}(A)$ is equal to the term rank of A.
2. Starting with a real matrix whose rank is $\operatorname{mr}(A)$ and changing one entry at a time to eventually reach a real matrix whose rank is $\operatorname{MR}(A)$, all ranks between $\operatorname{mr}(A)$ and $\operatorname{MR}(A)$ are achieved by real matrices in $Q(A)$.
3. [HS93] A sign pattern A requires a fixed rank r if and only if A is permutationally equivalent to a sign pattern of the form $\begin{bmatrix} X & Y \\ Z & 0 \end{bmatrix}$, where X is $k \times (r-k), 0 \le k \le r$, and Y and Z^T are L-matrices.
4. [AS00] If the maximum number of sign changes in the rows of a full sign pattern A is k, then $\operatorname{mr}(A) \le k+1$.
5. [HLW01] For every symmetric sign pattern A, $\operatorname{MR}(A)=\operatorname{SMR}(A)$.
6. [For02] Let A be a full $m \times n$ sign pattern and let B be the $(1,-1)$ matrix in $Q(A)$. Then $\operatorname{mr}(A) \ge \frac{\sqrt{mn}}{\|B\|_2}$.
7. [RS10] Let $B = [b_{ij}]$ be a nonzero $m \times n$ real matrix and suppose that all but h of the entries of B satisfy $|b_{ij}| \ge \gamma$ for some positive numbers h and γ. Then
$$\operatorname{mr}(\operatorname{sgn}(B)) \ge \frac{mn\gamma}{\gamma h + \sqrt{mn}\|B\|_2}.$$
8. [AHK05] Let A be an $m \times n$ sign pattern matrix. If $\operatorname{mr}(A) \le 2$, or $\operatorname{mr}(A) \ge n-1$, or A is entrywise nonzero, then $\operatorname{mr}(A)$ can be realized by a rational matrix in $Q(A)$.

9. [DHH06] For a symmetric tree sign pattern A, there is an algorithm to construct a symmetric integer matrix $B \in Q(A)$ realizing the minimum rank of A. This allows computation of the minimum rank of any tree sign pattern because for a nonsymmetric tree sign pattern A, there is a diagonal sign pattern D such that DA is symmetric [CHL03], and $\mathrm{mr}(A) = \mathrm{mr}(DA)$.
10. [KR08] There is a 12×12 sign pattern matrix A with $\mathrm{mr}(A) = 3$ such that there is no real matrix in $Q(A)$ with rank 3.
11. [BFH08] There are two zero-nonzero patterns Z_1 and Z_2 such that the minimum rank of matrices described by Z_1 is less over the complex numbers than over the real numbers, and the minimum rank of matrices described by Z_2 is less over the real numbers than over the rational numbers.
12. [AHL09a] If A is a sign pattern with $\mathrm{MR}(A) - \mathrm{mr}(A) = 1$, then there is a rational matrix $B \in Q(A)$ such that $\mathrm{rank}(B) = \mathrm{mr}(A)$.
13. [AHL12] For every $m \times n$ sign pattern A with $\mathrm{mr}(A) = n - 2$, rational realization of the minimum rank is possible.
14. [AHL12] For each integer $n \geq 12$, there exists a nonnegative integer m such that there exists an $n \times m$ sign pattern matrix with minimum rank $n - 3$ for which rational realization is not possible.
15. [LGA13] A sign pattern matrix A has minimum rank 2 if and only if its condensed sign pattern A_c satisfies the following conditions:
    (i) A_c has at least two rows and two columns,
    (ii) each row and each column of A_c has at most one zero entry, and
    (iii) there are signature sign patterns D_1 and D_2 and permutation sign patterns P_1 and P_2 such that each row and each column of $P_1D_1A_cD_2P_2$ is nondecreasing.
16. [LGA13] Let A be an $m \times n$ sign pattern with $\mathrm{mr}(A) = 2$. Suppose that the condensed sign pattern of A is $m' \times n'$. Then there is an integer matrix $B = [b_{ij}] \in Q(A)$ such that $\mathrm{rank}(B) = 2$ and $|b_{ij}| \leq 2\min\{m', n'\} - 3$ for all i, j. Furthermore, if each row of the condensed sign pattern of A contains exactly one zero entry, then there is an integer matrix $B = [b_{ij}] \in Q(A)$ such that $\mathrm{rank}(B) = 2$ and $|b_{ij}| \leq \min\{m'-1, n'-1\}$ for all i, j.
17. [HLW01] A symmetric sign pattern A requires a unique symmetric inertia if and only if $\mathrm{smr}(A)=\mathrm{SMR}(A)$.
18. [HLW01] For the symmetric sign pattern $A = \begin{bmatrix} 0 & A_1 \\ A_1^T & 0 \end{bmatrix}$ of order n, we have
$$\mathrm{si}(A) = \{(k, k, n - 2k) \colon \mathrm{mr}(A_1) \leq k \leq \mathrm{MR}(A_1)\}.$$
In particular, $2\,\mathrm{mr}(A_1) = \mathrm{smr}(A)$.
19. [KW10] Let A be a full symmetric sign pattern of order n. If a nonnegative integer triple (p, q, r) with $1 \leq r \leq n - 1$ is in $\mathrm{si}(A)$, then each nonnegative integer triple (p', q', r') with $p' \in \{p, \ldots, p+r\}, q' \in \{q, \ldots, q+r\}, r' \in \{0, \ldots, r\}$ and $p'+q'+r' = n$, is in $\mathrm{si}(A)$.
20. [KW10] The sets $M_0 = \{(0, 0, n)\}, M_1 = \{(p, q, r) \in \mathbb{N}^3 : p > 1, p + q + r = n\}$ and $M_2 = \{(p, q, r) \in \mathbb{N}^3 : q > 1, p + q + r = n\}$ are the only maximal symmetric inertia sets of symmetric sign patterns of order n. Furthermore, these maximal symmetric inertia sets are achieved by the $n \times n$ zero sign pattern, the $n \times n$ sign pattern J_n all of whose entries are $+$ and $-J_n$, respectively.

For further reading see [CHL03], [SSG04], [Hog05], [GS05], [KI07], [daF06], [CHM06], [GS06a], [AHL09b], [Hog11], [DS12], [BDM12], and references [Nyl96], [JL99], [BFH04], and [BHL04] in Chapter 46.

Examples:

1. [HLW01] Let
$$A = \begin{bmatrix} + & 0 & + & + \\ 0 & + & + & + \\ + & + & - & 0 \\ + & + & 0 & - \end{bmatrix}.$$
Then $\text{si}(A) = (2, 2, 0)$, $\text{smr}(A) = SMR(A) = 4$, but $3 = \text{mr}(A) < \text{smr}(A) = 4$.
2. [HL01, KW10] Let J_n be the $n \times n$ sign pattern with all entries equal to $+$. Then
$$\text{si}(J_n) = \{(s, t, n - s - t) : s \geq 1,\ t \geq 0,\ s + t \leq n\}.$$
3. [Gao01, GS03, HL01] Let A be the $n \times n$ ($n \geq 3$) sign pattern all of whose diagonal entries are zero and all of whose off-diagonal entries are $+$. Then
$$\text{in}(A) = \{(s, t, n - s - t) : s \geq 1,\ t \geq 2,\ s + t \leq n\}.$$

Applications:

1. [PS86] For any finite sets X and Y and any function $f : X \times Y \to \{0, 1\}$, the unbounded-error randomized communication complexity of f, denoted $U(f)$, satisfies
$$\log(\text{mr}(A_f)) \leq U(f) \leq \log(\text{mr}(A_f)) + 1,$$
where the (i, j) entry of A_f is $+$ if $f(i, j) = 1$ and is $-$ if $f(i, j) = 0$.

42.7 Spectrally Arbitrary, and Inertially Arbitrary Sign Patterns

Definitions:

A sign pattern A of order n is an **inertially arbitrary pattern** if every possible ordered triple (p, q, z) of nonnegative integers $p, q,$ and z with $p + q + z = n$ can be achieved as the inertia of some $B \in Q(A)$.

A sign pattern A of order n is **spectrally arbitrary** if every monic real polynomial of degree n can be achieved as the characteristic polynomial of some matrix $B \in Q(A)$.

A zero-nonzero $m \times n$ pattern $A = [a_{ij}]$ over $\mathbb{R}$ is a matrix whose entries come from the set $\{0, *\}$ and the qualitative class of A consists of all $m \times n$ real matrices $B = [b_{ij}]$ such that $b_{ij} \neq 0$ if and only if $a_{ij} = *$.

Facts:

1. [DJO00] The nilpotent-Jacobi method (or NJ-method for short), described as follows, is a useful way for proving that a sign pattern is spectrally arbitrary. Let A be an $n \times n$ sign pattern matrix, let $B \in Q(A)$ be a nilpotent matrix, and let $V = \{(j_1, k_1), \ldots, (j_n, k_n)\}$ be positions of n selected nonzero entries of B. Consider the matrix Z obtained from B by replacing its (j_s, k_s)-entry by the indeterminate y_s for $s = 1, 2, \ldots, n$. Let $c_Z = \det(xI - Z)$ be the characteristic polynomial of Z. Then there exist polynomials $q_1, \ldots, q_n$ in the y_s such that $c_Z = x^n + q_1 x^{n-1} + q_2 x^{n-2} + \cdots + q_n$. Set J to be the Jacobi matrix of the polynomials $q_1, \ldots, q_n$ with respect to $y_1, \ldots, y_n$;

that is, the (j,k)-entry of J is $\dfrac{\partial q_j}{\partial y_k}$. If $J|_{Z=B}$ is nonsingular, then A as well as every superpattern of A is a spectrally arbitrary sign pattern.

2. [DJO00], [GS12], [BDH12] Let T_n be the $n \times n$ tridiagonal sign pattern with each superdiagonal entry positive, each subdiagonal entry negative, the $(1,1)$ entry negative, the (n,n) entry positive, and every other entry zero. It is shown in [BDH12] that T_n allows a nilpotent matrix. It was conjectured in [DJO00] and proved in [GS12] that T_n is spectrally arbitrary for all $n \geq 2$.
3. [MOT03] Suppose $1 \leq p \leq n-1$. Then every $n \times n$ sign pattern with p columns with all $+$ entries and $n-p$ columns with all $-$ entries is spectrally arbitrary.
4. [BMO04] Every irreducible spectrally arbitrary $n \times n$ $(n \geq 2)$ sign pattern has at least $2n-1$ nonzero entries. Example 1 is a family of spectrally arbitrary $n \times n$ sign patterns having $2n$ nonzero entries.
5. [MTD05] For a star sign pattern S_n $(n \geq 2)$, the following are equivalent:
   (a) S_n is spectrally arbitrary.
   (b) S_n is inertially arbitrary.
   (c) S_n is potentially nilpotent and has a loop at each of the $n-1$ leaves in its graph.
   (d) S_n and $-S_n$ are both potentially stable and S_n has a loop at each of the $n-1$ leaves in its graph.
   (e) S_n is potentially nilpotent and potentially stable.
6. [DHH07] There exists a reducible spectrally arbitrary sign pattern A such that one of the irreducible components of A is not spectrally arbitrary. The direct sum of two spectrally arbitrary sign patterns may not be spectrally arbitrary.
7. [DHH07] The $2n$-conjecture is affirmed for $n = 5$.
8. [Per07] Every potentially nilpotent full sign pattern is spectrally arbitrary.
9. [GS01] Let S_n be the $n \times n$ $(n \geq 2)$ sign pattern with each strictly upper (respectively, lower) triangular entry positive (respectively, negative), the $(1,1)$ entry negative, the (n,n) entry positive, and all other diagonal entries zero. Then S_n is inertially arbitrary. [ML02] Further, if the $(1,n)$ and $(n,1)$ entries of S_n are replaced by zero, the resulting sign pattern is also inertially arbitrary.
10. [CV05] Not every inertially arbitrary sign pattern is spectrally arbitrary.
11. [CM07] There are 4×4 inertially arbitrary zero-nonzero patterns that are not spectrally arbitrary.
12. [KMO07] There exist inertially arbitrary zero-nonzero patterns, for which there exist superpatterns that are not inertially arbitrary.
13. [KOD07] If every real monic polynomial of degree n having a positive coefficient of x^{n-2} is the characteristic polynomial of some matrix in $Q(A)$, then A is inertially arbitrary.
14. [KOD07] There are irreducible inertially arbitrary sign patterns that are not potentially nilpotent (and thus not spectrally arbitrary).
15. [CV07] There exists an irreducible zero-nonzero pattern Z which is inertially arbitrary but no sign pattern obtained by replacing the nonzero entries of Z by $+$ or $-$ is inertially arbitrary.
16. [KOS09]For any potentially nilpotent sign pattern A of order n, the $2n \times 2n$ sign patterns $\begin{bmatrix} A & V \\ A & V \end{bmatrix}$ and $\begin{bmatrix} A & V \\ -A & -V \end{bmatrix}$ are potentially nilpotent for any $n \times n$ sign pattern V.
17. [Cav10] If B is a zero-nonzero pattern of order n, and A is an inertially arbitrary zero-nonzero pattern of order at least $2(n-1)$, then $A \oplus B$ is inertially arbitrary if and only if B allows the inertias $(0,0,n), (0,n,0)$, and $(n,0,0)$.

18. [AHL10] A 4×4 tree sign pattern is spectrally arbitrary if and only if it is potentially nilpotent and potentially stable.

For further reading, see [CKS05], [BOD07], [LSG08], [GLS08], [LG09], and [KOD09].

Conjectures and Open Problems

1. It is conjectured (and known as the $2n$ conjecture) that every $n \times n$ spectrally arbitrary sign pattern must have at least $2n$ nonzero entries. Facts 2, 4, and 7 above are related to this open question.

Examples:

1. [BMO04] The $n \times n$ Hessenberg sign pattern that has all $+$ entries in the first column, all $-$ entries on the first superdiagonal, a $-$ in the (n, n) position, and all other entries equal to zero is an example of a spectrally arbitrary $n \times n$ sign pattern with $2n$ nonzero entries.
2. [GS06b] For each odd $n \geq 3$, the $n \times n$ full sign pattern A with all entries below the main diagonal equal to $-$ and all entries on or above the main diagonal equal to $+$, except that the $(1, 1)$ entry is $-$ is an SAP.

42.8 Patterns That Allow Certain Types of Inverses

Definitions:

A sign pattern matrix A is **nonnegative (positive)**, denoted $A \geq 0$ ($A > 0$), if all of its entries are nonnegative (positive).

An **inverse nonnegative (inverse positive)** sign pattern matrix is a square sign pattern A that allows an entrywise nonnegative (positive) inverse.

Let both B and X be real matrices or nonnegative sign pattern matrices. Consider the following conditions.

(1) $BXB = B$.
(2) $XBX = X$.
(3) BX is symmetric.
(4) XB is symmetric.

For a real matrix B, there is a unique matrix X satisfying all four conditions above and it is called the **Moore–Penrose inverse** of B, and denoted by $B^{\dagger}$. More generally, let $B\{i, j, \ldots, l\}$ denote the set of matrices X satisfying conditions $(i), (j), \ldots, (l)$ from among conditions (1)–(4). A matrix $X \in B\{i, j, \ldots, l\}$ is called an **$(i, j, \ldots, l)$-inverse** of B. For example, if (1) holds, X is called a (1)-inverse of B; if (1) and (2) hold, X is called a (1, 2)-inverse of B, and so forth. See Section 5.7 and Chapter 27.

For a nonnegative sign pattern matrix B, if there is a nonnegative sign pattern X satisfying (1) to (4), then X is unique and it is called the Moore–Penrose inverse of B. An $(i, j, \ldots, l)$-inverse of B is defined similarly as in the preceding paragraph.

Facts:

The first three facts below are contained in [BS95, Chap. 9].

1. [JLR79] Let A be an $n \times n$ $(+, -)$-pattern, where $n \geq 2$. Then A is inverse positive if and only if A is not permutationally equivalent to a pattern of the form $\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}$,

where $A_{12} < 0, A_{21} > 0$, the blocks A_{11}, A_{22} are square or rectangular, and one (but not both) of A_{11}, A_{22} may be empty.

2. The above result in [JLR79] is generalized in [FG81] to $(+, -, 0)$-patterns, and additional equivalent conditions are established. Let e denote the column vector of all ones, J the $n \times n$ matrix all of whose entries equal 1, and A' the matrix obtained from A by replacing all negative entries with zeros. For an $n \times n$ fully indecomposable sign pattern A, the following are equivalent:
   (a) A is inverse positive.
   (b) A is not permutationally equivalent to a pattern of the form $\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}$, where $A_{12} \leq 0, A_{21} \geq 0$, the blocks A_{11}, A_{22} are square or rectangular, and one (but not both) of A_{11}, A_{22} may be empty.
   (c) The pattern $\begin{bmatrix} 0 & A \\ -A^T & 0 \end{bmatrix}'$ is irreducible.
   (d) There exists $B \in Q(A)$ such that $Be = B^T e = 0$.
   (e) There exists a doubly stochastic matrix D such that $(D - \frac{1}{n}J) \in Q(A)$.
3. [Joh83] For an $n \times n$ fully indecomposable sign pattern A, the following are equivalent: A is inverse nonnegative; A is inverse positive; $-A$ is inverse nonnegative; $-A$ is inverse positive.
4. [Fie83] An $n \times n$ $(n \geq 2)$ sign pattern A is the sign pattern of an $n \times n$ real matrix of the form BC^{-1}, with both B and C entrywise positive matrices, if and only if each row of A has at least one + entry.
5. [EHL97] If an $n \times n$ sign pattern A allows B and B^{-1} to be in $Q(A)$, then
   (a) $\mathrm{MR}(A) = n$.
   (b) A^2 is compatible with I.
   (c) adj A is compatible with A and $\det(A)$ is compatible with $+$, or, adj A is compatible with $-A$ and $\det(A)$ is compatible with $-$, where adj A is the adjoint of A.
6. In [EHL94b], the class $\mathcal{G}$ of all square patterns A that allow $B, C \in Q(A)$ where $BCB = B$ is investigated; it is shown for nonnegative patterns that $\mathcal{G}$ coincides with the class of square patterns that allow $B \in Q(A)$ where $B^3 = B$.
7. [HLR04] An $m \times n$ nonnegative sign pattern A has a nonnegative $(1,3)$-inverse (Moore–Penrose inverse) if and only if A allows a nonnegative $(1,3)$-inverse (Moore–Penrose inverse).

For further reading, see [BF87], [Tho89], [BS95, Theorem 9.2.6], [Kir95], [SS01], [SS02], [KOS07], [KS08], [AT09], [ZBW12a], and [ZBW12b].

Examples:

1. By Facts 2 and 3, the sign pattern

$$A = \begin{bmatrix} + & 0 & + & + \\ 0 & + & + & + \\ - & - & - & 0 \\ - & - & 0 & - \end{bmatrix}$$

is not inverse nonnegative.

2. [EHL97] The sign pattern

$$A = \begin{bmatrix} + & + & + & + \\ 0 & + & + & + \\ 0 & + & - & - \\ 0 & - & + & + \end{bmatrix}$$

satisfies all the necessary conditions in Fact 4, but it does not allow an inverse pair B and B^{-1} in $Q(A)$.

42.9 Orthogonality

Definitions:

A square sign pattern A is **potentially orthogonal (PO)** if A allows an orthogonal matrix.

A square sign pattern A that does not have a zero row or zero column is **sign potentially orthogonal** (**SPO**) if every pair of rows and every pair of columns allows orthogonality.

Two vectors $\mathbf{x} = [x_1, \ldots, x_n]$ and $\mathbf{y} = [y_1, \ldots, y_n]$ are **combinatorially orthogonal** if $|\{i : x_i y_i \neq 0\}| \neq 1$.

A square sign pattern A is said to be **k-regular** if each row and each column of A contains exactly k nonzero entries.

Facts:

1. Every PO sign pattern is SPO.
2. [BS94], [Wat96] For $n \leq 4$, every $n \times n$ SPO sign pattern is PO.
3. [Wat96] There is a 5×5 fully indecomposable SPO sign pattern that is not PO.
4. [JW98] There is a 6×6 $(+, -)$ sign pattern that is SPO but not PO.
5. [BBS93] Let A be an $n \times n$ fully indecomposable sign pattern whose rows are combinatorially orthogonal and whose columns are combinatorially orthogonal. Then A has at least $4(n-1)$ nonzero entries. This implies that a conjecture of Fiedler [Fie64], which says a fully indecomposable orthogonal matrix of order n has at least $4(n-1)$ nonzero entries, is true.
6. [CJL99] For $n \geq 2$, there is an $n \times n$ fully indecomposable orthogonal matrix with k zero entries if and only if $0 \leq k \leq (n-2)^2$.
7. [EHH99] Let S be any skew symmetric sign pattern of order n all of whose off-diagonal entries are nonzero. Then $I + S$ is PO.
8. [GS07]
   (a) For any even n, there is a k-regular SPO sign pattern of order n if and only if $1 \leq k \leq n$.
   (b) For every odd $n \neq 5$, there is a k-regular SPO sign pattern of order n if and only if $1 \leq k \leq n$ and $k \neq 2$.
   (c) For $n = 5$, there is a k-regular SPO sign pattern of order n if and only if $k \neq 2$ and $k \neq 3$.
9. [HS12] There is a zero-nonzero pattern that is not potentially orthogonal but does allow a complex unitary matrix.

For further reading, see [Lim93], [Sha98], [CS99], [CHR03], and [FH12].

Conjectures and Open Problems

1. [EHH99] It is an open question as to whether every sign pattern A that allows an inverse in $Q(A^T)$ is PO. Fact 7 is related to this open question.

Examples:

1. [BS94] Every 3×3 ± SPO sign pattern can be obtained from the following sign pattern by using permutation equivalence and multiplication by signature patterns:
$$\begin{bmatrix} + & + & + \\ + & + & - \\ + & - & + \end{bmatrix}.$$
2. [Wat96] The sign pattern
$$\begin{bmatrix} - & + & 0 & + & - \\ + & + & - & 0 & - \\ 0 & + & + & + & + \\ + & 0 & - & + & + \\ - & - & - & + & + \end{bmatrix}$$
is SPO but not PO.
3. [SSG06] The sign pattern $\begin{bmatrix} - & + & + & \cdots & + \\ 0 & - & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & \ddots & + \\ 0 & \cdots & 0 & - & + \\ + & \cdots & + & + & + \end{bmatrix} \in Q_n \ (n \geq 3)$ is PO.

42.10 Sign-Central Patterns

Definitions:

A real matrix B is **central** if the zero vector is in the convex hull of the columns of B. A real or sign pattern matrix A is **sign-central** if A requires centrality.

A **minimal sign-central matrix** A is a sign-central matrix that is not sign-central if any column of A is deleted.

A **tight sign-central** matrix is a sign-central matrix A for which the Hadamard (entrywise) product of any two columns of A contains a negative component.

A **nearly sign-central matrix** is a matrix that is not sign-central but can be augmented to a sign-central matrix by adjoining a column.

Facts:

1. [AB94] An $m \times n$ matrix A is sign-central if and only if the matrix DA has a nonnegative column vector for every strict signing D of order m.
2. [HKK03] Every tight sign-central matrix is a minimal sign-central matrix.
3. [LC00] If A is nearly sign-central and $[A \mid \alpha]$ is sign-central, then $[A \mid \alpha']$ is also sign-central for every $\alpha' \neq 0$ obtained from α by zeroing out some of its entries.

For further reading, see [BS95, Sect. 5.4], [DD90], [LLS97], [BJS98], and [HKK05].

Examples:

1. [BS95, p. 100], [HKK03] For each positive integer m, the $m \times 2^m$ ± sign pattern E_m such that each m-tuple of $+$'s and $-$'s is a column of E_m, is a tight sign-central sign pattern.

42.11 Power Positivity

Definitions:

A real square matrix A is **power-positive** if there is a positive integer k such that A^k is entrywise positive.

A real square matrix A is **eventually positive** (respectively, **eventually nonnegative**) if there exists a positive integer k_0 such that $A^k > 0$ (respectively, $A^k \geq 0$) for all $k \geq k_0$.

For a sign pattern A, A^+ is the sign pattern obtained from A by changing all $-$ entries to 0.

Facts:

1. [EHT10] A square sign pattern A requires eventual positivity if and only if it is nonnegative and primitive. Sign patterns that require eventual nonnegativity have also been characterized.
2. [CHO10] A sign pattern A requires power-positivity if and only if either A or $-A$ is nonnegative and has a primitive digraph, or equivalently, either A or $-A$ requires eventual positivity.
3. [CHO10] A sign pattern A allows power-positivity if and only if A or $-A$ allows eventual positivity.
4. [BCD10] For $n \geq 2$, the minimum number of $+$ entries in any $n \times n$ sign pattern that allows eventual positivity is n + 1.
5. [BCD10] Let A be a square sign pattern such that A^+ is primitive. Then A allows eventual positivity.
6. [BCD10] Let $\hat{A}$ be the sign pattern obtained from a sign pattern A by changing all 0 and $-$ diagonal entries to $+$. If A allows eventual positivity, then $\hat{A}$ allows eventual positivity.

For further reading, see [CEH12].

Examples:

1. [CHO10] The sign pattern $A \begin{bmatrix} + & + & - \\ - & 0 & + \\ + & - & - \end{bmatrix}$ allows power-positivity, and so does $-A$.
2. [BCD10] The sign pattern $B \begin{bmatrix} + & - & 0 \\ + & 0 & - \\ - & + & + \end{bmatrix}$ allows eventual positivity, but B^+ is reducible.

42.12 Complex Sign Patterns and Ray Patterns

Definitions:

A **complex sign pattern matrix** is a matrix of the form $A = A_1 + iA_2$ for some $m \times n$ sign patterns A_1 and A_2, and the **sign pattern class** or **qualitative class** of A is

$$Q(A) = \{B_1 + iB_2 \ : \ B_1 \in Q(A_1) \ \text{ and } \ B_2 \in Q(A_2)\} \ .$$

Many definitions for sign patterns, such as SNS, extend in the obvious way to complex sign patterns.

The **determinantal region** of a complex sign pattern A is the set

$$S_A = \{\det(B) \ : \ B \in Q(A)\}.$$

A **ray pattern** is a matrix each of whose entries is either 0 or a ray in the complex plane of the form $\{re^{i\theta} \ : \ r > 0\}$ (which is represented by $e^{i\theta}$). The **ray pattern class** of an $m \times n$ ray pattern A is

$$Q(A) = \{B = [b_{pq}] \in M_{m\times n}(\mathbb{C})\colon b_{pq} = 0 \text{ if and only if } a_{pq} = 0, \text{ and otherwise } \arg b_{pq} = \arg a_{pq}\}.$$

For $\alpha < \beta$, the **open sector** from the ray $e^{i\alpha}$ to the ray $e^{i\beta}$ is the set of rays $\{re^{i\theta} \ : \ r > 0, \, \alpha < \theta < \beta\}$.

The **determinantal region** of a ray pattern A is the set

$$R_A = \{\det(B) \ : \ B \in Q(A)\}.$$

An $n \times n$ ray pattern A is **ray nonsingular** if the Hadamard product $X \circ A$ is nonsingular for every entrywise positive $n \times n$ matrix X.

A **cyclically real** ray pattern is a square ray pattern A where the actual products of every cycle in A is real.

A complex sign pattern or ray pattern A of order n is **spectrally arbitrary** if every monic complex polynomial of degree n can be achieved as the characteristic polynomial of some matrix $B \in Q(A)$.

Facts:

1. [EHL98], [SS05] For a complex sign pattern A, the boundaries of S_A are always on the axes on the complex plane.
2. [EHL98], [SS05] For a sign nonsingular complex sign pattern A, S_A is either entirely contained in an axis of the complex plane or is an open sector in the complex plane with boundary rays on the axes.
3. [SS05] For a complex sign pattern or ray pattern A, the region $S_A\backslash\{0\}$ (or $R_A\backslash\{0\}$) is an open set (in fact, a disjoint union of open sectors) in the complex plane, except in the cases that S_A (R_A) is entirely contained in a line through the origin.
4. The results of [MOT97], [LMS00], and [LMS04] show that there is an entrywise nonzero ray nonsingular ray pattern of order n if and only if $1 \leq n \leq 4$.
5. [EHL00] An irreducible ray pattern A is cyclically real if and only if A is diagonally similar to a real sign pattern. More generally, a ray pattern A is diagonally similar to a real sign pattern if and only if A and $A + A^*$ are both cyclically real.
6. [MS08] The nilpotent-Jacobi method for sign patterns also holds for ray patterns. Every $n \times n$ irreducible spectrally arbitrary ray pattern has at least $3n - 1$ nonzero entries. There exists a family of $n \times n$ ($n \geq 3$) irreducible ray patterns with exactly $3n$ nonzero entries.
7. [GSF09] Every $n \times n$ irreducible spectrally arbitrary complex sign pattern matrix has at least $3n - 1$ nonzero entries. For every $n \geq 3$, there exists an $n \times n$ irreducible spectrally arbitrary complex sign pattern with exactly $3n$ nonzero entries.

For further reading, see [SLR06].

Examples:

1. [EHL98] If $A = \begin{bmatrix} + & - \\ + & + \end{bmatrix} + i \begin{bmatrix} + & 0 \\ 0 & - \end{bmatrix}$, then A is sign nonsingular and S_A is the open sector from the ray $e^{-i\pi/2}$ to the ray $e^{i\pi/2}$.
2. [MOT97] The ray pattern $\begin{bmatrix} e^{i\pi/2} & + & + & + \\ + & e^{i\pi/2} & + & + \\ + & + & e^{i\pi/2} & + \\ + & + & + & e^{i\pi/2} \end{bmatrix}$ is ray nonsingular.
3. [EHL00] Let

$$A = \begin{bmatrix} 0 & e^{-i\theta_1} & 0 & -e^{-i\theta_1} \\ 0 & + & -e^{-i\theta_2} & 0 \\ e^{i(\theta_1+\theta_2)} & -e^{i\theta_2} & 0 & -e^{i\theta_2} \\ e^{i\theta_1} & - & 0 & - \end{bmatrix},$$

where θ_1 and θ_2 are arbitrary. Then A is cyclically real, and A is diagonally similar (via the diagonal ray pattern $S = \text{diag}(+, e^{i\theta_1}, e^{i(\theta_1+\theta_2)}, -e^{i\theta_1})$ to

$$\begin{bmatrix} 0 & + & 0 & + \\ 0 & + & - & 0 \\ + & - & 0 & + \\ - & + & 0 & - \end{bmatrix}.$$

42.13 Powers of Sign Patterns and Ray Patterns

Definitions:

Let J_n (or simply J) denote the all + sign (ray) pattern of order n.

A square sign pattern or ray pattern A is **powerful** if all the powers $A^1, A^2, A^3, \ldots$, are unambiguously defined; that is, no entry in any A^k is a sum involving two or more distinct rays. For a square sign pattern or generalized sign pattern A, the smallest positive integers $l = l(A)$ and $p = p(A)$ such that $A^l = A^{l+p}$ are called the **base** and **period** of A, respectively.

For an irreducible sign pattern or ray pattern A, the **index of imprimitivity** $h(A)$ is the greatest common divisor of the lengths of all the simple cycles in A.

For a generalized sign pattern A, $|A|$ denotes the $(0, 1)$-matrix obtained from A by replacing each nonzero entry by 1. A square generalized sign pattern A is said to be **primitive** if $|A|$ is primitive (namely, A is irreducible and $h(A) = 1$).

A square sign pattern or ray pattern A is **k-potent** if k is the smallest positive integer such that $A = A^{k+1}$.

Facts:

1. [LHE94] An irreducible sign pattern A with index of imprimitivity h (see Section 40.7) is powerful if and only if all cycles of A with lengths odd multiples of h have the same sign and all cycles (if any) of A with lengths even multiples of h are positive (see [SS04]). A sign pattern A is powerful if and only if for every positive integer d and for every pair of matrices $B, C \in Q(A)$, $\text{sgn}(B^d) = \text{sgn}(C^d)$.
2. [LHE94] Let A be an irreducible powerful sign pattern, with index of imprimitivity h. Then the base and the period of A are given by $l(A) = l(|A|)$, $p(A) = h$ if A does not have any negative cycles, and $p(A) = 2h$ if A has a negative cycle.

3. [Esc93b] The only irreducible idempotent sign pattern of order $n \geq 2$ is the all $+$ sign pattern.
4. [LHE94, SEK99, SBS02], Every k-potent irreducible sign or ray pattern matrix is powerful.
5. [EL97] The maximum number of $-$ entries in the square of a sign pattern of order n is $n^2 - 2$; the maximum number of $-$ entries in the square of a $(+, -)$ sign pattern of order n is $\lfloor n^2/2 \rfloor$.
6. [HL01b] Let A be an $n \times n$ $(n \geq 3)$ sign pattern. If A^2 has only one entry that is not nonpositive, then A^2 has at most $n^2 - n$ negative entries.
7. [LHS02] Let A be an irreducible ray pattern. Then A is powerful if and only if A is diagonally similar to a subpattern of $e^{i\alpha}J$ for some $\alpha \in \mathbb{R}$, where J is the all $+$ ray pattern.
8. [LHS05] Suppose that $A = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}$ is a powerful ray pattern, where A_{11} (resp., A_{22}) is irreducible with index of imprimitivity h_1 (resp., h_2) and $0 \neq A_{11} \preceq c_1 J_{n_1}, 0 \neq A_{22} \preceq c_2 J_{n_2}$. If $A_{12} \neq 0$, then $\left(\frac{c_2}{c_1}\right)^{\operatorname{lcm}(h_1, h_2)} = 1$.
9. [CJK05] Let A be an irreducible $n \times n$ $(n \geq 2)$ ray pattern with $h(A) = h$. Then A is periodic with period p if and only if $h|p$ and A is ray diagonally similar to $\omega|A|$ where the period of ω^h is equal to p/h.
10. [YSS07] For a primitive nonpowerful generalized sign pattern A, the base of A is the smallest positive integer k such that all entries of A^k are $\#$.
11. [YSS07, AI04] For any primitive nonpowerful generalized sign pattern A of order n, $l(A) \leq 2(n-1)^2 + n = 2n^2 - 3n + 2$ and this upper bound is sharp.
12. [YSS07] For any irreducible sign pattern A of order $n \geq 3$, $l(A) \leq 2(n-1)^2 + n$ and $l(A) \notin [2n^2 - 4n + 6, 2n^2 - 3n]$.
13. [CL08] The set of bases of the combinatorially symmetric primitive sign patterns of order n $(n > 5)$ is $\{1, 2, \ldots, 2n\}$.
14. [JMS11] An $n \times n$ irreducible sign pattern A is powerful if and only if A^{n^2-2n+2} contains no ambiguous entry.
15. [YMS11] The possible bases of primitive, non-powerful sign pattern matrices of order n with exactly d nonzero diagonal entries are $\{2, 3, \ldots, 3n - d - 1\}$.

For further reading, see [SEK99], [Stu99], [SBS02], [LG01], [Stu03], [LY06], [Liu07], [LL08], [GSS09], [Hua09], [LLS10], [WLH10], and [CL10].

Examples:

1. [LHE94] The reducible sign pattern $A = \begin{bmatrix} 0 & + & + & + \\ 0 & + & 0 & + \\ 0 & 0 & - & - \\ 0 & 0 & 0 & 0 \end{bmatrix}$ satisfies $A^2 = \begin{bmatrix} 0 & + & - & \# \\ 0 & + & 0 & + \\ 0 & 0 & + & + \\ 0 & 0 & 0 & 0 \end{bmatrix}$ and $A^3 = A$. Thus, A is 2-potent and yet A is not powerful.
2. [SEK99] Let P_n be the $n \times n$ circulant permutation sign pattern with (1, 2) entry equal to $+$. Let Q_n be the sign pattern obtained from P_n by replacing the $+$ in the (n, 1) position with a $-$. Then P_n is n-potent and Q_n is $2n$-potent.
3. [SBS02] Suppose that $3|k$. Let $A = \omega \begin{bmatrix} 0 & J_{p \times q} & 0 \\ 0 & 0 & J_{q \times r} \\ J_{r \times p} & 0 & 0 \end{bmatrix}$, where $J_{m \times n}$ denotes the all ones $m \times n$ matrix and ω^3 is a primitive $k/3$-th root of unity. Then A is a k-potent ray pattern.

Ian M. Wanless
Monash University

The permanent is a matrix function introduced (independently) by Cauchy and Binet in 1812. At first sight it seems to be a simplified version of the determinant, but this impression is misleading. In some important respects the permanent is much less tractable than the determinant. Nonetheless, permanents have found a wide range of applications from pure combinatorics (e.g., counting problems involving permutations) right through to applied science (e.g., modeling subatomic particles). For further reading, see [Min78], [Min83], [Min87], [CW05], and the references therein.

43.1 Basic Concepts

Definitions:

Let $A = [a_{ij}]$ be an $m \times n$ matrix over a commutative ring, $m \leq n$. Let S be the set of all injective functions from $\{1, 2, \ldots, m\}$ to $\{1, 2, \ldots, n\}$ (in particular, if $m = n$, then S is the symmetric group on $\{1, 2, \ldots, n\}$).

The **permanent** of A is defined by

$$\operatorname{per}(A) = \sum_{\sigma \in S} \prod_{i=1}^{m} a_{i\sigma(i)}.$$

Two matrices A and B are **permutation equivalent** if there exist permutation matrices P and Q such that $B = PAQ$.

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Min78].

1. If A is any square matrix, then $\operatorname{per}(A) = \operatorname{per}(A^T)$.
2. Our definition implies that $\operatorname{per}(A) = 0$ for all $m \times n$ matrices A, where $m > n$. Some authors prefer to define $\operatorname{per}(A) = \operatorname{per}(A^T)$ in this case.
3. If A is any $m \times n$ matrix and P and Q are permutation matrices of respective orders m and n, then $\operatorname{per}(PAQ) = \operatorname{per}(A)$. That is, the permanent is invariant under permutation equivalence.
4. If A is any $m \times n$ matrix and c is any scalar, then $\operatorname{per}(cA) = c^m \operatorname{per}(A)$.
5. The permanent is a multilinear function of the rows. If $m = n$, it is also a multilinear function of the columns.
6. It is *not* in general true that $\operatorname{per}(AB) = \operatorname{per}(A)\operatorname{per}(B)$.
7. If M has block decomposition $M = \begin{bmatrix} A & \mathbf{0} \\ B & C \end{bmatrix}$, where either A or C is square, then $\operatorname{per}(M) = \operatorname{per}(A)\operatorname{per}(C)$.
8. Let A be an $m \times n$ matrix with $m \leq n$. Then $\operatorname{per}(A) = 0$ if A contains an $s \times (n-s+1)$ submatrix of zeroes, for some $s \in \{1, 2, \ldots, m\}$.
9. (Laplace expansion) If A is an $m \times n$ matrix, $2 \leq m \leq n$, and $\alpha \in Q_{r,m}$, where $1 \leq r < m \leq n$ then
$$\operatorname{per}(A) = \sum_{\beta \in Q_{r,n}} \operatorname{per}\big(A[\alpha, \beta]\big) \operatorname{per}\big(A(\alpha, \beta)\big).$$
In particular, for any $i \in \{1, 2, \ldots, m\}$,
$$\operatorname{per}(A) = \sum_{j=1}^{n} a_{ij} \operatorname{per}\big(A(i, j)\big).$$
10. If A and B are $n \times n$ matrices and s and t are arbitrary scalars, then
$$\operatorname{per}(sA + tB) = \sum_{r=0}^{n} s^r t^{n-r} \sum_{\alpha, \beta \in Q_{r,n}} \operatorname{per}\big(A[\alpha, \beta]\big) \operatorname{per}\big(B(\alpha, \beta)\big)$$
(where we interpret the permanent of a 0×0 matrix to be 1).
11. (Binet–Cauchy) If A and B are $m \times n$ and $n \times m$ matrices, respectively, where $m \leq n$, then
$$\operatorname{per}(AB) = \sum_{\alpha} \frac{1}{\mu(\alpha)} \operatorname{per}\big(A[\{1, 2, \ldots, m\}, \alpha]\big) \operatorname{per}\big(B[\alpha, \{1, 2, \ldots, m\}]\big).$$
The sum is over all nondecreasing sequences α of m integers chosen from the set $\{1, 2, \ldots, n\}$ and $\mu(\alpha) = \alpha_1!\, \alpha_2! \cdots \alpha_n!$, where α_i denotes the number of occurrences of the integer i in α.
12. [MM62], [Bot67] Let F be a field and $m \geq 3$ an integer. Let T be a linear transformation for which $\operatorname{per}\big(T(X)\big) = \operatorname{per}(X)$ for all $X \in F^{m \times m}$. Then there exist permutation matrices P and Q and diagonal matrices D_1 and D_2 such that $\operatorname{per}(D_1 D_2) = 1$ and either $T(X) = D_1 P X Q D_2$ for all $X \in F^{m \times m}$ or $T(X) = D_1 P X^T Q D_2$ for all $X \in F^{m \times m}$.
13. (Alexandrov's inequality) Let $A = [a_{ij}] \in \mathbb{R}^{n \times n}$ and $1 \leq r < s \leq n$. If $a_{ij} \geq 0$ whenever $j \neq s$, then
$$(\operatorname{per}(A))^2 \geq \sum_{i=1}^{n} a_{ir} \operatorname{per}(A(i, s)) \sum_{i=1}^{n} a_{is} \operatorname{per}(A(i, r)). \tag{43.1}$$
Moreover, if $a_{ij} > 0$ whenever $j \neq s$, then equality holds in Eq. (43.1) if and only if there exists $c \in \mathbb{R}$ such that $a_{ir} = c a_{is}$ for all i.

14. If G is a balanced bipartite graph (meaning the two parts have equal size), then $\operatorname{per}(\mathcal{B}_G)$ counts perfect matchings (also known as 1-factors) in G.
15. If D is a directed graph, then $\operatorname{per}(\mathcal{A}_D)$ counts the cycle covers of D. A cycle cover is a set of disjoint cycles which include every vertex exactly once.

Examples:

1. $\operatorname{per}\begin{bmatrix}1&2&3\\4&5&6\\7&8&9\end{bmatrix} = 1 \operatorname{per}\begin{bmatrix}5&6\\8&9\end{bmatrix} + 2 \operatorname{per}\begin{bmatrix}4&6\\7&9\end{bmatrix} + 3 \operatorname{per}\begin{bmatrix}4&5\\7&8\end{bmatrix}$

$$= 1\cdot5\cdot9+1\cdot6\cdot8+2\cdot4\cdot9+2\cdot6\cdot7+3\cdot4\cdot8+3\cdot5\cdot7 = 450.$$

2. $\operatorname{per}\begin{bmatrix}0&2&3&4\\5&6&0&8\\9&0&0&12\end{bmatrix} = 2\cdot5\cdot12+2\cdot8\cdot9+3\cdot5\cdot12+3\cdot6\cdot9+3\cdot6\cdot12+3\cdot8\cdot9+4\cdot6\cdot9 = 1254.$
3. If $A = \begin{bmatrix}2&3\\2&-2\end{bmatrix}$ and $B = \begin{bmatrix}-4&-2\\1&-1\end{bmatrix}$, then $AB = \begin{bmatrix}-5&-7\\-10&-2\end{bmatrix}$. Hence, $80 = \operatorname{per}(AB) \neq \operatorname{per}(A)\operatorname{per}(B) = 2 \times 2 = 4$.
4. Below is a bipartite graph G (Figure 43.1) and its biadjacency matrix $\mathcal{B}_G$.

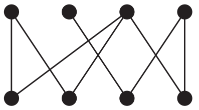

FIGURE 43.1

$$\begin{bmatrix}1&1&0&0\\0&0&1&0\\1&1&0&1\\0&0&1&1\end{bmatrix}$$

Now, $\operatorname{per}(\mathcal{B}_G) = 2$, which means that G has two perfect matchings (Figure 43.2 and Figure 43.3).

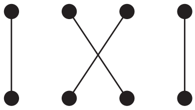

FIGURE 43.2

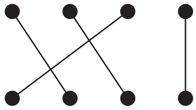

FIGURE 43.3

5. The matrix in the previous example can also be interpreted as $\mathcal{A}_D$ for the directed graph D (Figure 43.4). It has two cycle covers (Figure 43.5 and Figure 43.6).

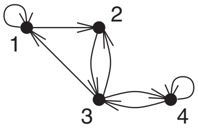

FIGURE 43.4

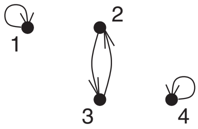

FIGURE 43.5

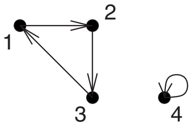

FIGURE 43.6

43.2 Doubly Stochastic Matrices

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Min78].

1. If $A \in \Omega_n$, then $\operatorname{per}(A) \leq 1$ with equality if and only if A is a permutation matrix.
2. [Ego81], [Fal81] If $A \in \Omega_n$ and $A \neq \frac{1}{n}J_n$, then $\operatorname{per}(A) > \operatorname{per}(\frac{1}{n}J_n) = n!/n^n$.

3. [Fri82] If $A \in \Omega_n$ and A has a $p \times q$ submatrix of zeros (where $p + q \leq n$), then

$$\operatorname{per}(A) \geq \frac{(n-p)!}{(n-p)^{n-p}} \frac{(n-q)!}{(n-q)^{n-q}} \frac{(n-p-q)^{n-p-q}}{(n-p-q)!}.$$

   Equality is achieved by any matrix permutation equivalent to the matrix $A = [a_{ij}]$ defined by

$$a_{ij} = \begin{cases} 0 & \text{if } i \leq p \text{ and } j \leq q, \\ \frac{1}{n-q} & \text{if } i \leq p \text{ and } j > q, \\ \frac{1}{n-p} & \text{if } i > p \text{ and } j \leq q, \\ \frac{n-p-q}{(n-p)(n-q)} & \text{if } i > p \text{ and } j > q. \end{cases}$$

   If $p + q \neq n - 1$, then no other matrix achieves equality.
4. [BN66] If A is any $n \times n$ row substochastic matrix and $1 \leq r \leq n$, then $\operatorname{per}(A) \leq m_r$, where m_r is the maximum permanent over all $r \times r$ submatrices of A.
5. [Min78, p. 41] If $A = [a_{ij}]$ is a fully indecomposable matrix, then the matrix $S = [s_{ij}]$ defined by $s_{ij} = a_{ij} \operatorname{per}\big(A(i,j)\big)/\operatorname{per}(A)$ is doubly stochastic and has the same zero pattern as A.

Conjectures:

1. [Min78] It is conjectured that for any n there exists k such that $\operatorname{per}(A^k) \leq \operatorname{per}(A)$ for all $A \in \Omega_n$.
2. [Min87] It is conjectured that among the matrices in Ω_n with zero trace, the minimum value of the permanent is achieved on the matrix where each off-diagonal entry is equal to $1/(n-1)$.

Examples:

1. The minimum value of the permanent in Ω_5 is 24/625, which is (uniquely) achieved by

$$\tfrac{1}{5}J_5 = \begin{bmatrix} 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \\ 1/5 & 1/5 & 1/5 & 1/5 & 1/5 \end{bmatrix}.$$

2. In the previous example, if we require that two specified entries in the same row must be zero, then the minimum value that the permanent can take is 1/24, which is (uniquely, up to permutation equivalence) achieved by

$$\begin{bmatrix} 0 & 0 & 1/3 & 1/3 & 1/3 \\ 1/4 & 1/4 & 1/6 & 1/6 & 1/6 \\ 1/4 & 1/4 & 1/6 & 1/6 & 1/6 \\ 1/4 & 1/4 & 1/6 & 1/6 & 1/6 \\ 1/4 & 1/4 & 1/6 & 1/6 & 1/6 \end{bmatrix}.$$

3. A nonnegative matrix of order $n \geq 3$ can have zero permanent even if we insist that each row and column sum is at least one. For example,

$$\operatorname{per}\begin{bmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix} = 0.$$

4. Suppose n identical balls are placed, one ball per bucket, in n labeled buckets on the back of a truck. When the truck goes over a bump the balls are flung into the air, but then fall back into the buckets. Suppose that the probability that the ball from bucket i lands in bucket j is p_{ij}. Then the matrix $P = [p_{ij}]$ is row stochastic and $\operatorname{per}(P)$ is the probability that we end up with one ball in each bucket. That is, $\operatorname{per}(P)$ is the *permanence* of the initial state.

43.3 Binary Matrices

Definitions:

A **binary matrix** is a matrix in which each entry is either 0 or 1.

Λ_n^k is the set of $n \times n$ binary matrices in which each row and column sum is k.

For an $m \times n$ binary matrix M the **complement** M^c is defined by $M^c = J_{mn} - M$.

A system of distinct representatives (**SDR**) for the finite sets $S_1, S_2, \dots, S_n$ is a choice of $x_1, x_2, \dots, x_n$ with the properties that $x_i \in S_i$ for each i and $x_i \neq x_j$ whenever $i \neq j$.

The **incidence matrix** for subsets $S_1, S_2, \dots, S_m$ of a finite set $\{x_1, x_2, \dots, x_n\}$ is the $m \times n$ binary matrix $M = [m_{ij}]$ in which $m_{ij} = 1$ if and only if $x_j \in S_i$.

$P_{(12\cdots n)}$ is the permutation matrix for the full cycle permutation $(12\cdots n)$.

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Min78].

1. The number of SDRs for a set of sets with incidence matrix M is $\operatorname{per}(M)$.
2. If $M \in \Lambda_n^k$, then $\frac{1}{k}M \in \Omega_n$, so the results of the previous section apply.
3. [Min78, p. 52] Let A be an $m \times n$ binary matrix where $m \leq n$. Suppose A has at least t positive entries in each row. If $t < m$ and $\operatorname{per}(A) > 0$, then $\operatorname{per}(A) \geq t!$. If $t \geq m$, then $\operatorname{per}(A) \geq t!/(t-m)!$.
4. If $A \in \Lambda_n^k$, then there exist permutation matrices $P_1, P_2, \dots, P_k$ such that
$$A = \sum_{i=1}^{k} P_i.$$
5. [Brè73], [Sch78] Let A be any $n \times n$ binary matrix with row sums $r_1, r_2, \dots, r_n$. Then
$$\operatorname{per}(A) \leq \prod_{i=1}^{n} (r_i!)^{1/r_i} \tag{43.2}$$
with equality if and only if A is permutation equivalent to a direct sum of square matrices each of which contains only 1s.
6. [MW98] If $m \geq 5$, then $(J_k \oplus J_k \oplus \cdots \oplus J_k)^c$ (where there are m copies of J_k) maximizes the permanent in Λ_{mk}^{mk-k}. The result is not true for $m = 3$.
7. [Wan99b] For each $k \geq 1$ there exists N such that for all $n \geq N$ a matrix M maximizes the permanent in Λ_n^k if and only if $M \oplus J_k$ maximizes the permanent in Λ_{n+k}^k.
8. [Wan03] If $n = tk + r$ with $0 \leq r < k \leq n$, then $k!^t r! \leq \max\limits_{A \in \Lambda_n^k} \operatorname{per}(A) \leq (k!)^{n/k}$.
9. [Wan03] If $k = o(n)$ as $n \to \infty$, then $\Big(\max\limits_{A \in \Lambda_n^k} \operatorname{per}(A)\Big)^{1/n} \sim (k!)^{1/k}$.
10. [GM90] Suppose $0 \leq k = O(n^{1-\delta})$ for a constant $\delta > 0$ as $n \to \infty$. Then

$$\operatorname{per}(A) = n!\Big(\frac{n-k}{n}\Big)^n \exp\left(\frac{k}{2n} + \frac{3k^2-k}{6n^2} + \frac{2k^3-k}{4n^3} + \frac{15k^4+70k^3-105k^2+32k}{60n^4} + \frac{z}{n^4} + \frac{2z(2k-1)}{n^5} + O\Big(\frac{k^5}{n^5}\Big)\right)$$

for all $A \in \Lambda_n^{n-k}$, where z denotes the number of 2×2 submatrices of A that contain only zeros. In particular, if $0 \le k = O(n^{1-\delta})$ for a constant $\delta > 0$ as $n \to \infty$, then $\operatorname{per}(A)$ is asymptotically equal to $n!(1-k/n)^n$ for all $A \in \Lambda_n^{n-k}$.

11. [Wan06] If $2 \le k \le n$ as $n \to \infty$, then
$$\Big(\min_{A\in\Lambda_n^k} \operatorname{per}(A)\Big)^{1/n} \sim \frac{(k-1)^{k-1}}{k^{k-2}}.$$
12. [BN65] For any integers $k \ge 1$ and $n \ge \log_2 k + 1$ there exists a binary matrix A of order n such that $\operatorname{per}(A) = k$.
13. The permanent of a square binary matrix counts *permutations with restricted positions.* This means that for each point being permuted there is some set of allowable images, while other images are forbidden.

Examples:

1. If $D_n = I_n^c$, then
$$\operatorname{per}(D_n) = n!\Big(1 - \frac{1}{1!} + \frac{1}{2!} - \cdots + (-1)^n\frac{1}{n!}\Big)$$
is the number of *derangements* of n things, that is, the number of permutations of n points that leave no point in its original place. The 4th derangement number is
$$\operatorname{per}(D_4) = \operatorname{per}\begin{bmatrix} 0 & 1 & 1 & 1\\ 1 & 0 & 1 & 1\\ 1 & 1 & 0 & 1\\ 1 & 1 & 1 & 0\end{bmatrix} = 9.$$
2. The number of ways that n married couples can sit around a circular table with men and women alternating and so that nobody sits next to their spouse is $2\,n!\,M_n$, where M_n is known as the n-th *menagé number* and is given by
$$M_n = \operatorname{per}\big((I_n + P_{(12\cdots n)})^c\big) = \sum_{r=0}^{n}(-1)^r\frac{2n}{2n-r}\binom{2n-r}{r}(n-r)!.$$
The 5th menagé number is $M_5 = \operatorname{per}\begin{bmatrix} 0 & 0 & 1 & 1 & 1\\ 1 & 0 & 0 & 1 & 1\\ 1 & 1 & 0 & 0 & 1\\ 1 & 1 & 1 & 0 & 0\\ 0 & 1 & 1 & 1 & 0\end{bmatrix} = 13.$
3. SDRs are important for many combinatorial problems. For example, a $k \times n$ *Latin rectangle* (where $k \le n$) is a $k \times n$ matrix in which n symbols occur in such a way that each symbol occurs exactly once in each row and at most once in each column. The number of extensions of a given $k \times n$ Latin rectangle R to a $(k+1)\times n$ Latin rectangle is the number of SDRs of the sets $S_1, S_2, \ldots, S_n$ defined so that S_i consists of the symbols not yet used in column i of R.

4. [CW05] For $n \leq 11$ the minimum values of $\text{per}(A)$ for $A \in \Lambda_n^k$ are as follows:

k	$n=2$	3	4	5	6	7	8	9	10	11
1	1	1	1	1	1	1	1	1	1	1
2	2	2	2	2	2	2	2	2	2	2
3	–	6	9	12	17	24	33	42	60	83
4	–	–	24	44	80	144	248	440	764	1316
5	–	–	–	120	265	578	1249	2681	5713	12105

10	–	–	–	–	–	–	–	–	3628800	14684570
11	–	–	–	–	–	–	–	–	–	39916800

43.4 Nonnegative Matrices

Definitions:

Δ_n^k is the set of $n \times n$ matrices of nonnegative integers in which each row and column sum is k.

Facts:

1. [Min78, p. 33] Let A be an $m \times n$ nonnegative matrix with $m \leq n$. Then $\text{per}(A) = 0$ if and only if A contains an $s \times (n-s+1)$ submatrix of zeros, for some $s \in \{1, 2, \ldots, m\}$.
2. [Min78, p. 38] Let A be a nonnegative matrix of order $n \geq 2$. Then A is fully indecomposable if and only if $\text{per}\big(A(i,j)\big) > 0$ for all i, j.
3. [Sch98] $\left(\dfrac{(k-1)^{k-1}}{k^{k-2}}\right)^n \leq \min\limits_{A \in \Delta_n^k} \text{per}(A) \leq \dfrac{k^{2n}}{\binom{kn}{n}}$.
4. [Sou03] Let Γ denote the gamma function and let A be a nonnegative matrix of order n. In row i of A, let m_i and r_i denote, respectively, the largest entry and the total of the entries. Then,

$$\operatorname{per}(A) \le \prod_{i=1}^{n} m_i \left(\Gamma\left(\frac{r_i}{m_i}+1\right)\right)^{m_i/r_i}. \qquad (43.3)$$

5. [Min78, p. 62] Let A be a nonnegative matrix of order n. Define s_i to be the sum of the i smallest entries in row i of A. Similarly, define S_i to be the sum of the i largest entries in row i of A. Then
$$\prod_{i=1}^{n} s_i \le \operatorname{per}(A) \le \prod_{i=1}^{n} S_i.$$
6. [Gib72] If A is nonnegative and π is a root of $\operatorname{per}(zI-A)$, then $|\pi| \le \rho(A)$.

Conjectures:

1. [Min83] It is conjectured that $\min\limits_{A\in\Delta_n^k} \operatorname{per}(A) = \min\limits_{A\in\Lambda_n^k} \operatorname{per}(A)$.
2. [Min83], [CW12] Let $A=[a_{ij}]$ be an $n\times n$ nonnegative matrix with $\sum_{i,j} a_{ij} = n$. The Dittert-Hajek conjecture asserts that
$$\phi(A) = \prod_{i=1}^{n}\sum_{j=1}^{n} a_{ij} + \prod_{j=1}^{n}\sum_{i=1}^{n} a_{ij} - \operatorname{per}(A)$$
is maximized when $A = \frac{1}{n}J_n$.

Examples:

1. [BB67] If A is row substochastic, the roots of $\operatorname{per}(zI-A)=0$ satisfy $|z|\le 1$.
2. If Soules' bound (43.3) is applied to matrices in Λ_n^k, it reduces to Brègman's bound (43.2).

43.5 (±1)-Matrices

Facts:

1. [KS83] If A is a (±1)-matrix of order n, then $\operatorname{per}(A)$ is divisible by $2^{n-\lfloor \log_2(n+1)\rfloor}$.
2. [Wan74] If H is an $n\times n$ Hadamard matrix, then $|\operatorname{per}(H)| \le |\det(H)| = n^{n/2}$.
3. [KS83], [Wan05] There is no solution to $|\operatorname{per}(A)| = |\det(A)|$ among the nonsingular (±1)-matrices of order n when $n\in\{2,3,4\}$ or $n=2^k-1$ for $k\ge 2$, but there are solutions when $n\in\{5,\ldots,20\}\setminus\{7,15\}$.
4. [Wan05] There exists a (±1)-matrix A of order n satisfying $\operatorname{per}(A)=0$ if and only if $n+1$ is not a power of 2.

Examples:

1. The 11×11 matrix $A=[a_{ij}]$ defined by
$$a_{ij} = \begin{cases} -1 & \text{if } j-i\in\{1,2,3,5,7,10\}, \\ +1 & \text{otherwise,}\end{cases}$$
satisfies $\operatorname{per}(A)=0$. No smaller (±1)-matrix of order $n\equiv 3 \bmod 4$ has this property.
2. The following matrix has per = det = 16, and is the smallest example (excluding the trivial

case of order 1) for which per = det among ±1-matrices.

$$\begin{bmatrix} +1 & +1 & +1 & +1 & +1 \\ +1 & -1 & -1 & +1 & +1 \\ +1 & -1 & +1 & +1 & +1 \\ +1 & +1 & +1 & -1 & -1 \\ +1 & +1 & +1 & -1 & +1 \end{bmatrix}.$$

43.6 Matrices over $\mathbb{C}$

Facts:

1. If $A = [a_{ij}] \in \mathbb{C}^{m\times n}$ and $B = [b_{ij}] \in \mathbb{R}^{m\times n}$ satisfy $b_{ij} = |a_{ij}|$, then $|\operatorname{per}(A)| \leq \operatorname{per}(B)$.
2. If $A \in \mathbb{C}^{n\times n}$, then $\operatorname{per}(\overline{A}) = \overline{\operatorname{per}(A)} = \operatorname{per}(A^*)$.
3. [Min78, p. 113] If $A \in \mathbb{C}^{n\times n}$ is normal with eigenvalues $\lambda_1, \lambda_2, \ldots, \lambda_n$, then
$$|\operatorname{per}(A)| \leq \frac{1}{n}\sum_{i=1}^{n} |\lambda_i|^n.$$
4. [Min78, p. 115] Let $A \in \mathbb{C}^{n\times n}$ and let $\lambda_1, \ldots, \lambda_n$ be the eigenvalues of AA^*. Then
$$|\operatorname{per}(A)|^2 \leq \frac{1}{n}\sum_{i=1}^{n} \lambda_i^n.$$
5. [Lie66] If $A = \begin{bmatrix} B & C \\ C^* & D \end{bmatrix} \in \mathrm{PD}_n$, then $\operatorname{per}(A) \geq \operatorname{per}(B)\operatorname{per}(D)$.
6. [JP87] Suppose $\alpha \subseteq \beta \subseteq \{1, 2, \ldots, n\}$. Then for any $A \in \mathrm{PD}_n$,
$$\det(A[\beta,\beta])\operatorname{per}(A(\beta,\beta)) \leq \det(A[\alpha,\alpha])\operatorname{per}(A(\alpha,\alpha)).$$
(We interpret det or per of a 0×0 matrix to be 1.)
7. [MN62] If $A \in \mathbb{C}^{m\times n}$ and $B \in \mathbb{C}^{n\times m}$, then
$$|\operatorname{per}(AB)|^2 \leq \operatorname{per}(AA^*)\operatorname{per}(B^*B).$$
8. [Bre59] If $A = [a_{ij}] \in \mathbb{C}^{n\times n}$ satisfies $|a_{ii}| > \sum_{j\neq i} |a_{ij}|$ for each i, then $\operatorname{per}(A) \neq 0$.
9. [CLL06] If $A = [a_{ij}] \in \mathbb{C}^{n\times n}$ then
$$|\operatorname{per}(A)| \leq \frac{n!}{n^{n/2}} \prod_{i=1}^{n}\left(\sum_{j=1}^{n} |a_{ij}|^2\right)^{1/2}.$$

Examples:

1. If U is a unitary matrix, then $|\operatorname{per}(U)| \leq 1$.

43.7 Subpermanents

Definitions:

The k-th **subpermanent sum**, $\operatorname{per}_k(A)$ of an $m \times n$ matrix A, is defined to be the sum of the permanents of all order k submatrices of A. That is,

$$\mathrm{per}_k(A) = \sum_{\substack{\alpha \in Q_{k,m} \\ \beta \in Q_{k,n}}} \mathrm{per}(A[\alpha, \beta]).$$

By convention, we define $\mathrm{per}_0(A) = 1$.

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Min78].

1. For each k, per_k is invariant under permutation equivalence and transposition.
2. If A is any $m \times n$ matrix and c is any scalar, then $\mathrm{per}_k(cA) = c^k \mathrm{per}_k(A)$.
3. [BN66] If A is any $n \times n$ row substochastic matrix and $1 \leq r \leq n$, then $\mathrm{per}_r(A) \leq \binom{n}{r}$.
4. [Fri82] $\mathrm{per}_k(A) \geq \mathrm{per}_k(\frac{1}{n} J_n)$ for every $A \in \Omega_n$ and integer k.
5. [Wan03] If $A \in \Lambda_n^k$ and $i \leq k$, then $\mathrm{per}_i(A) \geq \binom{n}{i} \dfrac{k!}{(k-i)!}$.
6. [Wan03] For $1 \leq i, k \leq n$ and $A \in \Lambda_n^k$,
$$\binom{kn}{i} - kn(k-1)\binom{kn-2}{i-2} \leq \mathrm{per}_i(A) \leq \binom{kn}{i}.$$
7. [Wan03] For $A \in \Lambda_n^k$, let $\xi_i = \left(\mathrm{per}_i(A)/\binom{n}{i}\right)^{1/i}$. Then
$$\frac{(k-1)^{k-1}}{k^{k-2}} \leq \xi_n \leq \xi_{n-1} \leq \cdots \leq \xi_1 = k.$$
8. [Nij76], [HLP52, p. 104] Let A be a nonnegative $m \times n$ matrix with $\mathrm{per}(A) \neq 0$. For $1 \leq i \leq m-1$,
$$\frac{\mathrm{per}_i(A)}{\mathrm{per}_{i-1}(A)} \geq \frac{(i+1)(m-i+1)}{i(m-i)} \frac{\mathrm{per}_{i+1}(A)}{\mathrm{per}_i(A)} > \frac{\mathrm{per}_{i+1}(A)}{\mathrm{per}_i(A)}.$$
9. [Wan99b] For $A \in \Lambda_n^k$,
$$\frac{\mathrm{per}_i(A)}{\mathrm{per}_{i+1}(A)} \geq \frac{i+1}{(n-i)^2}.$$
10. [Wan99a] Let $k \geq 0$ be an integer. There exists no polynomial $p_k(n)$ such that for all n and $A \in \Lambda_n^3$,
$$\frac{\mathrm{per}_{n-k-1}(A)}{\mathrm{per}_{n-k}(A)} \leq p_k(n).$$
11. If G is a bipartite graph, then $\mathrm{per}_k(\mathcal{B}_G)$ counts the k-matchings in G. A k-matching in G is a set of k edges in G such that no two edges share a vertex.

Examples:

1. For any matrix A the sum of the entries in A is $\mathrm{per}_1(A)$.
2. Any $m \times n$ matrix A has $\mathrm{per}_m(A) = \mathrm{per}(A)$.
3. $\mathrm{per}_k(J_n) = k!\binom{n}{k}^2$.
4. [Wan99a] Let $A \in \Lambda_n^k$ have s submatrices which are copies of J_2. Then
   (a) $\mathrm{per}_1(A) = kn$.
   (b) $\mathrm{per}_2(A) = \frac{1}{2}kn(kn - 2k + 1)$.

(c) $\text{per}_3(A) = \frac{1}{6}kn(k^2n^2 - 6k^2n + 3kn + 10k^2 - 12k + 4)$.

(d) $\text{per}_4(A) = \frac{1}{24}kn\big(k^3n^3 - 12k^3n^2 + 6k^2n^2 + 52k^3n - 60k^2n + 19kn - 84k^3 + 168k^2 - 120k + 30\big) + s$.

(e) $\text{per}_5(A) = \frac{1}{120}kn\big[k^4n^4 - 20k^4n^3 + 10k^3n^3 + 160k^4n^2 - 180k^3n^2 + 55k^2n^2 - 620k^4n + 1180k^3n - 800k^2n + 190kn + 1008k^4 - 2880k^3 + 3240k^2 - 1680k + 336\big] + (nk - 8k + 8)s$.

5. The subpermanent sums are also known as **rook numbers** since they count the number of placements of rooks in mutually nonattacking positions on a chessboard. Let A be a binary matrix in which each 1 denotes a permitted position on the board and each 0 denotes a forbidden position for a rook. Then $\text{per}_i(A)$ is the number of placements of i rooks on permitted squares so that no two rooks occupy the same row or column. For example, the number of ways of putting 4 nonattacking rooks on the white squares of a standard chessboard is

$$\text{per}_4 \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix} = 8304.$$

43.8 Rook Polynomials

Definitions:

Let A be an $m \times n$ binary matrix.

The polynomials $\rho_1(A,x) = \sum_{i=0}^{m} \text{per}_i(A)x^i$ and $\rho_2(A,x) = \sum_{i=0}^{m}(-1)^i\text{per}_i(A)x^{m-i}$ are both called **rook polynomials** because they are generating functions for the rook numbers.

Let $\ell_k(x)$ be the k^{th} Laguerre polynomial, normalized to be monic. That is,

$$\ell_k(x) = (-1)^k k! \sum_{i=0}^{k} \binom{k}{i} \frac{(-x)^i}{i!}.$$

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Rio58].

1. When A is an $m \times n$ binary matrix, $\rho_1(A,x) = (-x)^m \rho_2(A, -\frac{1}{x})$.
2. If $A = B \oplus C$, then $\rho_1(A,x) = \rho_1(B,x)\rho_1(C,x)$ and $\rho_2(A,x) = \rho_2(B,x)\rho_2(C,x)$.
3. [HL72], [Nij76] For any nonnegative matrix A, all the roots of $\rho_1(A,x)$ and $\rho_2(A,x)$ are real.
4. [HL72] For $2 \leq k \leq n$ and $A \in \Lambda_n^k$, the roots of $\rho_1(A,x)$ are less than $-1/(4k-4)$, while the roots of $\rho_2(A,x)$ lie in the interval $(0, 4k-4)$.
5. [JR80], [God81] For a square binary matrix A, with complement A^c,

$$\text{per}(A) = \int_0^\infty e^{-x} \rho_2(A^c, x)\,\text{dx}.$$

6. [God81] For an $n \times n$ binary matrix M,

$$\rho_2(M, x) = \sum_{i=0}^{n} \operatorname{per}_i(M^c)\ell_{n-i}(x).$$

7. [Sze75, p. 100] For any j, k let $\delta_{j,k}$ denote the Kronecker delta. Then

$$\int_0^\infty e^{-x}\ell_j(x)\ell_k(x)\,\mathrm{dx} = \delta_{j,k}k!^2.$$

Examples:

1. $\rho_1(P, x) = (x+1)^n$ and $\rho_2(P, x) = (x-1)^n$ for a permutation matrix $P \in \Lambda_n^1$.
2. $\rho_2(J_k, x) = \ell_k(x)$.
3. Let $C_n = I_n + P_{(12\cdots n)}$. Then

$$\rho_1(C_n, x) = \sum_{i=0}^{n} \frac{2n}{2n-i}\binom{2n-i}{i}x^i$$

and $\rho_2(C_n, 4x^2) = 2T_{2n}(x)$, where $T_n(x)$ is the n^{th} Chebyshev polynomial of the first kind.
4. $\rho_2(I_n^c, x) = \sum_{i=0}^{n}\binom{n}{i}\ell_i(x)$ for any integer $n \geq 1$.
5. The ideas of this chapter allow a quick computation of the permanent of many matrices that are built from blocks of ones by recursive use of direct sums and complementation. For example,

$$\begin{aligned}\operatorname{per}\left(\left(J_k \oplus I_{k+1}^c\right)^c\right) &= \int_0^\infty e^{-x}\rho_2(J_k \oplus I_{k+1}^c)\,\mathrm{dx} = \int_0^\infty e^{-x}\rho_2(J_k)\rho_2(I_{k+1}^c)\,\mathrm{dx} \\ &= \int_0^\infty e^{-x}\ell_k(x)\sum_{i=0}^{k+1}\binom{k+1}{i}\ell_i(x)\,\mathrm{dx} = \binom{k+1}{k}k!^2 = (k+1)!\,k!.\end{aligned}$$

43.9 Evaluating Permanents

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Min78].

1. Since the permanent is *not* invariant under elementary row operations, it cannot be calculated by Gaussian elimination.
2. (Ryser's formula) If $A = [a_{ij}]$ is an $n \times n$ matrix over a commutative ring,

$$\operatorname{per}(A) = \sum_{r=1}^{n}(-1)^r \sum_{\alpha \in Q_{r,n}} \prod_{i=1}^{n}\sum_{j \in \alpha} a_{ij}.$$

3. [Gly10] If $A = [a_{ij}]$ is an $n \times n$ matrix over a field of characteristic other than 2, then

$$\operatorname{per}(A) = \frac{1}{2^{n-1}}\sum_{\delta}\left(\prod_{k=1}^{n}\delta_k\right)\prod_{j=1}^{n}\sum_{i=1}^{n}\delta_i a_{ij}$$

where the outer sum is over all 2^{n-1} vectors $\delta = [\delta_1, \ldots, \delta_n] \in \{\pm 1\}^n$ with $\delta_1 = 1$.
4. [NW78], [BHKK10] A straightforward implementation of Ryser's formula has time complexity $\Theta(n^2 2^n)$. By enumerating the α in Gray Code order (i.e., by choosing an ordering in which any two consecutive α's differ by a single entry), Nijenhuis/Wilf

improved this to $\Theta(n2^n)$. They cut the execution time by a further factor of two by exploiting the relationship between the term corresponding to α and that corresponding to $\{1, 2, \ldots, n\} \setminus \alpha$. This second savings is not always desirable when calculating permanents of integer matrices, since it introduces fractions.

Ryser/Nijenhuis/Wilf (RNW) Algorithm for calculating per(A) for $A = [a_{ij}]$ of order n.

```
$p := -1$;
for $i$ from 1 to $n$ do
    $x_i := a_{in} - \frac{1}{2}\sum_{j=1}^{n} a_{ij}$;
    $p := p * x_i$;
    $g_i := 0$;
$s := -1$;
for $k$ from 2 to $2^{n-1}$ do
    if $k$ is even then
        $j := 1$;
    else
        $j := 2$;
        while $g_{j-1} = 0$ do
            $j := j + 1$;
    $z := 1 - 2 * g_j$;
    $g_j := 1 - g_j$;
    $s := -s$;
    $t := s$;
    for $i$ from 1 to $n$ do
        $x_i := x_i + z * a_{ij}$;
        $t := t * x_i$;
    $p := p + t$;
return$\big(2(-1)^n p\big)$
```

5. For sufficiently sparse matrices, a simple enumeration of nonzero diagonals by backtracking, or a recursive Laplace expansion, will be faster than RNW.
6. A hybrid approach is to use Laplace expansion to expand any rows or columns that have very few nonzero entries, then employ RNW.
7. [BHKK10] Ryser's formula can be extended to rectangular matrices, but faster methods are known for matrices that are far from square.
8. [DL92] The calculation of the permanent is a $\#P$-complete problem. This is still true if attention is restricted to matrices in Λ_n^3. So, it is extremely unlikely that a polynomial time algorithm for calculating permanents exists.
9. [Lub90] As a result of the above, much work has been done on approximation algorithms for permanents.

43.10 Connections between Determinants and Permanents

Definitions:

For any partition λ of n let χ_λ denote the irreducible character of the symmetric group S_n associated with λ by the standard bijection (see Section 85.6 or [Mac95, p. 114]) between partitions and irreducible characters.

Let ε_n be the identity in S_n.

The matrix function f_λ defined by

$$f_\lambda(M) = \frac{1}{\chi_\lambda(\varepsilon_n)} \sum_{\sigma \in S_n} \chi_\lambda(\sigma) \prod_{i=1}^{n} m_{i\sigma(i)},$$

for each $M = [m_{ij}] \in \mathbb{C}^{n\times n}$, is called a **normalized immanant** (without the factor of $1/\chi_\lambda(\varepsilon_n)$ it is an **immanant**).

The partial order $\lhd$ is defined on the set of partitions of an integer n by stating that $\lambda \lhd \mu$ means that $f_\lambda(H) \le f_\mu(H)$ for all $H \in \mathrm{PD}_n$.

Facts:

For facts for which no specific reference is given and for background reading on the material in this section, see [Mer97].

1. If $\lambda = (n)$, then χ_λ is the principal/trivial character and f_λ is the permanent.
2. If $\lambda = (1^n)$, then χ_λ is the alternating character and f_λ is the determinant.
3. [Sch18] $f_\lambda(H)$ is a nonnegative real number for all $H \in \mathrm{PD}_n$ and all λ.
4. [MM61] For $n \ge 3$ there is no linear transformation T such that $\mathrm{per}(A) = \det\big(T(A)\big)$ for every $A \in \mathbb{R}^{n\times n}$. In particular, there is no way of affixing minus signs to some entries that will convert the permanent into a determinant.
5. [DGKO11] Suppose $n \ge 3$ and F is a field of finite order m and odd characteristic. If m is sufficiently large relative to n, then there is no bijection $\phi : F^{n\times n} \mapsto F^{n\times n}$ for which $\mathrm{per}(A) = \det\big(\phi(A)\big)$.
6. [Lev73] For all sufficiently large n there exists a fully indecomposable matrix $A \in \Lambda_n^3$ such that $\mathrm{per}(A) = \det(A)$.
7. [Sch18], [Mar64] If $A = [a_{ij}] \in \mathrm{PD}_n$, then $\det(A) \le \prod_{i=1}^{n} a_{ii} \le \mathrm{per}(A)$. Equality holds if and only if A is diagonal or A has a zero row/column.
8. [Sch18] For arbitrary λ, if $A \in \mathrm{PD}_n$, then $f_\lambda(A) \ge \det(A)$. In other words, $(1^n) \lhd \lambda$ for all partitions λ of n.
9. [Hey88] The hook immanants are linearly ordered between det and per. That is, $(1^n) \lhd (2, 1^{n-2}) \lhd (3, 1^{n-3}) \lhd \cdots \lhd (n-1, 1) \lhd (n)$.
10. For two partitions λ, μ of n to satisfy $\lambda \lhd \mu$, it is necessary but not sufficient that μ majorizes λ.

Conjectures:

1. A special case of the *permanental dominance conjecture* (Example 85.6.8) asserts that $\lambda \lhd (n)$ for all partitions λ of n. This has been proven only for special cases, which include (a) $n \le 13$, (b) partitions with no more than three parts that exceed 2, and (c) the hook immanants mentioned above.

Examples:

1. Although $\mu = (3,1)$ majorizes $\lambda = (2,2)$, neither $\lambda \lhd \mu$ nor $\mu \lhd \lambda$. This is demonstrated by taking $A = J_2 \oplus J_2$ and $B = J_1 \oplus J_3$ and noting that $f_\lambda(A) = 2 > \frac{4}{3} = f_\mu(A)$ but $f_\lambda(B) = 0 < 2 = f_\mu(B)$.

An $m \times n$ matrix W whose entries are all 1 or -1 is called a (± 1)-design matrix; if the entries of W are 0 or 1, then W is a $(0, 1)$-design matrix. Each design matrix corresponds to a weighing design; that is, a scheme for estimating the weights of n objects in m weighings. Since the weights of n objects cannot be estimated in fewer than n weighings, we consider only those pairs (m, n) with $m \geq n$. The rows of W encode a two-pan or one-pan weighing design with n objects $x_1, ..., x_n$ being weighed in m weighings. If $W \in \{\pm 1\}^{m \times n}$, an entry of 1 in the (i, j)-th position of W indicates that object x_j is put in the right pan in the i-th weighing while an entry of -1 means that x_j is placed in the left pan. If $W \in \{0, 1\}^{m \times n}$, an entry of 1 in the (i, j)-th position indicates that object x_j is included in the i-th weighing while an entry of 0 means that the object is not included. In the presence of errors for the scale, we can expect only to find estimators $\hat{w_1}, ..., \hat{w_n}$ for the actual weights $w_1, ..., w_n$ of the objects. We want to choose a weighing design that is optimal with respect to some condition, an idea going back to Hotelling [Hot44] and Mood [Moo46]. See also [HS79] and [Slo79]. Under certain assumptions on the error of the scale, we can express optimality conditions in terms of $W^T W$ (see [Puk93]). The value of $\det W^T W$ is inversely proportional to the volume of the confidence region of the estimators of the weights of the objects. Thus, matrices for which $\det W^T W$ is large correspond to weighing designs that are desirable.

The connection between designs and inscribed simplices of the n-dimensional unit cube is explored by Zong [Zon06].

44.1 Introduction

This section includes basic definitions; facts and examples can be found in the following sections.

Definitions:

A matrix $W \in \{\pm 1\}^{m \times n}$ is a (± 1)-**design matrix**; $W \in \{0, 1\}^{m \times n}$ is a $(0, 1)$-**design matrix**.

A matrix $W \in \{\pm 1\}^{m \times n}$ (respectively, $W \in \{0, 1\}^{m \times n}$) is called **D-optimal** if $\det W^T W$ is maximal over all matrices in $\{\pm 1\}^{m \times n}$ (respectively, $\{0, 1\}^{m \times n}$).

$\alpha(m,n) = \max\{\det W^T W | W \in \{\pm 1\}^{m\times n}\}$.
$\beta(m,n) = \max\{\det W^T W | W \in \{0,1\}^{m\times n}\}$.
We write $\alpha(n)$ and $\beta(n)$ for $\alpha(n,n)$ and $\beta(n,n)$.

44.2 The (± 1) and $(0,1)$ Square Case

Definitions:

For a matrix $V \in \{0,1\}^{(n-1)\times(n-1)}$, define

$$W_V = \left[\begin{array}{c|ccc} 1 & 1 & \cdots & 1 \\ \hline -1 & & & \\ \vdots & & 2V - J_{n-1} & \\ -1 & & & \end{array}\right] \in \{\pm 1\}^{n\times n}.$$

For a matrix $W \in \{\pm 1\}^{n\times n}$, define $V_W \in \{0,1\}^{(n-1)\times(n-1)}$ by

$$V_W = \frac{1}{2}\left(W(1) + J_{n-1}\right),$$

where $W(1)$ is obtained from W by deleting the first row and column.

A **signature matrix** is a ± 1 diagonal matrix.

A **Hadamard matrix** of order n is a matrix $H_n \in \{\pm 1\}^{n\times n}$ with $H_n H_n^T = nI_n$.

A **2-design** with parameters (v,k,λ) (also called a (v,k,λ)-**design**) is a collection of k-subsets B_i, called **blocks**, of a finite set X with cardinality v, such that each 2-subset of X is contained in exactly λ blocks.

The (± 1)-**incidence matrix** $W = (w_{ij})$ of a 2-design is a matrix whose rows are indexed by the elements x_i of X and whose columns are indexed by the blocks B_j. The entry $w_{ij} = -1$ if $x_i \in B_j$ and $w_{ij} = +1$ otherwise.

Facts:

1. For any $W \in \{\pm 1\}^{n\times n}$, there exist signature matrices S_1, S_2 such that for $W' = (S_1 W S_2)$, $W'_{1j} = 1$ for $j = 1,\dots,n$ and $W'_{i1} = -1$ for $i = 2,\dots,n$. W is D-optimal if and only if W' is D-optimal.
2. $\det W_V = 2^{n-1}\det V$.
3. [Wil46] The (± 1) square case in dimension n is related to the $(0,1)$ square case in dimension $n-1$ by the previous two facts, and $\alpha(n) = 4^{n-1}\beta(n-1)$. Facts are stated here for $\alpha(n)$ only, since the facts for $\beta(n)$ can be easily derived from these.
4. [Had93], [CD96], [BJL93], [WPS72] Hadamard matrices
   (a) A necessary condition for the existence of a Hadamard matrix of order n is $n = 1, n = 2$, or $n \equiv 0 \pmod 4$.
   (b) Let H_m and H_n be two Hadamard matrices of orders m and n, respectively. Then $H_m \otimes H_n$ is a Hadamard matrix of order mn.
   (c) There exist infinitely many values n for which a Hadamard matrix H_n exists.
   (d) It is conjectured that for all $n = 4k$ there exists a Hadamard matrix H_n.
   (e) The smallest n for which the existence of a Hadamard matrix is in question (at the time of the writing of this chapter) is $n = 668$.
5. [Had93], [CD96], [BJL93], [WPS72] D-optimal (± 1)-matrices: the case $n = 4k$
   (a) $\alpha(4k) \le (4k)^{4k}$.

   (b) A necessary and sufficient condition for equality to occur in this case is the existence of a Hadamard matrix of order n.

6. [Bar33], [Woj64], [Ehl64a], [Coh67], [Neu97] D-optimal (± 1)-matrices: the case $n = 4k+1$
   (a) $\alpha(4k+1) \leq (8k+1)\,(4k)^{4k}$.
   (b) For equality to occur in this case, it is necessary and sufficient that $8k+1$ is the square of an integer and that there exists a matrix $W \in \{\pm 1\}^{m\times n}$ with $W^T W = (n-1)I_n + J_n$.
   (c) Equality occurs for infinitely many values of $n = 4k+1$. A.E. Brouwer [Bro83] constructed an infinite family of 2-designs with parameters $(n = 2q^2+2q+1, q^2, (q^2-q)/2)$. The ($\pm 1$)-incidence matrix W_n of such a design satisfies $W_n^T W_n = (n-1)I_n + J_n$.
   (d) The results in [MK82] and [CMK87] provide upper bounds, which are stronger than $(8k+1)(4k)^{4k}$ in case $8k+1$ is not the square of an integer.

7. [Ehl64a], [Woj64] D-optimal (± 1)-matrices: the case $n = 4k+2$
   (a) $\alpha(4k+2) \leq (8k+2)^2\,(4k)^{4k}$.
   (b) For equality to occur in this case, it is necessary that $n-1$ is the sum of two squares and that there exists a matrix $W_n \in \{\pm 1\}^{n\times n}$ such that

$$W_n^T W_n = \begin{bmatrix} (n-2)I_{\frac{n}{2}} + 2J_{\frac{n}{2}} & 0_n \\ 0_n & (n-2)I_{\frac{n}{2}} + 2J_{\frac{n}{2}} \end{bmatrix}. \tag{44.1}$$

   (c) It is conjectured that the bound is attained whenever this is the case.
   (d) The bound is attained infinitely often.
   (e) If $n-1$ is a square and there exists a matrix $W_{\frac{n}{2}} \in \{\pm 1\}^{\frac{n}{2}\times\frac{n}{2}}$ such that $W_{\frac{n}{2}}^T W_{\frac{n}{2}} = \frac{n-2}{2} I_{\frac{n}{2}} + J_{\frac{n}{2}}$, then construct the matrix $W_n = W_{\frac{n}{2}} \otimes H_2$ where $H_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$. Then $W_n \in \{\pm 1\}^{n\times n}$ satisfies Eq. (44.1) and attains the bound. Such a matrix $W_{\frac{n}{2}}$ exists if $\frac{n}{2} = 2q^2+2q+1$.

8. [Ehl64b] D-optimal (± 1)-matrices: The case $n = 4k+3$

$$\alpha(4k+3) \leq (4k)^{4k+3-s}(4k+4r)^u(4k+4+4r)^v \left(1 - \frac{ur}{4k+4r} - \frac{v(r+1)}{4k+4+4r}\right),$$

   where $s = 5$ for $k = 1$, $s = 5$ or 6 for $k = 2$, $s = 6$ for $3 \leq k \leq 14$, and $s = 7$ for $k \geq 15$ and where $r = \lfloor (4k+3)/s \rfloor$, $4k+3 = rs+v$, and $u = s-v$.
   (a) This case is the least well understood of the four.
   (b) For equality to occur for $n \geq 63$, it is necessary that $n = 112j^2 \pm 28j + 7$ and that there exists a matrix $W_n \in \{\pm 1\}^{n\times n}$ with

$$W_n^T W_n = I_7 \otimes \left[(n-3)I_{\frac{n}{7}} + 4J_{\frac{n}{7}}\right] - J_n.$$

   (c) However, it is not known if this bound is attainable for any $n \geq 63$.
   (d) The best lower bound seems to be the one in [NR97]. In [NR97], an infinite family of matrices is constructed whose determinants attain about 34% of the bound above.

9. [Wil46], [EZ62], [Orr05], [BOO11] D-optimal matrices are known for $n = 3, 7, 11, 15, 19$.
10. See [OS] for (± 1)-matrices with largest known determinant for $n \leq 103$.

Examples:

1. The following matrices are Hadamard matrices in $\{\pm 1\}^{4\times 4}$ and $\{\pm 1\}^{12\times 12}$:

$$H_4 = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix}$$

$$H_{12} = \begin{bmatrix} J & A & A & A \\ A & -J & A & -A \\ A & -A & -J & A \\ A & A & -A & -J \end{bmatrix},$$

where $A = J_3 - 2I_3$ and $J = J_3$. $H_4 H_4^T = 4I_4$ and $H_{12}H_{12}^T = 12I_{12}$.

2. Let $A = J_5 - 2I_5$. Then $A^T A = 4I_5 + J_5$ and $\det(A^T A)$ achieves the upper bound in Fact 6.
3. Let

$$W = \begin{bmatrix} A & A \\ A & -A \end{bmatrix} = A \otimes H_2 \in \{\pm 1\}^{10\times 10},$$

where $A = J_5 - 2I_5$. Then

$$W^T W = \begin{bmatrix} 8I_5 + 2J_5 & 0 \\ 0 & 8I_5 + 2J_5 \end{bmatrix},$$

and, hence, $\det(W^T W)$ achieves the upper bound in Fact 7.

4. To obtain the upper bound in Fact 6 for $n = 13$, let $V \in \{0,1\}^{13\times 13}$ be the $(0,1)$ line-point incidence matrix for a projective plane of order 3. Then $V^T V = 3I_{13} + J_{13}$ and the matrix $W = J_{13} - 2V \in \{\pm 1\}^{13\times 13}$ satisfies $W^T W = 12I_{13} + J_{13}$ and its determinant attains the upper bound.
5. For $n \geq 11$ and $n \equiv 3 \pmod 4$, no (± 1)-matrix is known to have a determinant that equals the upper bound in Fact 8. However, the following matrix $W \in \{\pm 1\}^{15\times 15}$, which is listed in [OS], satisfies

$$\det(W^T W) = 174755568785817600,$$

which is about 94% of the upper bound 185454889323724800 in Fact 8 with $k = 3$, $s = 6$.

$$W = \begin{bmatrix}
-1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 & 1 & -1 & 1 & 1 & 1 & 1 & -1 \\
-1 & -1 & -1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 & 1 & -1 & 1 & 1 \\
-1 & -1 & -1 & 1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & -1 & 1 & 1 & 1 \\
-1 & 1 & 1 & -1 & -1 & 1 & 1 & 1 & -1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & 1 & -1 & 1 & -1 & -1 & 1 & 1 & 1 & -1 & 1 & -1 & -1 & -1 & -1 \\
1 & -1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & 1 & 1 & 1 & 1 & 1 & -1 & 1 & 1 & 1 & 1 & -1 & -1 & 1 & -1 \\
-1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 & 1 & -1 & 1 & -1 & 1 & 1 & 1 \\
1 & 1 & 1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 & -1 & 1 & 1 & 1 & 1 \\
1 & -1 & 1 & -1 & -1 & -1 & -1 & 1 & -1 & -1 & 1 & 1 & -1 & 1 & 1 \\
1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 & 1 & -1 \\
1 & 1 & -1 & -1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 & -1 & 1 & 1 \\
1 & -1 & 1 & 1 & -1 & 1 & 1 & -1 & -1 & -1 & -1 & -1 & 1 & 1 & -1 \\
-1 & 1 & 1 & 1 & 1 & -1 & 1 & -1 & -1 & -1 & -1 & 1 & -1 & 1 & -1 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & -1 & -1 & -1 & 1 & 1 & 1 & -1 & 1
\end{bmatrix}.$$

44.3 The (± 1) Nonsquare Case

Facts:

1. [Had93] $\alpha(4k, n) \leq (4k)^n$.
2. [Pay74] $\alpha(4k+1, n) \leq (4k+n)(4k)^{n-1}$.
3. [Pay74]

$$\alpha(4k+2, n) \leq \begin{cases} (4k+n)^2(4k)^{n-2}, & \text{if } n \text{ is even,} \\ (4k+n+1)(4k+n-1)(4k)^{n-2}, & \text{if } n \text{ is odd.} \end{cases} \tag{44.2}$$

4. [GK80b] If $m = 4k - 1 \geq 2n - 5$, then $\alpha(m, n) \leq (4k-n)(4k)^{n-1}$.

Examples:

1. If $m = 4k$, equality can be achieved by taking W_0 to be the matrix consisting of any n columns of a Hadamard matrix of order $4k$. Then $W_0^T W_0 = 4kI_n$ and, hence, $\det W_0^T W_0 = \alpha(4k, n)$.
2. If $m = 4k+1$, adjoin a row of all 1s to W_0 and call the new matrix W_1. We have $W_1 \in \{\pm 1\}^{(4k+1)\times n}$ and $W_1^T W_1 = mI_n + J$. Hence, $\det W_1^T W_1 = \alpha(4k+1, n)$.
3. If $m = 4k+2$, let $r_1 = (1, 1, \ldots, 1)$ and $r_2 = (1, \ldots, 1, -1, \ldots, -1)$ be n-tuples with $r_1 \cdot r_2 = 0$, if n is even, and $r_1 \cdot r_2 = 1$, if n is odd. Adjoin rows r_1 and r_2 to W_0. Call the resulting matrix W_2. Then $W_2 \in \{\pm 1\}^{(4k+2)\times n}$ and

$$W_2^T W_2 = \begin{bmatrix} 4kI_l + 2J_l & 0_l \\ 0_l & 4kI_l + 2J_l \end{bmatrix} \quad \text{if } n = 2l \text{ is even}$$

and

$$W_2^T W_2 = \begin{bmatrix} 4kI_{l+1} + 2J_{l+1} & 0_{l+1,l} \\ 0_{l,l+1} & 4kI_l + 2J_l \end{bmatrix} \quad \text{if } n = 2l+1 \text{ is odd.}$$

   Thus, $\det W_2^T W_2 = \alpha(4k+2, n)$.
4. If $m = 4k-1$, we may assume without loss of generality that the first row of W_0 is an all 1s row. Remove this first row of W_0 and call that matrix W_{-1}. Note that $W_{-1} \in \{\pm 1\}^{(4k-1)\times n}$ and that $W_{-1}^T W_{-1} = 4kI_n - J_n$. Hence, $\det W_{-1}^T W_{-1} = \alpha(4k-1, n)$.
5. It is not necessary to have a Hadamard matrix H_m of order m. All we require is the existence of a matrix $W \in \{\pm 1\}^{4k\times n}$ with $W^T W = mI_n$. See [GK80a] for details.
6. Upper bounds on $\alpha(4k-1, n)$ when $m = 4k-1 \leq 2n-5$ are given in [GK80b], [KF84], [SS91].

44.4 The $(0, 1)$ Nonsquare Case: Regular D-Optimal Matrices

Definitions:

Let W be a $(0,1)$-design matrix in $\{0,1\}^{m\times n}$. For n odd, W is **balanced** if every row of W has exactly $(n+1)/2$ ones; for n even, W is **balanced** if every row of W has exactly $n/2$ ones or exactly $(n+2)/2$ ones.

A design matrix $W \in \{0,1\}^{m\times n}$ is **regular** if it is balanced and $W^TW = t(I+J)$ for some integer t.

Facts:

1. [HKL96] If n is odd, then $\beta(m,n) \leq (n+1)\left(\frac{(n+1)m}{4n}\right)^n$, with equality if and only if W is regular.
2. [NWZ97] If n is even, then $\beta(m,n) \leq (n+1)\left(\frac{(n+2)m}{4(n+1)}\right)^n$, with equality if and only if W is regular.
3. [NWZ98a] A regular matrix exists in $\{0,1\}^{m\times n}$ only if
$$\begin{aligned} 2(n+1) \text{ divides } m \text{ for } n &\equiv 0 \pmod 4, \\ 2n \text{ divides } m \text{ for } n &\equiv 1 \pmod 4, \\ n+1 \text{ divides } m \text{ for } n &\equiv 2 \pmod 4, \\ n \text{ divides } m \text{ for } n &\equiv 3 \pmod 4. \end{aligned}$$
4. [NWZ98a] If $n = 4t-1$ and $H \in \{0,1\}^{m\times n}$ is the incidence matrix for a $(4t-1, 2t-1, t-1)$-design, then $W = J - H$ is a regular D-optimal matrix and $[\overbrace{W^T, \cdots, W^T}^{k}]^T$ is a regular D-optimal matrix in $\{0,1\}^{kn\times n}$. Let W_1 be the matrix obtained by deleting any column from W. Then $[\overbrace{W_1^T, \cdots, W_1^T}^{k}]^T$ is a regular D-optimal matrix in $\{0,1\}^{kn\times(n-1)}$.
5. [NWZ98a] If $n = 4t+1$ is a power of a prime integer, then a D-optimal regular matrix $W_2 \in \{0,1\}^{2n\times n}$ exists. Let $W_3 \in \{0,1\}^{2n\times(n-1)}$ be the matrix obtained by deleting any column from W_2. Then $[\overbrace{W_2^T, \cdots, W_2^T}^{k}]^T$ and $[\overbrace{W_3^T, \cdots, W_3^T}^{k}]^T$ are regular D-optimal matrices.

Examples:

1. Let $n = 4$ and $m = 10$. The following matrix is balanced and regular:
$$W^T = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 1 & 1 \end{bmatrix}, \qquad W^TW = \begin{bmatrix} 6 & 3 & 3 & 3 \\ 3 & 6 & 3 & 3 \\ 3 & 3 & 6 & 3 \\ 3 & 3 & 3 & 6 \end{bmatrix}.$$
The inequality in Fact 2 is attained at W:
$$\beta(10,4) = 5\left(\frac{6\cdot 10}{4\cdot 5}\right)^4 = 405 = \det(W^TW).$$
Thus, W is D-optimal.
2. A regular matrix exists for the case $n = 9, m = 18$. (Fact 3, where $n \equiv 1 \pmod 4$ and $2n = 18$ divides $m = 18$.) The regular matrix is constructed from the Galois field $GF(9)$ with nine elements. Choosing $GF(9) = \mathbb{Z}_3/(x^2+1)$, the element $\theta = x+2$ of order 8, generates the nonzero elements in $GF(9)$. The nonzero quadratic residues of $GF(9)$ are $Q = \{1, \theta^2, \theta^4, \theta^6\}$. Define $K_1 \in \{0,1\}^{9\times 9}$ by
$$(K_1)_{\rho,\tau} = \begin{cases} 1, & \text{if } \tau \in \rho + Q, \\ 0, & \text{if otherwise,} \end{cases}$$

where the rows and columns ρ, τ are indexed by $\{0, 1, \theta, \theta^2, \ldots, \theta^7\}$. Then

$$K_1 = \begin{bmatrix} 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}.$$

Define K_2 in the same way but with the nonzero quadratic nonresidues $R = \{\theta, \theta^3, \theta^5.\theta^7\}$ in place of Q. Then the matrix $[K_1, K_2] \in \{0,1\}^{9\times 18}$ satisfies

$$K_1 K_1^T + K_2 K_2^T = 5I_9 + 3J_9.$$

Let $W = [J_9 - K_1, J_9 - K_2]$. Then W is a D-optimal regular design matrix: $WW^T = 5(I_9 + J_9)$.

3. The following matrix N is the incidence matrix for a $(7, 3, 1)$-design:

$$N = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 0 & 0 \end{bmatrix}.$$

Then (Fact 4) $W = J_7 - H$ is a regular D-optimal matrix in $\{0,1\}^{7\times 7}$ and $[W^T, \ldots, W^T]^T$ is a regular D-optimal matrix in $\{0,1\}^{7k\times 7}$.

44.5 The (0, 1) Nonsquare Case: Nonregular D-Optimal Matrices

It is clear from Fact 44.4.3 that for most pairs (m, n), no regular D-optimal matrix exists. For example, if $n = 7$, then the only values of m for which a regular D-optimal matrix exists are $m = 7t$. Thus, for $m = 7t + r$, with $0 \le r \le 6$, a D-optimal matrix cannot be regular unless $r = 0$. The only values of n for which $\beta(m, n)$ is known for all values of m are $n = 2, 3, 4, 5, 6$.

Facts:

1. [HKL96] $n = 2$, $m = 3t + r$ with $r = 0, 1, 2$:

$$\beta(m, 2) = \begin{cases} 3t^2 \quad , & \text{for } r = 0 \\ 3t^2 + 2t, & \text{for } r = 1 \end{cases}.$$

2. [HKL96] $n = 3$, $m = 3t + r$ with $r = 0, 1, 2$:

$$\beta(m, 3) = 4t^{3-r}(t + 1)^r.$$

3. [NWZ98b] $n = 4$, $m = 10t + r$ with $0 \le r \le 9$:

$$\beta(m,4) = \begin{cases} 405\,t^4 & , \quad \text{for } r = 0 \\ 81\,t^3\,(2+5\,t) & , \quad \text{for } r = 1 \\ 3\,t\,(1+3\,t)^2\,(2+15\,t) & , \quad \text{for } r = 2 \\ 3\,t\,(1+3\,t)^2\,(8+15\,t) & , \quad \text{for } r = 3 \\ 3\,(1+3\,t)^3\,(3+5\,t) & , \quad \text{for } r = 4 \\ (1+3\,t)^2\,\left(19+60\,t+45\,t^2\right) & , \quad \text{for } r = 5 \\ 3\,(2+3\,t)^3\,(2+5\,t) & , \quad \text{for } r = 6 \\ 3\,(1+t)\,(2+3\,t)^2\,(7+15\,t) & , \quad \text{for } r = 7 \\ 3\,(1+t)\,(2+3\,t)^2\,(13+15\,t), & \quad \text{for } r = 8 \\ 81\,(1+t)^3\,(3+5\,t) & , \quad \text{for } r = 9 \end{cases}.$$

4. [NWZ98b] In the case $n = 5$, all D-optimal matrices are balanced except when $m = 5, 6, 7, 8, 15, 16, 17, 27$. For $m = 10t + r$ with $0 \le r \le 9$ and m not equal to any of the exceptional values, we have

$$\beta(m,5) = \begin{cases} 1458\,t^5 & , \quad \text{for } r = 0 \\ 729\,t^4\,(1+2\,t) & , \quad \text{for } r = 1 \\ 162\,t^3\,(1+3\,t)\,(2+3\,t) & , \quad \text{for } r = 2 \\ 27\,t^2\,(1+3\,t)^2\,(5+6\,t) & , \quad \text{for } r = 3 \\ 54\,t\,(1+t)\,(1+3\,t)^3 & , \quad \text{for } r = 4 \\ 9\,(1+t)\,(1+3\,t)^2\,\left(1+15\,t+18\,t^2\right), & \quad \text{for } r = 5 \\ 54\,(1+t)^2\,(1+3\,t)^3 & , \quad \text{for } r = 6 \\ 27\,(1+t)^2\,(1+3\,t)^2\,(5+6\,t) & , \quad \text{for } r = 7 \\ 162\,(1+t)^3\,(1+3\,t)\,(2+3\,t) & , \quad \text{for } r = 8 \\ 729\,(1+t)^4\,(1+2\,t) & , \quad \text{for } r = 8 \end{cases}.$$

The values of $\beta(m, 5)$ for the eight exceptional values of m are

$$\begin{array}{llll} \beta(5,5) = 25 & \beta(6,5) = 64 & \beta(7,5) = 192 & \beta(8,5) = 384 \\ \beta(15,5) = 9880 & \beta(16,5) = 13975 & \beta(17,5) = 19500 & \beta(27,5) = 202752. \end{array}$$

Each of these is greater than the value of the corresponding polynomial above. For example, if $m = 16$ so that $t = 1$ and $r = 6$, then $54\,(1+t)^2\,(1+3\,t)^3 = 13824$, which is less than 13975.

5. [NWZ00] For $n = 6$, all D-optimal matrices are balanced except when $m = 6, 8, 9, 13$.

For $m = 7t + r$ with $0 \le r \le 6$ and $m \ne 6, 8, 9, 13$:

$$\beta(m,6) = \begin{cases} 448\,t^6 & , \quad \text{for } r = 0 \\ 16\,t^4\,(1+2\,t)\,(5+14\,t) & , \quad \text{for } r = 1 \\ 4\,t^2\,(1+2\,t)^3\,(3+14\,t) & , \quad \text{for } r = 2 \\ (1+2\,t)^5\,(1+14\,t) & , \quad \text{for } r = 3 \\ (1+2\,t)^5\,(13+14\,t) & , \quad \text{for } r = 4 \\ 4\,(1+t)^2\,(1+2\,t)^3\,(11+14\,t), & \quad \text{for } r = 5 \\ 16\,(1+t)^4\,(1+2\,t)\,(9+14\,t)\,, & \quad \text{for } r = 6 \end{cases}$$

The values of $\beta(6, m)$ for the four exceptional values of m are

$$\beta(6,6) = 81 \qquad \beta(8,6) = 832 \qquad \beta(9,6) = 1620 \qquad \beta(13,6) = 16512.$$

As in the case for $n = 5$, the values of $\beta(m, 6)$ exceed the value of the corresponding polynomial.

Examples:

1. Design matrices are exhibited for the above cases in the sources listed. For example, if $n = 4$, let

$$W_0 = \begin{bmatrix} 1 & 1 & 1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 & 1 & 0 & 0 & 1 & 1 & 0 \\ 1 & 0 & 1 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 1 & 1 & 1 & 0 & 0 & 1 & 0 & 1 & 1 \end{bmatrix}^T,$$

v_i be the ith row of W_0. If $r = 3$, then the matrix $[\overbrace{W_0^T, \cdots, W_0^T}^{t}, v_8^T, v_9^T, v_{10}^T]^T$ is a D-optimal matrix in $\{0,1\}^{(4t+3)\times 4}$.

44.6 The (0, 1) Nonsquare Case: Large m

Facts:

1. [NWZ98a] For each value of n, all D-optimal matrices in $\{0,1\}^{m\times n}$ are balanced for sufficiently large values of m.
2. [NW02], [AFN03], [LN10], [NP10] In addition to the values $n = 2, 3, 4, 5, 6$, for which $\beta(m, n)$ is known for all m, the only other values of n for which $\beta(m, n)$ is known for all sufficiently large values of m are $n = 7, 8, 10, 11, 15, 19, 23, 27$.

Examples:

1. [NW02]

$$\beta(7t + r, 7) = 2^{10} t^{7-r} (t + 1)^r,$$

for sufficiently large values of $m = 7t + r$.

44.7 The (0, 1) Nonsquare Case: $n \equiv -1 \pmod 4$

The theory for D-optimal $(0, 1)$-designs is most developed for the cases where $n \equiv -1 \pmod 4$.

Definitions:

For an $n \times n$ matrix A, the **trace-sequence** A is $(\text{trace}(A), \text{trace}(A^2), \cdots, \text{trace}(A^n))$.

$\mathcal{G}(v, \delta)$ is the set of all δ-regular graphs on v vertices.

Let graph G be a graph in $\mathcal{G}(v, \delta)$ and let $\mathcal{A}_G$ be the adjacency matrix of G. The graph G is **trace-minimal** if the **trace-sequence** of its adjacency matrix $(\text{trace}(\mathcal{A}_G), \text{trace}(\mathcal{A}_G^2), \cdots, \text{trace}(\mathcal{A}_G^n))$ is least in lexicographic order among all graphs in $\mathcal{G}(v, \delta)$.

Facts:

1. [AFN03] If $n \equiv -1 \pmod 4$, then for each $0 \leq r < n$ and all sufficiently large values of t, $\beta(nt + r, n)$ is a polynomial in t of degree n. These polynomials are related to the adjacency matrices $\mathcal{A}_G$ of certain regular graphs G.
2. [AFN03], [AFN06] The polynomial $\beta(nt + r, n)$ depends on a trace-minimal graph in $\mathcal{G}(v, \delta)$. Once a trace-minimal graph G is found in the appropriate graph class $\mathcal{G}(v, \delta)$, the polynomial $\beta(nt+r, n)$ can be computed. There are four theorems [AFN03] governing this situation; one for each congruence class of $r \pmod 4$.
3. [AFN03] Trace-minimal graphs are known for all of the graph classes necessary to obtain formulas for $\beta(nt + r, n)$ for $n = 3, 7, 11, 15, 19, 23,$ and 27 and t sufficiently large.
4. [AFN06] Let G be a connected strongly regular graph with no three cycles. Then G is trace-minimal.
5. [AFN06] The following graphs are trace-minimal in their graph class:

Graph Class	G
$\mathcal{G}(v, 0)$	Graph with v vertices and no edges
$\mathcal{G}(2v, 1)$	vK_2, a matching of $2v$ vertices
$\mathcal{G}(v, 2)$	C_v, the cycle graph on v vertices
$\mathcal{G}(2v, v)$	$K_{v,v}$, the complete bipartite graph with v vertices in each set of the bipartition
$\mathcal{G}(2v, 2v-2)$	$K_{2v} - vK_2$, the complement of a matching
$\mathcal{G}(v, v-1)$	K_v, the complete graph on v vertices

6. [Sae08] $G = I_{v-1} \nabla C_{v+1}$, the join of the empty graph on $v - 1$ vertices and the cycle on $v + 1$ vertices, is the unique trace-minimal graph in $\mathcal{G}(2v, v + 1)$.
7. [AFN06] Let G be a connected regular graph with girth g such that $\mathcal{A}_G$ has $k + 1$ distinct eigenvalues. If g is even, then $g \leq 2k$ with equality only if G is trace-minimal. If g is odd, then $g \leq 2k + 1$ with equality only if G is trace-minimal.

Examples:

1. Let $n = 4p - 1 \equiv -1 \pmod 4$ and $r = 4d + 2 \equiv 2 \pmod 4$. Let G be a trace-minimal graph in $\mathcal{G}(2p, p + d)$. Then
$$\beta(nt + r, n) = \frac{4t[p_{\mathcal{A}_G}(pt + d)]^2}{(t-1)^2},$$
for sufficiently large values of t. Taking $n = 15, r = 10$, we have $p = 4, d = 2$. The appropriate graph class is $\mathcal{G}(8, 6)$. There is only one graph G in this class, namely the complement of the matching $4K_2$. Thus, it is trace-minimal. Since $p_{\mathcal{A}_G}(x) = (x - 6)x^4(x + 2)^3$,
$$\beta(15t + 10, 15) = \frac{4t[p_{\mathcal{A}_G}(4t + 2)]^2}{(t-1)^2} = 16(4t)(4t + 2)^8(4t + 4)^6,$$
for sufficiently large t.

2. Let $n = 4p - 1 \equiv -1 \pmod 4$ and $r = 4d + 1 \equiv 1 \pmod 4$. Let G be a trace-minimal graph in $\mathcal{G}(2p, d)$. Then

$$\beta(nt + r, n) = \frac{4(t+1)[p_{\mathcal{A}_G}(pt + d)]^2}{t^2},$$

for sufficiently large t. Taking $n = 15, r = 9$ we have $p = 4, d = 2$. The appropriate graph class is $\mathcal{G}(8, 2)$. There are three (nonisomorphic) graphs in this class: C_8, $C_5 \cup C_3$, and $C_4 \cup C_4$, where C_k stands for a k-cycle graph. The trace sequences for these three graphs are

$$(\mathrm{trace}(\mathcal{A}_G), \mathrm{trace}(\mathcal{A}_G^2), \cdots, \mathrm{trace}(\mathcal{A}_G^8)) = \begin{cases} (0, 16, 0, 48, 0, 160, 0, 576) \quad , & \text{for } G = C_8 \\ (0, 16, 6, 48, 40, 166, 196, 608), & \text{for } G = C_5 \cup C_3 \\ (0, 16, 0, 64, 0, 256, 0, 1024) \quad , & \text{for } G = C_4 \cup C_4. \end{cases}$$

Thus, C_8 is the only trace-minimal graph in the graph class $\mathcal{G}(8, 2)$. The characteristic polynomial for $\mathcal{A}_{C_8}$ is

$$(x - 2)x^2(x + 2)(x^2 - 2)^2.$$

Thus,

$$\beta(15t + 9, 15) = \frac{4(t+1)[p_{\mathcal{A}_G}(4t + 2)]^2}{t^2} = 16(4t + 2)^4(4t + 4)^3(16t^2 + 16t + 2)^4.$$

3. The Petersen graph (Figure 44.1(a)) is an example of a strongly regular graph. (See Fact 4.) It is trace-minimal in $\mathcal{G}(10, 3)$:

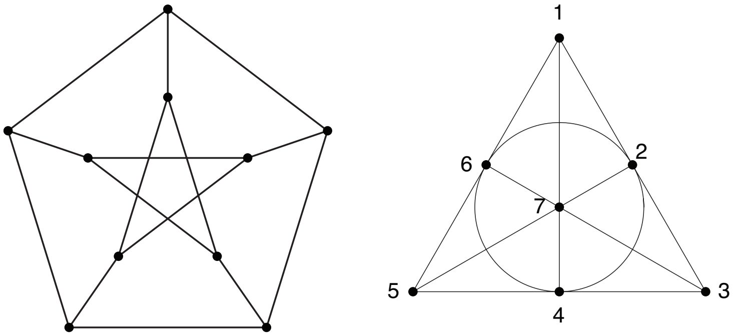

FIGURE 44.1 (a) (b)

4. Let P be the projective geometry with seven points, $1, 2, 3, 4, 5, 6, 7$ and seven lines, $123, 147, 156, 257, 246, 367, 345$ (Figure 44.1(b)). The line-point incidence matrix for P is:

$$N = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 1 & 1 & 1 & 0 & 0 \end{bmatrix}.$$

Let G be the incidence graph of P having 14 vertices and adjacency matrix given by

$$\mathcal{A}_G = \begin{bmatrix} 0 & N \\ N^T & 0 \end{bmatrix}.$$

Then G is trace-minimal by Fact 7: G is a regular graph of degree 3. The girth of G is $g = 6$. The characteristic polynomial of $\mathcal{A}_G$ is $(x-3)(x+3)(x^2-2)^6$ and so $\mathcal{A}_G$ has $k+1 = 4$ distinct eigenvalues. Since $2k = g$, it follows that G is trace-minimal in $\mathcal{G}(14, 3)$.

44.8 Balanced (0, 1)-Matrices and (±1)-Matrices

Let $n = 2k-1$ be odd. There is a connection between balanced $(0,1)$-design matrices and (± 1)-design matrices.

Facts:

1. [NWZ98a] Let W be a balanced design matrix in $\{0,1\}^{m\times n}$, so that each row of W contains exactly k ones and $k-1$ zeros. Let q be a positive integer and

$$L(W) = \begin{bmatrix} J_{n,1} & J_{n,m} - 2W^T \\ J_{q,1} & J_{q,m} \end{bmatrix}.$$

Then $\det L(W)^T L(W) = q4^m \det W^T W$. It follows that for sufficiently large m, if W is a balanced $(0,1)$-design matrix and $L(W)$ is a D-optimal design matrix, then W is also D-optimal.

A tournament is a directed graph whose adjacency matrix A satisfies the matrix equation $A + A^T + I = J$, where J is a matrix of 1's. The matrix equation is the key to the interplay between the graph-theoretic structure of tournaments and properties of their adjacency matrices. The classic book by Moon [Moo68] and the more recent surveys by Reid and Beineke [RB78] and Reid [Rei04] emphasize graph-theoretic aspects of tournaments. In this chapter, we emphasize properties of tournaments related to linear algebra and combinatorial matrix theory.

45.1 Tournaments and Tournament Matrices

Suppose that a round-robin tournament is held among a set of players. Each player meets each other player once, and no game ends in a tie. The entire competition can be summarized by a directed graph known as a tournament, whose vertices represent the players, and whose directed edges record the outcomes of the games. The formal definition is below.

Definitions:

A **tournament** is a simple directed graph $\Gamma = \Gamma(V, E)$ in which exactly one of the two arcs (i, j) and (j, i) is present for each pair of distinct vertices i and j. Thus, a tournament arises by assigning a direction to each edge of a complete graph. We often let the set of vertices be $V = \{1, 2, \ldots, n\}$.

The vertices of a tournament are called **players**.

When arc (i, j) is in a tournament, we write $i \to j$ and say that i **defeats** or **dominates** or **beats** j.

The usual terminology (walks, subgraphs, ...) for directed graphs applies to tournaments. (See Chapter 40.)

The **walk** $p_1 \to p_2 \to \cdots \to p_{k+1}$ of length k with distinct vertices is **simple**.

The walk $p_1 \to p_2 \to \cdots \to p_{k+1}$ is a k**-cycle** provided the vertices are distinct except that $p_{k+1} = p_1$.

A 3-cycle is a **cyclic triple**.

A simple walk of length $n - 1$ is a **Hamilton path**.

An n-cycle is a **Hamilton cycle**.

A **subtournament** of a tournament Γ is a subdigraph of Γ that is itself a tournament.

A tournament is **transitive** provided $i \to k$ whenever both $i \to j$ and $j \to k$.

A tournament Γ is **strong** provided it is strongly connected, i.e., for each ordered pair of players

i and j there is a walk from i to j. In particular, a tournament with one vertex is strong.

The **score** or **out-degree** s_i of player i is the number of players defeated by player i. The **score sequence** is $(s_1, s_2, \ldots, s_n)$.

The adjacency matrix of a tournament is a **tournament matrix** or **dominance matrix**. If a tournament Γ has n vertices, then the corresponding tournament matrix $A = [a_{ij}]$ is a $(0, 1)$-matrix of order n with $a_{ij} = 1$ when $i \to j$ and $a_{ij} = 0$ otherwise.

We make free use of the correspondence between a digraph and its adjacency matrix and sometimes apply matrix terminology to the tournaments themselves or graph-theoretic terminology to tournament matrices. For instance, a tournament is **reducible** or **irreducible** according as its tournament matrix is reducible or irreducible. (See Chapters 10, 38, and 40).

Facts:

The following facts are in Chapters 2 and 5 of [Bru06] and the cited pages of [Moo68].

1. A tournament matrix A of order n satisfies $A + A^T + I = J$, where J denotes the all 1's matrix of order n.
2. There is a one-to-one correspondence between tournaments with vertex set $\{1, 2, \ldots, n\}$ and $(0, 1)$-matrices A of order n that satisfy the matrix equation in Fact 1.
3. [Moo68, p. 21] Every tournament has a Hamilton path. (*Rédei's theorem*) Every tournament has an odd number of Hamilton paths.
4. [Moo68, p. 14] Let Γ be a tournament on n players with adjacency matrix A. The following assertions are equivalent:
   (a) Γ is transitive.
   (b) Γ contains no cycles.
   (c) Γ contains a unique Hamilton path.
   (d) No two scores of Γ are equal.
   (e) The scores of Γ are 0, 1, …, $n-1$ in some order.
   (f) There is a permutation matrix P such that PAP^T is a lower triangular matrix.
   (g) Every principal submatrix of A has a row of 0's.
5. An induced subdigraph of a tournament Γ is a subtournament of Γ.
6. Every subtournament of a transitive tournament is transitive.
7. [Moo68, p. 14] Every tournament on n vertices has a transitive subtournament on $1 + \lfloor \log_2(n) \rfloor$ vertices.
8. The reduced digraph (see Chapter 40) of a tournament is a transitive tournament.
9. A tournament with score sequence $(s_1, s_2, \ldots, s_n)$ has $\sum_{i=1}^{n} \binom{s_i}{2}$ transitive subtournaments on three vertices and $\binom{n}{3} - \sum_{i=1}^{n} \binom{s_i}{2}$ cyclic triples.
10. A tournament on n vertices ($n \geq 2$) is strong if and only if it has a Hamilton cycle.
11. [Moo68, p. 6] A strong tournament on n vertices ($n \geq 3$) has a k-cycle for each $k = 3$, 4, …, n.
12. A tournament is irreducible if and only if it is strong. (See Section 40.5 for the more general equivalence between irreducible matrices and strong digraphs.)
13. A tournament is reducible if and only if it is possible to partition the players into two nonempty sets such that every player in the first set defeats every player in the second set.
14. [Moo68, p. 35] A tournament matrix of order n is primitive (see Chapter 40) if and only if it is irreducible and $n \geq 4$.
15. Let Γ be a tournament with score sequence $(s_1, s_2, \ldots, s_n)$ and tournament matrix A. The number of 1's in row i of A is s_i, and the number of 1's in column i of A is $n - 1 - s_i$ ($i = 1, 2, \ldots, n$).

16. Let Γ be a tournament with tournament matrix A of order n. If P is a permutation matrix of order n, then PAP^T is a tournament matrix that corresponds to Γ with the vertex labels permuted according to P.
17. A tournament matrix A of order n has term rank equal to n or $n-1$. (See Chapter 38 for the definition of term rank.) The term rank is $n-1$ if and only if the Frobenius normal form of A has an irreducible component of order 1.

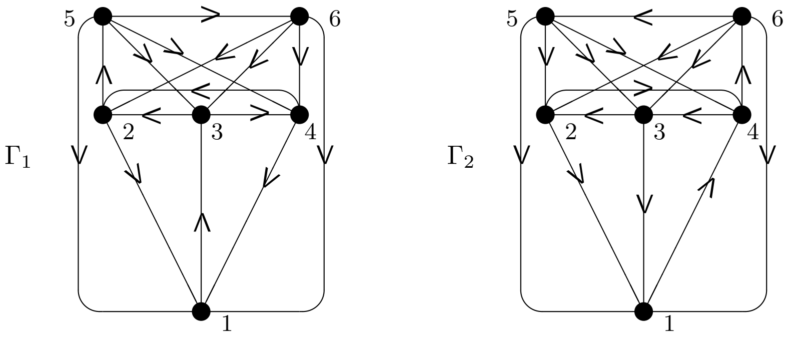

FIGURE 45.1 Two tournaments with score sequence (1,2,2,2,4,4).

Examples:

1. The tournaments Γ_1 and Γ_2 in Figure 45.1 both have score sequence $(1,2,2,2,4,4)$. The tournaments Γ_1 and Γ_2 possess respective Hamilton cycles $1\rightarrow 3\rightarrow 2\rightarrow 5\rightarrow 6\rightarrow 4\rightarrow 1$ and $1\rightarrow 4\rightarrow 6\rightarrow 5\rightarrow 3\rightarrow 2\rightarrow 1$. The tournament Γ_2 has a transitive subtournament with vertex set $\{1,2,3,5,6\}$. Both tournaments are strong.
2. The tournament matrices for the tournaments Γ_1 and Γ_2 in Figure 45.1 are

$$\begin{bmatrix}0&0&1&0&0&0\\1&0&0&0&1&0\\0&1&0&1&0&0\\1&1&0&0&0&0\\1&0&1&1&0&1\\1&1&1&1&0&0\end{bmatrix} \quad\text{and}\quad \begin{bmatrix}0&0&0&1&0&0\\1&0&0&1&0&0\\1&1&0&0&0&0\\0&0&1&0&0&1\\1&1&1&1&0&0\\1&1&1&0&1&0\end{bmatrix}.$$

45.2 Score Sequences and the Class $\mathcal{T}(s)$

The scores provide a straightforward method to rank the players and contain local information about a tournament. Thus, it is natural to seek connections between score sequences and the combinatorial structure of tournaments and tournament matrices. The fundamental issue of existence of a tournament with a putative score sequence was answered by Landau in 1953 (Fact 2).

Definitions:

The sequence $s=(s_1,s_2,\ldots,s_n)$ is **realizable** provided there exists a tournament with score sequence s.

The class of tournaments with score sequence s is denoted by $\mathcal{T}(s)$. Equivalently, $\mathcal{T}(s)$ is the class of tournament matrices with **score vector** $\mathbf{s}=[s_1,s_2,\ldots,s_n]^T$.

The real nonnegative matrix $A = [a_{ij}]$ of order n is a **generalized tournament matrix** provided $A + A^T + I = J$. The entry a_{ij} can be viewed as an *a priori* probability that player i defeats player j.

In a generalized tournament matrix the **score** s_i of player i is the sum of the elements in row i of A, and the **score vector** is $[s_1, s_2, \ldots, s_n]^T$.

A **Δ-interchange** reverses the directions of the three arcs in a 3-cycle in a tournament.

A **transitive partition** of a tournament Γ is a partition $V = V_1 \cup V_2 \cup \cdots \cup V_k$ of the vertex set such that V_i induces a transitive subtournament of Γ for $i = 1, 2, \ldots, k$. We have a **transitive $(n_1, n_2, \ldots, n_k)$-partition** when $|V_i| = n_i$ for $i = 1, 2, \ldots, k$.

Facts:

Facts without references appear in Chapters 2 and 5 of [Bru06] or are clear from the definitions.

1. A sequence of nonnegative integers is realizable if and only if every permutation of the sequence is realizable. Thus, we often assume the sequence is nondecreasing.
2. (*Landau's theorem*) The nondecreasing sequence $(s_1, s_2, \ldots, s_n)$ of nonnegative integers is realizable if and only if the inequality

$$s_1 + s_2 + \cdots + s_k \geq \binom{k}{2}$$

   holds for $k = 1, 2, \ldots, n$ with equality for $k = n$.
3. Let $s = (s_1, s_2, \ldots, s_n)$ be a nondecreasing sequence of nonnegative integers. The following statements are equivalent:
   (a) There is a tournament with score sequence s.
   (b) (*Majorization condition*) $(s_n, s_{n-1}, \ldots, s_1) \preceq (n-1, n-2, \ldots, 1, 0)$.
   (c) The inequality

$$\sum_{i \in W} s_i \geq \frac{1}{2} \sum_{i \in W} (i-1) + \frac{1}{2}\binom{|W|}{2}$$

   holds for each nonempty subset W of $\{1, 2, \ldots, n\}$ with equality for $W = \{1, 2, \ldots, n\}$.
4. Let $s = (s_1, s_2, \ldots, s_n)$ be a nondecreasing sequence of nonnegative integers. The following statements are equivalent:
   (a) There is an irreducible tournament with score sequence s.
   (b) There exists a tournament with score sequence s, and every such tournament is irreducible.
   (c) The strict inequality

$$s_1 + s_2 + \cdots + s_k > \binom{k}{2}$$

   holds for $k = 1, 2, \ldots, n-1$ and $s_1 + s_2 + \cdots + s_n = \binom{n}{2}$.
   (d) $(s_n, s_{n-1}, \ldots, s_1) \preceq (n-2, n-2, n-3, \ldots, 3, 2, 1, 1)$.
5. If $(s_1, s_2, \ldots, s_n)$ is a nondecreasing score sequence, then

$$\frac{i-1}{2} \leq s_i \leq \frac{n+i-2}{2} \qquad (i = 1, 2, \ldots, n).$$

6. Every tournament matrix is a generalized tournament matrix.

7. Let $\mathbf{s} = [s_1, s_2, \ldots, s_n]^T$ be a vector of nonnegative real numbers satisfying $s_1 \leq s_2 \leq \cdots \leq s_n$. There is a generalized tournament matrix with score vector $\mathbf{s}$ if and only if the conditions in Landau's theorem (Fact 2) hold.
8. Every generalized tournament matrix of order n is a convex combination of tournament matrices of order n.
9. Performing a Δ-interchange on a tournament does not change the score sequence. If two tournaments have the same score sequence, then there is a sequence of Δ-interchanges that transforms one to the other.
10. A Δ-interchange replaces either one of the principal submatrices

$$\begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix} \qquad \text{and} \qquad \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}$$

of a tournament matrix by the other.

11. The sequence $(s_1, s_2, \ldots, s_n)$ is realizable $(n \geq 2)$ if and only if the sequence obtained by deleting the largest score $s_{\max}$ and decreasing the $n - 1 - s_{\max}$ next largest scores by 1 is realizable.
12. Ryser's algorithm produces a tournament with a prescribed nondecreasing realizable score sequence. The tie-breaking convention guarantees that the updated score sequence is nondecreasing.

Ryser's algorithm:
Input: A nondecreasing score sequence $(s_1, s_2, \ldots, s_n)$.
Output: The arcs in a tournament with vertex set $\{1, 2, \ldots, n\}$ and given score sequence.

1. If $n = 1$, stop.
2. Define arcs incident with vertex n.
   Let $N^+(n)$ be the set of vertices in $\{1, 2, \ldots, n-1\}$ with the s_n smallest scores, favoring the vertices with higher labels in case of ties. Insert arc (n, j) for each j in $N^+(n)$ and arc (j, n) for each j in $\{1, 2, \ldots, n-1\} - N^+(n)$.
3. Update the score sequence.
   Decrease s_j by 1 if (j, n) is an arc. Delete the score s_n. Replace n by $n - 1$.
4. Return to step 1.

13. [AH98] [GGT98] If $s = (s_1, s_2, \ldots, s_n)$ is a realizable score sequence, then there is a tournament in $\mathcal{T}(s)$ with a transitive $(\lceil n/2 \rceil, \lfloor n/2 \rfloor)$-partition. If s is nondecreasing, then there is a tournament in $\mathcal{T}(s)$ in which $V_1 = \{1, 3, 5, \ldots\}$ and $V_2 = \{2, 4, 6, \ldots\}$ each induce transitive subtournaments.
14. [BCJ10] Let τ denote the maximum order of a transitive subtournament among all tournaments in $\mathcal{T}(s)$. If $n = n_1 + n_2 + \cdots + n_k$ is a partition of n with largest part at most τ, then there is a tournament in $\mathcal{T}(s)$ with a transitive $(n_1, n_2, \ldots, n_k)$-partition.

Examples:

1. The sequence $(0, 1)$ is certainly realizable. Fact 11 implies that each of the following sequences is realizable: $(0, 1)$; $(1, 1, 1)$; $(1, 1, 2, 2)$; $(1, 2, 2, 2, 3)$; $(1, 2, 2, 2, 4, 4)$.
2. When we apply Ryser's algorithm to the score sequence $(1, 2, 2, 2, 4, 4)$, we construct the tournament Γ_1 in Figure 45.1. The first pass through step 2 defines the set of vertices $N^+(6) = \{1, 2, 3, 4\}$ dominated by vertex 6; the updated sequence is $(1, 2, 2, 2, 3)$. The second pass through step 2 defines the vertex set $N^+(5) = \{1, 3, 4\}$ according to the tie-breaking convention.
3. Because the score sequence $s = (1, 2, 2, 2, 4, 4)$ satisfies the strict inequalities of Fact 4(c), all tournaments in the class $\mathcal{T}(s)$ are irreducible.

4. An instance of a generalized tournament matrix written as a convex combination of tournament matrices (Fact 8) is

$$\begin{bmatrix} 0 & 0.5 & 0 & 0 \\ 0.5 & 0 & 0.8 & 0 \\ 1 & 0.2 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{bmatrix} = 0.2 \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{bmatrix} + 0.3 \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{bmatrix} + 0.5 \begin{bmatrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 0 \\ 1 & 0 & 0 & 1 \\ 1 & 1 & 0 & 0 \end{bmatrix}.$$

5. The tournaments Γ_1 and Γ_2 in Figure 45.1 have score sequence $s = (1, 2, 2, 2, 4, 4)$.
   (a) Start with Γ_1 and reverse the following 3-cycles in turn to produce Γ_2. $1 \to 3 \to 4 \to 1$; $2 \to 5 \to 4 \to 2$; $4 \to 5 \to 6 \to 4$.
   (b) In the tournament Γ_1 the subtournaments induced by the vertex sets $\{1, 3, 5\}$ and $\{2, 4, 6\}$ are both transitive in accordance with Fact 13.
   (c) It is easy to verify that among all tournaments with score sequence s the maximum order of a transitive subtournament is 5. The tournament Γ_2 has a transitive $(5, 1)$-partition with vertex sets $V_1 = \{1, 2, 3, 5, 6\}$ and $V_2 = \{4\}$ in accordance with Fact 14.

45.3 Regular and Doubly Regular Tournaments

Definitions:

Let Γ be a tournament with vertex set $\{1, 2, \ldots, n\}$.

Then Γ is **regular** provided all scores are equal; in this case, the tournament matrix of Γ is also called **regular**.

A non-regular tournament is **almost regular** provided any two scores differ by at most 1; in this case, the tournament matrix of Γ is also called **almost regular**.

The number of players defeated by both of the distinct players i and j in Γ is the **joint score** of i and j.

A tournament is **doubly regular** provided the joint scores of all pairs of distinct players are equal.

Let $\{f_1, f_2, \ldots, f_q\}$ be the elements of a field $\mathbb{F}_q$ with q elements, where $q \equiv 3 \pmod 4$. The **quadratic residue tournament** or **Paley tournament** $QR(q)$ has vertex set $\{1, 2, \ldots, q\}$ and arc (i, j) occurs provided $f_j - f_i$ is a quadratic residue (nonzero square) in $\mathbb{F}_q$.

Facts:

Facts without references appear in [RB78] or Chapters 2 and 5 of [Bru06], or are clear from the definitions.

1. In a regular tournament on n vertices, n must be odd; all scores equal $(n-1)/2$.
2. In an almost regular tournament on n vertices, n must be even; half of the scores equal $n/2$ and half of the scores equal $(n-2)/2$.
3. [Moo68, p. 9] A tournament on n vertices has at most $(n^3 - n)/24$ cyclic triples and at least $n(n-1)(n-3)/8$ transitive subtournaments on three vertices. Equality occurs in either count if and only if the tournament is regular.
4. [Moo68, p. 9] If n is even, then a tournament on n vertices has at most $(n^3 - 4n)/24$ cyclic triples. Equality holds if and only if the tournament is almost regular.
5. [Cae91] A tournament is regular if and only if its adjacency matrix A is normal: $AA^T = A^T A$.
6. Let A be a tournament matrix. The (i, j)-entry of AA^T equals the joint score of players i and j if $i \neq j$ and equals the score of player i if $i = j$.

7. A doubly regular tournament on n vertices is regular with all scores equal to $(n-1)/2$ and all joint scores equal to $(n-3)/4$.
8. Let Γ be a tournament on n vertices with adjacency matrix A. The following statements are equivalent:
   (a) The tournament Γ is doubly regular.
   (b) The tournament matrix A satisfies
   $$AA^T = \left(\frac{n+1}{4}\right) I + \left(\frac{n-3}{4}\right) J.$$
   (c) The $(1,-1)$-matrix
   $$H = \left[\begin{array}{c|ccc} 1 & 1 & \cdots & 1 \\ \hline -1 & & & \\ \vdots & & A - A^T + I & \\ -1 & & & \end{array}\right]$$
   of order $n+1$ satisfies $HH^T = (n+1)I$ and $H + H^T = 2I$ and is thus a skew Hadamard matrix of order $n+1$. (See Chapter 44).
9. The quadratic residue tournament $QR(q)$ is doubly regular.
10. [Rys56] The determinant of a tournament matrix A order n satisfies
   $$|\det(A)| \leq \frac{n-1}{2}\left(\frac{n+1}{4}\right)^{(n-1)/2}$$
   with equality if and only if A is a doubly regular tournament matrix.

Conjectures:

1. (*Kelly's conjecture*) The arc set of a regular tournament on n vertices can be partitioned into $(n-1)/2$ Hamilton cycles.
2. If $n \equiv 3 \pmod 4$, then there exists a doubly regular tournament of order n.

It is easy to show that Kelly's conjecture holds for circulant tournaments when n is prime. However, the general case has remained unsolved since 1968. The strongest result along these lines occurs in [KOT10].

Fact 8 shows that Conjecture 2 implies the well-known conjecture on the existence of Hadamard matrices (See Chapter 44).

Examples:

1. Let $c_1, c_2, \ldots, c_{n-1}$ be a sequence of 0's and 1's with $c_k + c_{n-k} = 1$ for $k = 1, 2, \ldots, n-1$. Note that n must be odd. The circulant matrix
   $$\begin{bmatrix} 0 & c_1 & c_2 & \cdots & c_{n-2} & c_{n-1} \\ c_{n-1} & 0 & c_1 & \cdots & c_{n-3} & c_{n-2} \\ c_{n-2} & c_{n-1} & 0 & \cdots & c_{n-4} & c_{n-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ c_2 & c_3 & c_4 & \cdots & 0 & c_1 \\ c_1 & c_2 & c_3 & \cdots & c_{n-1} & 0 \end{bmatrix}$$
   of order n is a regular tournament matrix.

2. Let L_m denote the tournament matrix of order m with 1's below the diagonal and 0's above and on the diagonal. The **Brualdi-Li** tournament matrix of (even) order n is

$$B_n = \left[\begin{array}{c|c} L_{n/2}^T & L_{n/2} + I \\ \hline L_{n/2} & L_{n/2}^T \end{array}\right].$$

   The Brualdi-Li tournament matrix is almost regular.
3. The quadratic residue tournament $QR(7)$ has the circulant tournament matrix

$$\begin{bmatrix} 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 & 1 \\ 1 & 1 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}.$$

45.4 Singularity, Rank, and Eigenvalues

This section focuses on the linear-algebraic properties of tournament matrices (rank, singularity, eigenvalues, and spectral radius) and the graph-theoretic structure of the corresponding tournaments. Results in this area typically involve inequalities for a parameter of a tournament matrix and information about the tournaments in the extremal cases. Two conjectures posed by Brualdi and Li [BL83] motivated the deepest results along these lines. The first conjecture dealt with the minimum spectral radius among irreducible tournament matrices of order n and was settled by Kirkland in 1996 (Fact 12). The second conjecture dealt with the maximum spectral radius among tournament matrices of even order n and was settled by Drury in 2012 (Fact 13).

Definitions:

Let A be a tournament matrix. By the Perron-Frobenius theorem (Chapter 10) if A is irreducible, then the real number $\rho = \rho(A)$ (the spectral radius of A) is a simple eigenvalue of A, called the **Perron value**; there is a corresponding eigenvector with positive components called a **Perron vector** of A.

Let A be a tournament matrix of order n. The **walk space** of A is the subspace of $\mathbb{R}^n$ spanned by the vectors in the set $\{\mathbf{e}, A\mathbf{e}, A^2\mathbf{e}, \ldots, A^{n-1}\mathbf{e}\}$, where $\mathbf{e}$ is the vector of 1's in $\mathbb{R}^n$.

Facts:

1. [Sha92] A tournament matrix is nonsingular if and only if the all 1's vector is in its column space.
2. [Sha92] A tournament matrix with score vector $[s_1, s_2, \ldots, s_n]^T$ is nonsingular if $s_1^2 + s_2^2 + \cdots + s_n^2 < n^2(n-1)/4$.
3. [CH89] [Kir91] Over a field of characteristic 0 a tournament matrix or generalized tournament matrix of order n has rank n or $n-1$.
4. [Cae91] [Mic95] Over a field of prime characteristic p a tournament matrix A of order n satisfies $\text{rank}(A) \geq (n-1)/2$ with equality if and only if n is odd and $AA^T = O$. Equality implies that p divides $(n-1)/2$. [Cae95] If $n \equiv p \equiv 3 \pmod 4$, then the rank inequality is strict.

5. [BG68] If A is a regular tournament matrix of order n, then $(n-1)/2$ is an eigenvalue of A, and all other eigenvalues have real part equal to $-1/2$.
6. [KS94] The dimension of the walk space of a tournament matrix A is the number of eigenvalues of A with real part greater than $-1/2$.
7. Let λ be an eigenvalue of a tournament matrix of order n.
   (a) [BG68] The real part of λ satisfies
   $$-\frac{1}{2} \leq \mathrm{re}(\lambda) \leq \frac{n-1}{2}.$$
   The equality $\mathrm{re}(\lambda) = (n-1)/2$ holds if and only if $\lambda = (n-1)/2$, which happens if and only if the tournament matrix is regular.
   (b) [BG72] The imaginary part of λ satisfies
   $$\mathrm{im}(\lambda) \leq \frac{1}{2} \cot\left(\frac{\pi}{2n}\right).$$
   [GKS92] There is a tournament matrix of order n with an eigenvalue λ for which equality holds if and only if $n \notin \{2, 4, 8, 16, \ldots\}$.
8. [MP90] Let λ be an eigenvalue of a tournament matrix.
   (a) If $\mathrm{re}(\lambda) \neq -1/2$, then the geometric multiplicity of λ is 1.
   (b) If $\mathrm{re}(\lambda) = -1/2$, then the geometric and algebraic multiplicities of λ are equal.
9. [MP70]. Let λ be an eigenvalue of a tournament matrix of order n and let $\mathbf{z}$ be a corresponding eigenvector. Then
   $$\mathrm{re}(\lambda) + \frac{\mathrm{var}(\mathbf{z})}{2\|\mathbf{z}\|^2} = \frac{n-1}{2},$$
   where $\mathrm{var}(\mathbf{z}) = \sum_{1 \leq i < j \leq n} |z_i - z_j|^2$ is the variance of $\mathbf{z} = [z_1, z_2, \ldots, z_n]^T$.
10. [CGK92] An irreducible tournament matrix of order n has exactly three distinct eigenvalues if and only if A is a doubly regular tournament matrix; the three eigenvalues are $(n-1)/2$ of multiplicity 1 and $(-1 \pm i\sqrt{n})/2$, each of multiplicity $(n-1)/2$.
11. [BG72] Let A be a tournament matrix with nondecreasing score vector $[s_1, s_2, \ldots, s_n]^T$. The spectral radius of A satisfies
    $$\rho \geq \min\{(s_1 s_2 s_3)^{1/3}, (s_1 s_3)^{1/2}\}.$$
12. [Kir96] Among all irreducible tournaments of order n ($n \geq 4$) the minimum spectral radius is achieved uniquely by the tournament obtained by reversing the arcs of the Hamilton path in a transitive tournament on n vertices. [CGK92] If $n \geq 8$, the minimum spectral radius is between 2 and 2.5.
13. [Dru12] The spectral radius of a tournament matrix A of even order n satisfies $\rho(A) \leq \rho(B_n)$ with equality if and only if A is permutation similar to the Brualdi-Li tournament matrix B_n in Example 45.3.2.

Examples:

1. A regular tournament matrix of order n ($n > 1$) must be nonsingular because the all 1's vector is in its column space.
2. An almost regular tournament matrix of order n ($n > 2$) must be nonsingular because the sum of the squares of the scores is $(n/2)(n/2)^2 + (n/2)((n-2)/2)^2 = n(n^2 - 2n + 2)/4$, which is less than $n^2(n-1)/4$.

3. Let $\widehat{A}$ be doubly regular tournament matrix of order $n-2$, and let p be a prime divisor of $(n-1)/4$. Over a field of characteristic p the tournament matrix
$$A = \left[\begin{array}{ccc|c|c} & & & 1 & 0 \\ & \widehat{A} & & \vdots & \vdots \\ & & & 1 & 0 \\ \hline 0 & \cdots & 0 & 0 & 0 \\ \hline 1 & \cdots & 1 & 1 & 0 \end{array}\right]$$
of order n satisfies $AA^T = O$, and thus $\text{rank}(A) = (n-1)/2$ by Fact 4.
4. Among all irreducible tournament matrices of order 7 the smallest spectral radius ($\rho \doteq 1.96702$) is achieved by
$$\begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 1 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 1 \\ 1 & 1 & 1 & 1 & 1 & 0 & 0 \end{bmatrix}.$$
5. Among all tournament matrices of order 8 the largest spectral radius ($\rho \doteq 3.45135$) is achieved by
$$B_8 = \left[\begin{array}{cccc|cccc} 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ \hline 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \end{array}\right].$$
6. The Kendall-Wei method (see Application 1 below) ranks all players in a regular tournament as tied because a Perron vector has all components equal.
7. Consider the tournament matrix
$$A = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 1 & 1 & 1 & 0 \end{bmatrix}$$
with score vector $\mathbf{s} = (1, 2, 2, 2, 4, 4)^T$. The spectral radius is $\rho \doteq 2.11063$, and the Perron vector $\mathbf{w}$ has components
$$w_1 \doteq 0.13218, \qquad w_2 = w_3 = w_4 \doteq 0.11901, \qquad w_5 \doteq 0.23179, \qquad w_6 \doteq 0.27899.$$
Thus, the Kendall-Wei method (see Application 1 below) ranks player 1 higher than players 2, 3, and 4, even though player 1 has the lowest score. Player 1 is rewarded for the win over the top-ranked player.
8. Consider the tournament in which the outcomes of all games in Example 7 are reversed. The tournament matrix is thus A^T. The Kendall-Wei method gives
$$w_1 \doteq 0.27898, \qquad w_2 = w_3 = w_4 \doteq 0.17540, \qquad w_5 \doteq 0.06262, \qquad w_6 \doteq 0.13218.$$

Note that the rankings of the players from A^T are not the reverse of the rankings from A; player 6 ranks better than player 5 in both tournaments, for instance.

Applications:

1. *The Kendall-Wei ranking method*

It is often desirable to rank the players in a round-robin tournament based on the outcomes of the games. The straightforward method of ranking players according to their scores usually produces ties—and also ignores the more subtle information contained in the tournament. Kendall [Ken55] and Wei [Wei52] proposed ranking the players according to the components of a Perron vector. We explain why this method is reasonable and give some examples.

We want to rank the players in a tournament Γ with irreducible tournament matrix A of order n and score vector $\mathbf{s} = [s_1, s_2, \ldots, s_n]^T$. Let $\mathbf{e}$ be the vector of 1's in $\mathbb{R}^n$. Note that $A\mathbf{e} = \mathbf{s}$, and the score s_i counts the number of walks of length 1 starting at vertex i in Γ. Ranking the players according to their scores gives a first measure of their relative strengths. The i-th component of the vector $A^m\mathbf{e}$ counts the number of walks of length m starting at vertex i for $m = 1, 2, \ldots,$ and ranking the players according to the components of $A^m\mathbf{e}$ gives a more refined measure of the relative strengths of the players. Let us work with the matrix $(1/\rho)A$ to guarantee convergence of our vectors. The matrix $(1/\rho)A$ has 1 as a simple eigenvalue; all other eigenvalues have modulus strictly less than 1 if we assume that $n \geq 4$ so that A is primitive. (See Fact 45.1.14.) The components of the limit vector

$$\lim_{m\to\infty} ((1/\rho)A)^m \mathbf{e}$$

measure the relative strengths of the players. It is not difficult to show that the limit is a Perron vector of A. For definiteness we use the Perron vector $\mathbf{w} = [w_1, w_2, \ldots, w_n]^T$ whose components sum to 1.

The Kendall-Wei method is a precursor to the modern techniques that rate web pages using eigenvectors of matrices associated with directed graphs whose arcs represent web links.

This chapter represents an overview of research related to a notion of the "*rank of a graph*" and the dual concept known as the "*nullity of a graph*," from the point of view of associating a fixed collection of symmetric or Hermitian matrices to a given graph. This topic and related questions have enjoyed a fairly large history within discrete mathematics, and have become very popular among linear algebraists recently, partly based on its connection to certain inverse eigenvalue problems, but also because of the many interesting applications (e.g., to communication complexity in computer science and to control of quantum systems in mathematical physics) and implications to several facets of graph theory.

This chapter is divided into eight parts, beginning in Section 46.1 with what we feel is the standard minimum rank problem concerning symmetric matrices over the real numbers associated with a simple graph. We continue with important variants of the standard minimum rank problem and related parameters, including the concept of minimum rank over other fields (Section 46.2), the positive semidefinite minimum rank of a graph (Section 46.3), graph coloring parameters known as *zero forcing numbers* (Section 46.4) and the more classical and celebrated parameters due to Y. Colin de Verdière (Section 46.5). Section 46.6 contains more advanced topics relevant to the previous five sections, and Section 46.7 discusses two well-known conjectures related to minimum rank. Whereas the first seven sections concern primarily symmetric matrices and the diagonal of the matrix is free, in Section 46.8 we discuss minimum rank problems with no symmetry assumption but the diagonal constrained.

NB: The topics discussed in this chapter are in an active research area and the facts presented here represent the state of knowledge as of the writing of this chapter in 2012.

46.1 Standard Minimum Rank of Graphs

For a given simple graph G, we associate, in a natural way, a collection of matrices whose entries reflect adjacency in G. We are interested in quantities such as the smallest possible rank and the largest possible nullity over all matrices in this collection. Of particular interest are the resulting connections between these extremal quantities and certain combinatorial properties of graphs, which partly motivates the fascination of this topic among many researchers in combinatorial matrix theory. All graphs in this section are simple.

Definitions:

Definitions of common graph theory terms not given here can be found in Section 39.1.

Notation: Let G be a simple graph with vertices $\{1, \dots, n\}$ and let $\mathcal{S}_n$ be the set of symmetric $n \times n$ real matrices.

For $B \in \mathcal{S}_n$, the **graph** of B, denoted $G(B)$, is the simple graph with vertices $\{1, \dots, n\}$ and edges $\{\{i, j\} : b_{ij} \neq 0 \text{ and } i \neq j\}$.

Let $\mathcal{S}(G) = \{B \in \mathcal{S}_n : G(B) = G\}$ be the **set of symmetric matrices associated with** G.

The **minimum rank** of G is $\mathrm{mr}(G) = \min\{\mathrm{rank}\, B : B \in \mathcal{S}(G)\}$.

The **maximum nullity** of G is $\mathrm{M}(G) = \max\{\mathrm{null}\, B : B \in \mathcal{S}(G)\}$.

The **maximum multiplicity** of G is $\max\{\alpha_B(\lambda) \mid B \in \mathcal{S}(G), \lambda \in \sigma(B))\}$.

The **path cover number** of G, $\mathrm{P}(G)$, is the minimum number of vertex disjoint paths occurring as induced subgraphs of G that cover all the vertices of G.

The **rank-spread** of G at vertex v is $r_v(G) = \mathrm{mr}(G) - \mathrm{mr}(G - v)$.

The **order** of G, denoted by $|G|$, is the cardinality of the vertex set of G.

For $W \subseteq \{1, \dots, n\}$, the subgraph of G induced by W is denoted $G[W]$.

A vertex v of a connected simple graph G is a **cut-vertex** if $G - v$ is disconnected.

The **girth** of G, denoted $\mathrm{g}(G)$, is the length of the shortest cycle in G (if G has a cycle); the girth of an acyclic graph is infinite.

An induced subgraph $G[W]$ of a graph G is a **clique** if $G[W]$ has an edge between every pair of vertices in W (i.e., $G[W]$ is isomorphic to $K_{|W|}$).

A set of subgraphs of G, each of which is a clique and such that every edge of G is contained in at least one of these cliques, is called a **clique covering** of G.

The **clique covering number** of G, denoted by $\mathrm{cc}(G)$, is the smallest number of cliques in a clique covering of G.

A graph is **planar** if it can be drawn in the plane without crossing edges.

A graph G is **outerplanar** it there exists a planar embedding of G in which all of the vertices of G lie in the boundary of a single face.

The **minimum degree** $\delta(G)$ of G is the minimum of the degrees of the vertices of G.

The **vertex connectivity** $\kappa(G)$ of G is the smallest number k such that there is a set of vertices S, with $|S| = k$, for which $G - S$ is disconnected, provided G is not complete. By convention, $\kappa(K_n) = n - 1$.

If $\kappa(G) \geq k$, then G is k**-connected**.

A k**-tree** is constructed inductively by starting with a complete graph on $k + 1$ vertices and connecting each new vertex to the vertices of an existing clique on k vertices.

A **partial** k**-tree** is a subgraph of a k-tree.

The **tree-width** $\mathrm{tw}(G)$ of G is the minimum k such that G is a partial k-tree.

The **Cartesian product** of graphs $G = (V, E)$ and $G' = (V', E')$, denoted by $G \times G'$ is the graph with vertex set $V \times V'$, where two distinct vertices (v, v') and (u, u') are adjacent if and only if (1) $v = u$ and $v'u' \in E(G')$, or (2) $v' = u'$ and $vu \in E(G)$.

The kth **hypercube** Q_k is defined recursively by $Q_1 = K_2, Q_{k+1} = Q_k \times K_2$.

The **dual** G^d of a plane embedding of a planar graph G is obtained as follows: Place a new vertex in each face of the embedding; these are the vertices of the dual. Two dual vertices are adjacent if and only if the two faces of G share an edge of G.

A **polygonal path** is a 2-connected graph G that can be embedded in the plane such that the graph obtained from the dual of G after deleting the vertex corresponding to the infinite face is a path. A polygonal path has been called an **LSEAC** graph, a **2-connected partial linear 2-tree**, or a linear 2-tree by some authors (the last of these terms is unfortunate, since a polygonal path need not be a 2-tree).

The graph H_n obtained from C_n by appending a leaf to each vertex on C_n is called an n-**sun**.

The **trimmed form** of G is the induced subgraph obtained by a sequence of trimming operations, namely deleting peripheral leaves, isolated paths and/or appropriate vertices until no further operations are possible (see [BFH05a] for details).

Let $e = \{u, v\}$ be an edge of G. Then G_e is the graph obtained from G by inserting a new vertex w into G, inserting the edges $\{u, w\}$ and $\{w, v\}$ and deleting e from G. We say that the edge e has been **subdivided** and call G_e an **edge subdivision of** G.

The **complete edge subdivision graph** of G, denoted $\overset{\circ}{\overline{G}}$ is obtained from G by subdividing each edge of G once.

The **union** of (simple) graphs $G_i = (V_i, E_i)$ is $\cup_{i=1}^h G_i = (\cup_{i=1}^h V_i, \cup_{i=1}^h E_i)$ (the vertex sets V_i are not required to be disjoint). In most of this chapter graphs are simple, so these are set unions, not multiset unions; multiple copies of the same edge are replaced by a single copy of the edge.

If G_1 and G_2 are disjoint graphs, the **join** of G_1 and G_2, denoted by $G_1 \vee G_2$, is the graph defined by $V(G_1 \vee G_2) = V(G_1) \cup V(G_2)$ and $E(G_1 \vee G_2) = E(G_1) \cup E(G_2) \cup E$, where E consists of all the edges $\{u, v\}$ with $u \in V(G_1)$, $v \in V(G_2)$.

Graph G is **decomposable** or a **co-graph** if it can be expressed as a sequence of joins or unions of isolated vertices.

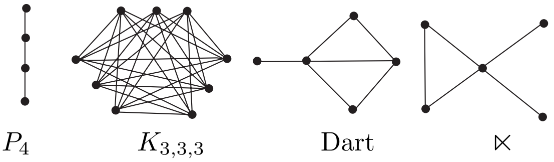
A **Hamiltonian path** of G is a subgraph of G that is a path and includes every vertex of G.

Facts:

Facts requiring proof for which no specific reference is given can be found in [FH07].
Additional relevant facts appear in Sections 46.4, 46.5, 46.6, and 46.7.
Notation: G is a simple graph with vertices $\{1, \ldots, n\}$.

1. For any graph G, $\mathrm{M}(G) + \mathrm{mr}(G) = |G|$.
2. For any graph G, $\mathrm{M}(G)$ is equal to maximum multiplicity of G.
3. For any graph G, $0 \leq \mathrm{mr}(G) \leq |G| - 1$, and if G contains at least one edge, then $1 \leq \mathrm{mr}(G) \leq |G| - 1$.
4. If the connected components of G are $G_1, \ldots, G_t$, then
$$\mathrm{mr}(G) = \sum_{i=1}^{t} \mathrm{mr}(G_i) \qquad \text{and} \qquad \mathrm{M}(G) = \sum_{i=1}^{t} \mathrm{M}(G_i).$$
5. [AIM08], [HCY10a], [FP07], [ADH10] Minimum rank has been computed for many families of graphs (including many Cartesian products and complements) that are listed in an online catalog [AIM].
6. [DGH10] Minimum rank has been computed for all graphs of order at most 7.
7. [BDG] Free open-source *Sage* software is available online that implements many of the techniques listed here and in other sections for computing minimum rank.
8. If $G[W]$ is an induced subgraph of G, then $\mathrm{mr}(G[W]) \leq \mathrm{mr}(G)$.
9. For a connected graph G, $\mathrm{diam}(G) \leq \mathrm{mr}(G)$.
10. [BFS08] The trees and unicyclic graphs for which $\mathrm{diam}(G) = \mathrm{mr}(G)$ have been characterized.
11. For a graph G that contains a cycle, $\mathrm{g}(G) - 2 \leq \mathrm{mr}(G)$.
12. If $G = \cup_{i=1}^h G_i$ then $\mathrm{mr}(G) \leq \sum_{i=1}^h \mathrm{mr}(G_i)$.
13. If G is a graph, $\mathrm{mr}(G) \leq \mathrm{cc}(G)$.
14. [JL99] For any tree T, $M(T) = \mathrm{P}(T) = |T| - \mathrm{mr}(T)$. There are algorithms for computing these parameters for trees [FH07].
15. [Nyl96] For any vertex v of G, $0 \leq \mathrm{mr}(G) - \mathrm{mr}(G - v) \leq 2$. In other words, $r_v(G) \leq 2$.
16. [Nyl96] Adding or removing an edge from a graph G can change the minimum rank by at most 1.

17. [Hsi01], [BFH04] If G has a cut-vertex, the problem of computing the minimum rank of G can be reduced to computing minimum ranks of certain subgraphs. Specifically, let v be a cut-vertex of G. For $i = 1, \dots, h$, let $W_i \subseteq V(G)$ be the vertices of the ith component of $G - v$ and let G_i be the subgraph induced by $\{v\} \cup W_i$. Then
$$r_v(G) = \min\left\{\sum_{i=1}^{h} r_v(G_i),\ 2\right\}$$
and thus
$$\mathrm{mr}(G) = \min\left\{\sum_{i=1}^{h} \mathrm{mr}(G_i),\ \sum_{i=1}^{h} \mathrm{mr}(G_i - v) + 2\right\}.$$
Equivalently,
$$\mathrm{M}(G) = \max\left\{\sum_{i=1}^{h} \mathrm{M}(G_i) - h + 1,\ \sum_{i=1}^{h} \mathrm{M}(G_i - v) - 1\right\}.$$
18. If $r_v(G_i) = 0$ for all but at most one of the G_i, then $\mathrm{mr}(G) = \sum_{i=1}^{h} \mathrm{mr}(G_i)$.
19. [Hol08a] A cut-set reduction formula, analogous to the one from Fact 17, has been established for cut-sets of size two. However, in this case the formula involves a minimum over six related graphs and multigraphs.
20. For $n \geq 2$, $\mathrm{mr}(K_n) = 1$, and if G is connected, $\mathrm{mr}(G) = 1$ implies $G = K_{|G|}$.
21. For $n \geq 1$, $\mathrm{mr}(P_n) = n - 1$ and [Fie69] if $\mathrm{mr}(G) = |G| - 1$, then $G = P_{|G|}$.
22. [BHL04] A connected graph G has $\mathrm{mr}(G) \leq 2$ if and only if G does not contain as an induced subgraph any of P_4, $K_{3,3,3}$ (the complete tripartite graph), Dart, or $\ltimes$ (all shown in Figure 46.1).



P_4 $K_{3,3,3}$ Dart $\ltimes$

FIGURE 46.1 Forbidden induced subgraphs for $\mathrm{mr}(G) \leq 2$.

23. [BHL04] A graph G has $\mathrm{mr}(G) \leq 2$ if and only if the complement of G is of the form
$$(K_{s_1} \cup K_{s_2} \cup K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$$
for appropriate nonnegative integers $k, s_1, s_2, p_1, q_1, \dots, p_k, q_k, r$ with $p_i + q_i > 0$ for all $i = 1, \dots, k$.
24. [BF07] A connected graph G has minimum rank 2 if and only if $G = \bigvee_{i=1}^{r} G_i$, $r > 1$, where either
    (a) $G_i = K_{m_i} \cup K_{n_i}$, for suitable $m_i \geqslant 1$, $n_i \geqslant 0$, or
    (b) $G_i = \overline{K}_{m_i}$, for a suitable $m_i \geqslant 3$;
    and option (b) occurs at most twice.
25. [HH06] Let G be a 2-connected graph. Then $\mathrm{mr}(G) = |G| - 2$ if and only if G is a polygonal path.
26. [JLS09] All graphs G that satisfy $\mathrm{mr}(G) = |G| - 2$ (or, equivalently $\mathrm{M}(G) = 2$) have been characterized, including those from Fact 25 along with a list of additional 1-connected graphs.
27. [BF07] (Complete multipartite graph) Let $n_1 \geq n_2 \geq \cdots \geq n_k \geq 0$, $n_1 > 1$, and $K_{n_1,n_2,\dots,n_k} := \overline{K}_{n_1} \vee \overline{K}_{n_2} \vee \cdots \vee \overline{K}_{n_k}$. Then

$$\mathrm{mr}(K_{n_1,n_2,\ldots,n_k}) = \begin{cases} 0 & \text{if } k = 1; \\ 2 & \text{if } k > 1, n_3 < 3; \\ 3 & \text{if } n_3 \geq 3. \end{cases}$$

28. [Sin10] For any outerplanar graph G, $\mathrm{M}(G) \leq \mathrm{P}(G)$.
29. [BFH05a] Let G be a unicyclic graph. Then
$$\mathrm{mr}(G) = \begin{cases} |G| - \mathrm{P}(G) + 1 & \text{if the trimmed form of } G \text{ is an } n\text{-sun, } n > 3, \text{ odd} \\ |G| - \mathrm{P}(G) & \text{otherwise.} \end{cases}$$
30. [BF07] The minimum rank of a decomposable graph can be computed recursively from its pieces as identified by the sequence of joins or unions of isolated vertices. Such a recursive formula exists for computing the minimum rank for the join of more general graphs in certain circumstances. See also Section 46.6.
31. [BBC09], [JLS09] If e is an edge of G, then $\mathrm{mr}(G) \leq \mathrm{mr}(G_e) \leq \mathrm{mr}(G) + 1$, or, equivalently, $\mathrm{M}(G) \leq \mathrm{M}(G_e) \leq \mathrm{M}(G) + 1$. If e is incident with a vertex of degree at most 2, then $\mathrm{mr}(G_e) = \mathrm{mr}(G) + 1$.
32. [BBC] For any graph G, $\mathrm{M}(\overset{\circ}{\overline{G}}) = \mathrm{Z}(\overset{\circ}{\overline{G}})$ and the value is determined. The first study of $\mathrm{mr}(\overset{\circ}{\overline{G}})$ was in [BBC09] where the equality of maximum nullity and zero forcing number and $\mathrm{mr}(\overset{\circ}{\overline{G}}) = 2|G| - 2$ were established for any graph with a Hamiltonian path; these results were extended to any graph with no cut-edge in [CCH12].

Examples:

Additional relevant examples appear in Sections 46.4, 46.5, 46.6, and 46.7.

1. For the matrix
$$B = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1 & 3.1 & -1.5 & 2 \\ 0 & -1.5 & 1 & 1 \\ 0 & 2 & 1 & 0 \end{bmatrix},$$
$G(B)$ is shown in Figure 46.2

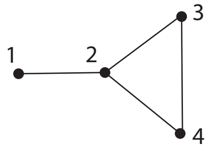


FIGURE 46.2 The graph $G = G(B)$ for matrix B in Example 1.

2. Let G be the graph in Figure 46.2 and let
$$A = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 2 & 1 & 1 \\ 0 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 \end{bmatrix}.$$
Since $G \neq K_4$, $\mathrm{mr}(G) \geq 2$. Since $G(A) = G$ and the matrix A above has rank 2, $\mathrm{mr}(G) = 2$, and hence $\mathrm{M}(G) = 2$.
3. For the cycle C_n on n vertices, $\mathrm{mr}(C_n) = n-2$. Since C_n is not P_n, we have $\mathrm{mr}(C_n) \leq n-2$, and since C_n contains P_{n-1} as an induced subgraph it follows that $\mathrm{mr}(C_n) = n-2$. Observe that C_n is an example of a polygonal path.
4. For $p, q \geq 1$ and $p + q \geq 3$, $\mathrm{mr}(K_{p,q}) = 2$.
5. For P_n with $n \geq 2$, the rank spreads of the two pendant vertices are one, whereas the rank spreads of all remaining vertices are two.

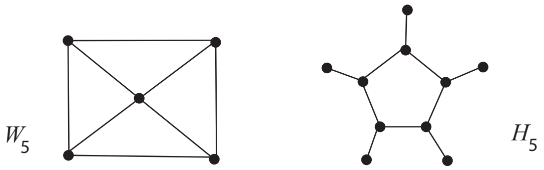

FIGURE 46.3 (a) The wheel W_5 and (b) the penta-sun H_5.

6. (Non-comparability of M(G) and P(G) for graphs in general) The wheel on 5 vertices W_5, shown in Figure 46.3(a), has $\mathrm{P}(W_5) = 2$ by inspection, and $\mathrm{mr}(W_5) = 2$ (by Fact 22), so $\mathrm{M}(W_5) = 3 > \mathrm{P}(W_5)$. The penta-sun, H_5, which is shown in Figure 46.3(b), has $\mathrm{P}(H_5) = 3$ by inspection. By repeated application of Fact 17, or Fact 29, we have $\mathrm{mr}(H_5) = 8$ and thus that $\mathrm{P}(H_5) > \mathrm{M}(H_5) = 2$.
7. This example illustrates the use of various facts for computing $\mathrm{mr}(G)$ when applicable. The graph G shown in Figure 46.4(a) has cut-vertex 4 and the induced subgraphs $G_1 = G[\{1,2,3,4\}]$ and $G_2 = G[\{4,5,6,7,8,9,10,11,12\}]$ associated with the two components (following the notation in Fact 17). By Facts 22 (or 23), and 21, $\mathrm{mr}(G_1) = 2 = \mathrm{mr}(G_1 - 4)$, so $r_4(G_1) = 0$. Thus by Fact 18, we know that $\mathrm{mr}(G) = \mathrm{mr}(G_1) + \mathrm{mr}(G_2)$. For G_2, using Fact 12 and observing that G_2 is the union of two copies of K_3 and one C_5, we have $\mathrm{mr}(G_2) \leq 1 + 1 + 3 = 5$. Further, since G_2 is outerplanar, we know that $\mathrm{mr}(G_2) \geq |G_2| - \mathrm{P}(G_2) = 5$. Thus, $\mathrm{mr}(G_2) = 5$, and $\mathrm{mr}(G) = 7$.

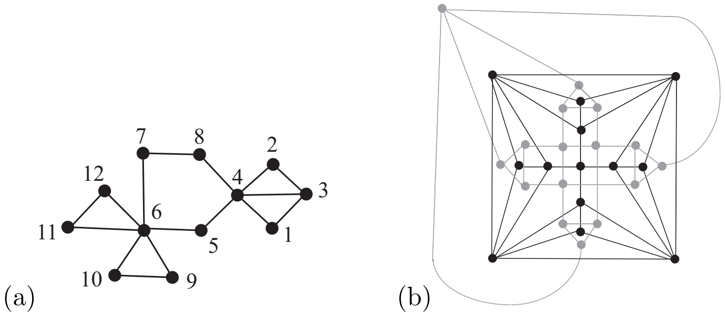

FIGURE 46.4 (a) A graph to which various facts are applied to compute minimum rank, and (b) a planar graph and its dual that have different maximum nullity.

8. [ADH10] A graph G is shown in Figure 46.4(b), with its dual G^d shown in gray. This graph G is a 3-connected planar graph and the maximum nullity of its dual graph G^d is different from the maximum nullity of G (such examples seem to be rare among small graphs). Specifically, $\mathrm{M}(G) = 7$ and $\mathrm{M}(G^d) = 5$.

46.2 Minimum Rank over Other Fields

In this section we survey the minimum rank of symmetric matrices described by a given simple graph G over an arbitrary field F. The two distinctions that become immediately apparent as sources of variation in minimum rank over arbitrary fields are the field characteristic (characteristic 2 versus everything else) and field cardinality (especially finite versus infinite). All graphs in this section are simple.

Definitions:

Notation: Let G be a simple graph with vertices $\{1, \ldots, n\}$ and let F be a field.

Let $\mathcal{S}_n(F)$ be the set of symmetric $n \times n$ matrices over F. In this section, $\mathcal{S}_n$ will be denoted by $\mathcal{S}_n(\mathbb{R})$.

For $B \in \mathcal{S}_n(F)$, the **graph** of B, denoted $G(B)$, is the graph with vertices $\{1, \ldots, n\}$ and edges $\{\{i,j\} | \ b_{ij} \neq 0 \text{ and } i \neq j\}$.

Let $\mathcal{S}^F(G) = \{B \in \mathcal{S}_n(F) : G(B) = G\}$ be the **set of symmetric matrices over F associated with G**.

The **minimum rank of G over F** is $\mathrm{mr}^F(G) = \min\{\mathrm{rank}\, B \,|\, B \in \mathcal{S}^F(G)\}$. In this section, $\mathrm{mr}(G)$ will be denoted by $\mathrm{mr}^{\mathbb{R}}(G)$.

The **maximum nullity of G over F** is $\mathrm{M}^F(G) = \max\{\mathrm{null}\, B : B \in \mathcal{S}^F(G)\}$. In this section, $\mathrm{M}(G)$ will be denoted by $\mathrm{M}^{\mathbb{R}}(G)$.

A graph G is **field independent** if $\mathrm{mr}^F(G) = \mathrm{mr}(G)$ for all fields F.

The **rank-spread of G over field F** at vertex v is defined as $r_v^F(G) = \mathrm{mr}^F(G) - \mathrm{mr}^F(G - v)$.

A **universally optimal matrix** is a symmetric integer matrix A such that every off-diagonal entry of A is 0, 1, or -1 and for all fields F, $\mathrm{rank}^F(A) = \mathrm{mr}^F(G(A))$.

Facts:

Facts requiring proof (beyond that given over the real numbers) for which no specific reference is given can be found in [FH07].

Notation: G is a simple graph with vertices $\{1, \ldots, n\}$ and F is a field.

1. $\mathrm{M}^F(G) + \mathrm{mr}^F(G) = |G|$.
2. If F is a subfield of the field K, then $\mathrm{mr}^F(G) \geq \mathrm{mr}^K(G)$ and $\mathrm{M}^F(G) \leq \mathrm{M}^K(G)$. Fact 23 below, which is illustrated by the graph in Example 2 below, shows these inequalities can be strict. (See also Fact 3 next, where strict inqualities may occur for the case of infinite fields.)
3. [BFH08] Examples are known of graphs G_1 and G_2 such that $\mathrm{mr}^{\mathbb{R}}(G_1) > \mathrm{mr}^{\mathbb{C}}(G_1)$ and $\mathrm{mr}^{\mathbb{Q}}(G_2) > \mathrm{mr}^{\mathbb{R}}(G_2)$. The graph G_2 provides a counterexample to a conjecture in [AHK05].
4. For every G, $0 \leq \mathrm{mr}^F(G) \leq |G| - 1$, and if G contains at least one edge, then $1 \leq \mathrm{mr}^F(G) \leq |G| - 1$.
5. If the connected components of G are $G_1, \ldots, G_t$, then
$$\mathrm{mr}^F(G) = \sum_{i=1}^{t} \mathrm{mr}^F(G_i) \qquad \text{and} \qquad \mathrm{M}^F(G) = \sum_{i=1}^{t} \mathrm{M}^F(G_i).$$
6. [AIM08], [DGH09], [HCY10b] Minimum rank over fields has been computed for many families of graphs (see also Fact 20 below).
7. $\mathrm{mr}^F(G[W]) \leq \mathrm{mr}^F(G)$.
8. For a connected graph G, $\mathrm{diam}(G) \leq \mathrm{mr}^F(G)$.
9. For a graph G that contains a cycle, $\mathrm{g}(G) - 2 \leq \mathrm{mr}^F(G)$.
10. For any vertex v of G, $0 \leq \mathrm{mr}^F(G) - \mathrm{mr}^F(G - v) \leq 2$. In other words, $r_v^F(G) \leq 2$.
11. Adding or removing an edge from a graph G can change minimum rank over F by at most 1.
12. If F is infinite and $G = \cup_{i=1}^{h} G_i$, then $\mathrm{mr}^F(G) \leq \sum_{i=1}^{h} \mathrm{mr}^F(G_i)$.
13. [FH07] If F is infinite, then $\mathrm{mr}^F(G) \leq \mathrm{cc}(G)$. This need not be true for finite fields (see Example 2 below).
14. [CDH07] For any tree T, $\mathrm{M}^F(T) = \mathrm{P}(T) = |T| - \mathrm{mr}^F(T)$.
15. [FH07] Cut-vertex reduction remains valid for every field. With the notation of Fact 46.1.17,
$$r_v^F(G) = \min\left\{\sum_{i=1}^{h} r_v^F(G_i),\ 2\right\}$$

and thus
$$\operatorname{mr}^F(G) = \min\left\{\sum_{i=1}^{h} \operatorname{mr}^F(G_i),\ \sum_{i=1}^{h} \operatorname{mr}^F(G_i - v) + 2\right\}.$$

16. If $r_v^F(G_i) = 0$ for all but at most one of the G_i, then $\operatorname{mr}^F(G) = \sum_{i=1}^{h} \operatorname{mr}^F(G_i)$.
17. [Hol08a] A cut-set reduction formula, analogous to the one from Fact 15, has been established for cut-sets of size two. However, in this case the formula involves a minimum over six related graphs and multigraphs.
18. For $n \geq 2$, $\operatorname{mr}^F(K_n) = 1$, and if G is connected, $\operatorname{mr}^F(G) = 1$ implies $G = K_{|G|}$.
19. For $n \geq 1$, $\operatorname{mr}^F(P_n) = n - 1$, and [Fie69, RS84, BL05, CDH07] if $\operatorname{mr}^F(G) = |G| - 1$, then $G = P_{|G|}$.
20. [DGH09] The following graphs are field independent and have universally optimal matrices:
    - (a) The path, $\operatorname{mr}^F(P_n) = n - 1$.
    - (b) The complete graph, $\operatorname{mr}^F(K_n) = 1$ $(n \geq 2), \operatorname{mr}^F(K_1) = 0$.
    - (c) The cycle, $\operatorname{mr}^F(C_n) = 2$.
    - (d) The complete bipartite graph with at least one of $p, q > 1$, $\operatorname{mr}^F(K_{p,q}) = 2$.
    - (e) Every tree T, $\operatorname{mr}^F(T) = P(T)$.
    - (f) Every polygonal path G, $\operatorname{mr}^F(G) = |G| - 2$.
    - (g) [Pet12], [AIM08] The kth hypercube, Q_k, satisfies $\operatorname{mr}^F(Q_k) = 2^{k-1}$.
    - (h) [BHL04] The graphs Dart and $\ltimes$ shown in Figure 46.1 both have minimum rank 3 over any field.
    - (i) [BBC] The complete subdivision graph $\overline{\mathring{G}}$ for any graph G.
21. [BHL04] Let F be an infinite field of characteristic $\neq 2$. The following statements are equivalent:
    - (a) $\operatorname{mr}^F(G) \leq 2$.
    - (b) $\overline{G}$ is of the form $(K_{s_1} \cup K_{s_2} \cup K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, s_1, s_2, p_1, q_1, \ldots, p_k, q_k, r$ with $p_i + q_i > 0$ for all $i = 1, \ldots, k$.
    - (c) G does not contain as an induced subgraph any of $P_4, \text{Dart}, \ltimes, P_3 \cup K_2, 3K_2,$ or $K_{3,3,3}$ $(P_4, \text{Dart}, \ltimes, K_{3,3,3}$ are shown in Figure 46.1).
22. [BHL04] Let F be an infinite field of characteristic 2. The following statements are equivalent:
    - (a) $\operatorname{mr}^F(G) \leq 2$.
    - (b) $\overline{G}$ is of one of the forms $(K_{s_1} \cup K_{s_2} \cup \cdots \cup K_{s_k}) \vee K_r$ or $(K_{s_1} \cup K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, s_1, s_2, p_1, q_1, \ldots, p_k, q_k, r$ with $p_i + q_i > 0$ for all $i = 1, \ldots, k$.
    - (c) G does not contain as an induced subgraph any of $P_4, \text{Dart}, \ltimes, P_3 \cup K_2, 3K_2,$ or $\overline{P_3 \cup 2K_3}$.
23. [BHL05] Let F be a finite field of prime characteristic $p \neq 2$ having p^t elements. The following statements are equivalent:
    - (a) $\operatorname{mr}^F(G) \leq 2$.
    - (b) $\overline{G}$ is of one of the forms:
      $(K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, p_1, q_1, \ldots, p_k, q_k,$ r, with $p_i + q_i > 0$ for all $i = 1, \ldots, k$ and $k \leq \frac{p^t+1}{2}$;
      or $(K_{s_1} \cup K_{s_2} \cup K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, s_1, s_2, p_1, q_1, \ldots, p_k, q_k, r$ with $p_i + q_i > 0$, for all $i = 1, \ldots, k$ and $k \leq \frac{p^t-1}{2}$.

(c) G does not contain as an induced subgraph any of P_4, Dart, $\ltimes$, $P_3 \cup K_2$, $3K_2$, $K_{3,3,3}$, $\overline{(m+2)K_2 \cup K_1}$, $\overline{K_2 \cup 2K_1 \cup mP_3}$, or $\overline{K_1 \cup (m+1)P_3}$ where $m = \frac{p^t-1}{2}$.

24. [BHL05] Let F be a finite field of characteristic 2 having 2^t elements. The following statements are equivalent:
    (a) $\operatorname{mr}^F(G) \leq 2$.
    (b) $\overline{G}$ is of one of the forms:
    $(K_{s_1} \cup \cdots \cup K_{s_k}) \vee K_r$ for appropriate nonnegative integers $k, s_1, \ldots, s_k, r$, with $k \leq 2^t + 1$;
    or $(K_{s_1} \cup K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, s_1, p_1, q_1, \ldots, p_k, q_k, r$ with $k \leq 2^{t-1}$.
    (c) G does not contain as an induced subgraph any of P_4, Dart, $\ltimes$, $P_3 \cup K_2$, $3K_2$, $\overline{P_3 \cup 2K_3}$, $\overline{(2^{t-1}+1)K_2 \cup (2^{t-1}+1)K_1}$, $\overline{P_3 \cup 2^{t-1}K_2 \cup K_1}$, $\overline{2K_3 \cup 2^tK_1}$, or $\overline{2^{t-1}P_3 \cup 2K_1}$.
25. [JLS09] Over an infinite field F, all simple graphs G that satisfy $\operatorname{mr}^F(G) = |G| - 2$ (or, equivalently $\operatorname{M}^F(G) = 2$) have been characterized.
26. [Sin10][1] For any outerplanar graph G, $\operatorname{M}^F(G) \leq \operatorname{P}(G)$.
27. [BBC09] If e is an edge of G, then $\operatorname{mr}^F(G) \leq \operatorname{mr}^F(G_e) \leq \operatorname{mr}^F(G) + 1$. If e is incident with a vertex of degree at most 2, then $\operatorname{mr}^F(G_e) = \operatorname{mr}^F(G)$.
28. [BBC] For any graph G, $\operatorname{M}^F(\overset{\circ}{\overline{G}}) = \operatorname{Z}(\overset{\circ}{\overline{G}})$, the value is determined, and it is shown that $\overset{\circ}{\overline{G}}$ has a universally optimal matrix. The first study of $\operatorname{mr}^F(\overset{\circ}{\overline{G}})$ was in [BBC09] where the equality of maximum nullity and zero forcing number and $\operatorname{mr}^F(\overset{\circ}{\overline{G}}) = 2|G| - 2$ were established for any graph with a Hamiltonian path; these results were extended to any graph with no cut-edge in [CCH12].
29. A symmetric integer matrix A can be interpreted as a matrix in $\mathbb{Q}$, or as a matrix in $\mathbb{Z}_p$ with p prime by considering entries mod p, and hence as in any field. Some nonzero integers (multiples of p) are interpreted as zero, but 1 and -1 are always nonzero. Thus if every off-diagonal entry of an integer matrix A is $0, 1$, or -1, then $G(A)$ does not depend on the field in which A is interpreted.
30. If $A \in \mathbb{Z}^{n \times n}$, then for every prime p, $\operatorname{rank}^{\mathbb{Z}_p} A \leq \operatorname{rank}^{\mathbb{Q}} A = \operatorname{rank}^{\mathbb{R}} A$.

Examples:

1. The simple graph G shown in Figure 46.2 is field independent and $\operatorname{mr}^F(G) = 2$, as can be seen by considering the (universally optimal) matrix
$$A = \begin{bmatrix} 1 & 1 & 0 & 0 \\ 1 & 2 & 1 & 1 \\ 0 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 \end{bmatrix}.$$
2. For the full house graph H shown in Figure 46.5(a) $\operatorname{mr}^{\mathbb{R}}(H) = 2$, as can be seen by considering the matrix $A = \begin{bmatrix} 1 & 1 & 1 & 0 & 0 \\ 1 & 2 & 2 & 1 & 1 \\ 1 & 2 & 2 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 & 1 \end{bmatrix}$, whereas $\operatorname{mr}^{\mathbb{Z}_2}(H) = 3$ by computation with all possible diagonal elements or by Fact 24.
3. $\operatorname{mr}^{\mathbb{Z}_3}(\overline{3K_2 \cup K_1}) = 3$ by Fact 23 and $\operatorname{mr}^F(\overline{3K_2 \cup K_1}) = 2$ where F is an infinite field of characteristic 3 by Fact 21. $\overline{3K_2 \cup K_1}$ is shown in Figure 46.5(b).

---

[1] The case $F \neq \mathbb{Z}_2$ is Theorem 4.4 in [Sin10]. The case $F = \mathbb{Z}_2$ then follows from Fact 2.

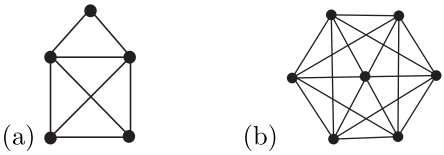

FIGURE 46.5 (a) The full house graph H for Example 2 and (b) $\overline{3K_2 \cup K_1}$ for Example 3.

46.3 Minimum Positive Semidefinite Rank

Orthogonal labelings of the vertices of a simple graph has long been a topic of interest among researchers in graph theory. Such labelings lead to an association between graphs and positive semidefinite matrices via the Gram matrix corresponding to the labeling vectors. In this section we explore this concept further including a list of many recent advances that have sparked additional current interest in this topic. All graphs in this section are simple except where noted otherwise.

Definitions:

Notation: Let G be a simple graph with vertices $\{1, \ldots, n\}$.

$\mathcal{S}_+(G)$ denotes the subset of $\mathcal{S}(G)$ consisting of all real positive semidefinite matrices.

$\mathcal{H}_+(G)$ denotes the subset of positive semidefinite matrices among all complex Hermitian matrices A such that $G(A) = G$.

For any graph G, $\operatorname{mr}_+(G) = \min\{\operatorname{rank} A : A \in \mathcal{S}_+(G)\}$ is called the **(real) minimum positive semidefinite rank of** G.

$\operatorname{mr}_+^{\mathbb{C}}(G) = \min\{\operatorname{rank} A : A \in \mathcal{H}_+(G)\}$ is called the **complex (or Hermitian) minimum positive semidefinite rank of** G; $\operatorname{mr}_+^{\mathbb{C}}(G)$ is also denoted by $\operatorname{msr}(G)$ or $\operatorname{hmr}_+(G)$.

$\operatorname{M}_+(G) = \max\{\operatorname{null} A : A \in \mathcal{S}_+(G)\}$ is called the **maximum positive semidefinite nullity of** G.

$\operatorname{M}_+^{\mathbb{C}}(G) = \max\{\operatorname{null} A : A \in \mathcal{H}_+(G)\}$ is called the **complex (or Hermitian) maximum positive semidefinite nullity of** G.

If G is a graph and each vertex $i \in V$ is assigned the vector $\mathbf{v}_i \in \mathbb{R}^d$ such that $\{i, j\} \notin E$ implies $\mathbf{v}_i^T \mathbf{v}_j = 0$, then $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n\}$ is an **orthogonal representation of** G. If in addition $\mathbf{v}_i^T \mathbf{v}_j = 0$ implies $\{i, j\} \notin E$, then $\{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n\}$ is a **faithful orthogonal representation of** G.

The **tree cover number** of G, $\operatorname{T}(G)$, is the minimum number of vertex disjoint trees occurring as induced subgraphs of G that cover all the vertices of G.

A set of vertices is called **independent** if the subgraph induced on these vertices has no edges.

The **independence number of** G, $\iota(G)$, is the size of the largest independent set of vertices in G. (The standard notation for independence number is $\alpha(G)$ but $\iota(G)$ is used here due to conflict with the use of $\alpha(G)$ to denote the algebraic connectivity of G in Chapter 48.)

A vertex v in a graph G is called **simplicial** if the subgraph induced by the neighbors of v forms a clique.

For a given graph G and a vertex v of G, the multigraph corresponding to the **orthogonal removal of** v, denoted by $G \ominus v$, is obtained from the induced subgraph $G - v$, by adding $e - 1$ edges between any two neighbors of v, say u and w, where e is the sum of the number of edges between u and v and the number of edges between w and v. (Note: The graph $G \ominus v$ may contain multiple edges. See, for example, [Hol03] or [BFM11] for definitions of $\mathcal{S}_+(G)$ and $\operatorname{mr}_+(G)$ for multigraphs.)

Facts:

Facts requiring proof for which no specific reference is given can be found in [FH07]. Additional relevant facts appear in Sections 46.4, 46.5, 46.6, and 46.7.
Notation: Let G be a simple graph with vertices $\{1, \ldots, n\}$.

1. For any graph G, $\text{mr}(G) \leq \text{mr}_+(G)$.
2. For any graph G, $\text{mr}_+(G) + \text{M}_+(G) = |G|$.
3. If the connected components of G are $G_1, \ldots, G_t$, then

$$\text{mr}_+(G) = \sum_{i=1}^{t} \text{mr}_+(G_i) \qquad \text{and} \qquad \text{M}_+(G) = \sum_{i=1}^{t} \text{M}_+(G_i).$$

4. $0 \leq \text{mr}_+(G) \leq |G| - 1$, and if G contains an edge, then $1 \leq \text{mr}_+(G) \leq |G| - 1$.
5. For $n \geq 2$, $\text{mr}_+(K_n) = 1$, and if G is connected, $\text{mr}_+(G) = 1$ implies $G = K_{|G|}$.
6. [Hol03] $\text{mr}_+(G) = |G| - 1$ if and only if G is a tree.
7. If $G[W]$ is an induced subgraph of G, then $\text{mr}_+(G[W]) \leq \text{mr}_+(G)$.
8. For a connected graph G, $\text{diam}(G) \leq \text{mr}_+(G)$
9. The smallest d such that the graph G admits a faithful orthogonal representation with vectors lying in $\mathbb{R}^d$ is equal to $\text{mr}_+(G)$.
10. If $G = \cup_{i=1}^{h} G_i$, then $\text{mr}_+(G) \leq \sum_{i=1}^{h} \text{mr}_+(G_i)$.
11. For any vertex v of G, $0 \leq \text{mr}_+(G) - \text{mr}_+(G - v) \leq \delta(v)$ (where $\delta(v)$ denotes the degree of v).
12. If G is a graph, $\text{mr}_+(G) \leq \text{cc}(G)$.
13. [BHH08] If G is a chordal graph, then $\text{mr}_+(G) = \text{cc}(G)$.
14. [LSS89, LSS00] $\text{mr}_+(G) \leq |G| - \kappa(G)$.
15. [Hol09], [BHH11] Let v be a cut-vertex of G. For $i = 1, \ldots, h$, let $W_i \subseteq V(G)$ be the vertices of the ith component of $G - v$ and let G_i be the subgraph induced by $\{v\} \cup W_i$. Then

$$\text{mr}_+(G) = \sum_{i=1}^{h} \text{mr}_+(G_i).$$

16. [Dea11] For triangle free graphs, $\text{mr}_+(G) \geq \lceil n/2 \rceil$.
17. [BHL04] A graph G has $\text{mr}_+(G) \leq 2$ if and only if the complement of G is of the form $(K_{p_1,q_1} \cup \cdots \cup K_{p_k,q_k}) \vee K_r$ for appropriate nonnegative integers $k, p_1, q_1, \ldots, p_k, q_k, r$ with $p_i + q_i > 0$ for all $i = 1, \ldots, k$.
18. [BBF12], [HHL09] If G and H are two graphs, then

$$\text{mr}_+(G \vee H) = \max\{\text{mr}_+(G \vee K_1), \text{mr}_+(H \vee K_1)\},$$

where K_1 is the complete graph on a single vertex.

19. If G and H do not contain any isolated vertices, then

$$\text{mr}_+(G \vee H) = \max\{\text{mr}_+(G), \text{mr}_+(H)\}.$$

20. For any graph G, $\text{mr}_+(G \vee K_1) = \text{mr}_+(G)$ plus the number of isolated vertices of G.
21. Let G be a decomposable graph with s isolated vertices. Then $\text{mr}_+(G) = \iota(G) - s$.
22. [Hol09] If G_e is obtained from G by an edge subdivision, then $\text{mr}_+(G_e) = \text{mr}_+(G) + 1$. (This fact also follows easily from Fact 27 in this section.)
23. [BFM11][2] If G is outerplanar or a partial 2-tree, then $\text{M}_+(G) = \text{T}(G)$.
24. [SH11] If G is a partial k-tree, then $\text{mr}_+(\overline{G}) \leq k + 2$.
25. [BHH08] For any vertex v of G, $M_+(G) \leq M_+(G \ominus v)$. However, $M_+(G \ominus v) - M_+(G)$ may be arbitrarily large.
26. [BHH08] For any simplicial vertex v of a connected graph G, $M_+(G) = M_+(G \ominus v)$.

---

[2] The proof given in [BFM11] for outerplaner graphs remains valid for partial 2-trees [EEH12].

27. [JMN08] If v is a vertex of degree two in a connected graph G, then $M_+(G) = M_+(G \ominus v)$.
28. [BBF10] For any graph G, $\mathrm{mr}_+^{\mathbb{C}}(G) \leq \mathrm{mr}_+(G)$ and there exist graphs for which $\mathrm{mr}_+^{\mathbb{C}}(G) < \mathrm{mr}_+(G)$.
29. The results in Facts 1 through 27 also hold for $\mathrm{mr}_+^{\mathbb{C}}(G)$ (adapted in the obvious way). For Fact 18, the first reference deals with the case of $\mathrm{mr}_+(G)$ and the second reference deals with the case of $\mathrm{mr}_+^{\mathbb{C}}(G)$. In other cases, the reference gives the result for $\mathrm{mr}_+^{\mathbb{C}}(G)$ and that implies the result for $\mathrm{mr}_+(G)$, or vice versa. Finally, for some facts the proof is clearly valid for both $\mathbb{R}$ and $\mathbb{C}$ (even if it is stated only for one).
30. $\mathrm{mr}_+(G) = \mathrm{mr}_+^{\mathbb{C}}(G) = \mathrm{mr}(G)$ has been computed for the following graphs (when the result is not obvious, the first reference is for minimum positive semidefinite rank and the second for minimum rank, or the single reference does both).

    (a) For $n \geq 1$, $\mathrm{mr}_+(P_n) = n - 1$.

    (b) For $n \geq 3$, $\mathrm{mr}_+(C_n) = n - 2$.

    (c) For $p, q \leq 1$, $\mathrm{mr}_+(K_{p,q}) = \max\{p, q\}$.

    (d) For $n \geq 4$, $\mathrm{mr}_+(W_n) = n - 3$, where $W_n = C_{n-1} \vee K_1$ is the wheel on n vertices.

    (e) [Pet12] $\mathrm{mr}_+(Q_k) = 2^{k-1}$, where Q_k is the kth hypercube.

    (f) [Pet12], [HH06] If G is a polygonal path, then $\mathrm{mr}_+(G) = |G| - 2$.

    (g) [Pet12], [AIM08] $\mathrm{mr}_+(K_s \times P_t) = s(t - 1)$.

    (h) [AIM08] $\mathrm{mr}_+(T_k) = \frac{1}{2}k(k - 1)$, where T_k is the kth supertriangle (see [AIM08] for the definition of supertriangle).

    (i) [Pet12], [DGH09] $\mathrm{mr}_+(\mathrm{Half}_k) = k$, where Half_k is the kth half-graph (see [DGH09] for the definition of half-graph).

    (j) [Pet12], [DGH09] $\mathrm{mr}_+(N_k) = 3k - 2$, where N_k is the kth necklace (see [DGH09] for the definition of necklace).

Examples:

Additional relevant examples appear in Sections 46.4, 46.5, 46.6, and 46.7.

1. If G is the graph from Figure 46.2, then assigning the standard basis vector $\mathbf{e}_1$ from $\mathbb{R}^2$ to vertex 1, $\mathbf{e}_2 \in \mathbb{R}^2$ to vertices 3 and 4, and $\mathbf{e}_1 + \mathbf{e}_2$ to vertex 2, is a faithful orthogonal representation of G. Further, if
$$B = \left[\mathbf{e}_1, \mathbf{e}_1 + \mathbf{e}_2, \mathbf{e}_2, \mathbf{e}_2\ \right],$$
then B is a 2×4 real matrix such that $B^T B$ is a positive semidefinite matrix in $\mathcal{S}(G)$ (in particular, $B^T B = A$ where A is the matrix in Example 2 in Section 46.1).
2. For the graph in Figure 46.4(a), we may compute $\mathrm{mr}_+(G)$ by using Facts 15 and/or 23. As noted in Example 46.1.7, G has cut-vertex 4 and the induced subgraphs $G_1 = G[\{1, 2, 3, 4\}]$ and $G_2 = G[\{4, 5, 6, 7, 8, 9, 10, 11, 12\}]$ associated with the two components. By Facts 12 and 5, $\mathrm{mr}_+(G[\{1, 2, 3, 4\}]) = 2$. Since G_2 is outerplanar, we know that $\mathrm{M}_+(G_2) = \mathrm{T}(G_2)$. Since every cycle contains a tree that is disjoint from the other cycles, it is easy to see that $\mathrm{T}(G_2) = 4$. Thus, $\mathrm{mr}_+(G_2) = 9 - 4 = 5$, and $\mathrm{mr}_+(G) = 2 + 5 = 7$.

46.4 Zero Forcing Parameters

Many of the parameters defined and utilized thus far are algebraic in nature and are therefore potentially dependent on the underlying field over which they are defined. In fact, this is easy to see for the parameter $\mathrm{mr}(\cdot)$ relative to finite fields and fields of characteristic two, but it is also true that minimum rank can differ over the fields $\mathbb{Q}$ or $\mathbb{C}$. Given that minimum rank relies heavily on graphs and their combinatorial properties, it is also appropriate to approach this issue from the point of view of purely combinatorial parameters.

One such avenue is the concept of *zero forcing parameters*. The underlying technique had been used previously, but the introduction of coloring notation at the AIM workshop "Spectra of Families of Matrices described by Graphs, Digraphs, and Sign Patterns" [AIM06] led to much wider use of this technique. Zero forcing is the same as graph infection used by physicists to study control of quantum systems [BG07], [Sev08] (see Application 1 for more information).

To begin with we consider a basic result for bounding the nullity of a given matrix. Suppose the dimension of the null space of a given matrix A is greater than k. Then, we may conclude that for any set of k indices I from $\{1, \ldots, n\}$, there exists a nonzero null vector of A for which all of its coordinates from I are zero. Indeed, if for a given index set I of size k, the only null vector for which the coordinates that correspond to the positions from I are zero is the zero vector, then it follows that the dimension of the null space is at most k. The operation of the color change rule reflects the forcing of zeros in a null vector, starting with zeros in the positions labelled by a zero forcing set, and arguing sequentially that the entries in all other positions must be zero. There is also an analogous zero forcing parameter for minimum positive semidefinite rank (discussed in this section) and other variants (discussed in Section 46.6). All graphs in this section are simple.

Definitions:

Let $G = (V, E)$ be a simple graph.

A subset $Z \subseteq V$ defines an initial set of black[3] vertices (with all vertices not in Z white); this is called a **coloring of** G.

The **color change rule** is to change the color of a white vertex w to black if w is the unique white neighbor of a black vertex u; in this case, we say u **forces** w and write $u \rightarrow w$.

Given a coloring of G, the **derived set** or **final coloring** is the set of black vertices obtained by applying the color change rule until no more changes are possible.

A **zero forcing set** for G is a subset of vertices Z such that if initially the vertices in Z are colored black and the remaining vertices are colored white, the derived set is V.

The **zero forcing number** $\mathrm{Z}(G)$ is the minimum of $|Z|$ over all zero forcing sets $Z \subseteq V$.

For a given zero forcing set, we construct the derived set, listing the forces in the order in which they were performed. This list is a **chronological list of forces**.

A **forcing chain** (for a particular chronological list of forces $\mathcal{F}$) is a sequence of vertices $(v_1, v_2, \ldots, v_s)$ such that for $i = 1, \ldots, k-1$, $v_i \rightarrow v_{i+1}$ in $\mathcal{F}$.

A **maximal forcing chain** is a forcing chain that is not a proper subsequence of another forcing chain.

The **forcing chain cover** (for a chronological list of forces $\mathcal{F}$) is the set of maximal forcing chains.

The **positive semidefinite color change rule** is: Let B be the set consisting of all the black vertices. Let $W_1, \ldots, W_k$ be the sets of vertices of the $k \geq 1$ components of $G - B$. Let $w \in W_i$. If $u \in B$ and w is the only white neighbor of u in $G[W_i \cup B]$, then change the color of w to black; in this case, we say u **forces** w and write $u \rightarrow w$.

A **positive semidefinite zero forcing set** for G is a subset of vertices B such that if initially the vertices in B are colored black and the remaining vertices are colored white, the set of black vertices obtained by applying the color change rule until no more changes are possible is V.

---

[3] In the literature, "black" is the term commonly used to indicate a zero entry in the null vector, but some authors are changing to "blue" to avoid negative social implications. Here we follow the literature as of 2012.

The **positive semidefinite zero forcing number** $\mathrm{Z}_+(G)$ is the minimum of $|X|$ over all positive semidefinite zero forcing sets $X \subseteq V$ (using the positive semidefinite color change rule).

For a given positive semidefinite zero forcing set, we perform forces to color all vertices black, listing the forces in the order in which they were performed. This list is a **chronological list of forces**.

For a vertex x in a positive semidefinite zero forcing set X, and chronological list of forces $\mathcal{F}$ of X, define V_x to be the set of vertices w such that there is a sequence of forces $x = v_1 \to v_2 \to \cdots \to v_k = w$ in $\mathcal{F}$ (the empty sequence of forces is permitted, i.e., $x \in V_x$). The **forcing tree** T_x is the induced subgraph $T_x = G[V_x]$.

The **forcing tree cover** (for a chronological list of forces $\mathcal{F}$) is $\{T_b \,|\, b \in B\}$.

Suppose $S = (v_1, v_2, \ldots, v_m)$ is an ordered subset of vertices from a given graph G. For each k with $1 \leq k \leq m$, let G_k be the subgraph of G induced by $\{v_1, v_2, \ldots, v_k\}$, and let H_k be the connected component of G_k that contains v_k. If for each k, there exists a vertex w_k that satisfies: $w_k \neq v_l$ for $l \leq k$, $\{w_k, v_k\} \in E$, and $\{w_k, v_s\} \notin E$, for all v_s in H_k with $s \neq k$, then S is called an **ordered set of vertices** in G, or an **OS-set**.

The **OS number** of a graph G, denoted by $\mathrm{OS}(G)$, is the maximum of $|S|$ over all OS-sets S of G.

If G is a graph, then H is called a **supergraph** of G, if H is obtained from G by adding some edges.

A graph G is called a **graph on two parallel paths** if V can be partitioned into disjoint nonempty subsets U_1 and U_2 so that the induced subgraphs $P_i = G[U_i], i = 1, 2$ are paths, G can be drawn in the plane with the paths P_1 and P_2 as parallel line segments, and edges between the two paths (drawn as line segments, not curves) do not cross. A single path is not considered a graph on two parallel paths, but a graph consisting of two disjoint paths is a graph on two parallel paths.

A graph G is a **unit interval graph** if there is an ordering on the vertices of G such that for each vertex v, the closed neighborhood of v (i.e., the union of v and its neighbors) is a set of consecutive vertices in that order.

Facts:

Additional relevant facts appear in Sections 46.6 and 46.7.
Notation: Let G be a simple graph.

Facts about $\mathrm{Z}(G)$

1. For any graph G, $1 \leq \mathrm{Z}(G) \leq |G|$, and if G contains at least one edge, $1 \leq \mathrm{Z}(G) \leq |G| - 1$.
2. If the connected components of G are $G_1, \ldots, G_t$, then
$$\mathrm{Z}(G) = \sum_{i=1}^{t} \mathrm{Z}(G_i).$$
3. [AIM08] For any graph G, $\mathrm{M}(G) \leq \mathrm{Z}(G)$. (In fact, $\mathrm{M}^F(G) \leq \mathrm{Z}(G)$.)
4. [BBF10] For any graph G, $\delta(G) \leq \mathrm{Z}(G)$.
5. [BBF10] For any graph G, $\mathrm{P}(G) \leq \mathrm{Z}(G)$. For any chronological list of forces of a zero forcing set, the forcing chain cover is a path cover.
6. [AIM08] For any tree T, $\mathrm{Z}(T) = \mathrm{M}(T)$ $(= \mathrm{P}(T))$.
7. [BDG] Free open-source *Sage* software is available online that computes $\mathrm{Z}(G)$.
8. [BBF10] If G is connected of order greater than one, then G does not have a unique minimum zero forcing set, and no single vertex is a member of every minimum zero forcing set for G.

9. [HCY10a] Let v be a cut-vertex of G. Suppose that $G - v$ is the disjoint union of two graphs induced on the vertices W_1 and W_2. For $i = 1, 2$, let G_i be the subgraph induced by $\{v\} \cup W_i$. Then
$$\mathrm{Z}(G) \leq \min\left\{\mathrm{Z}(G_1) + \mathrm{Z}(G_2 - v), \mathrm{Z}(G_2) + \mathrm{Z}(G_1 - v)\right\}.$$
10. [EHH12] For any vertex v and edge e of G, we have $-1 \leq \mathrm{Z}(G) - \mathrm{Z}(G - v) \leq 1$ and $-1 \leq \mathrm{Z}(G) - \mathrm{Z}(G - e) \leq 1$.
11. [AIM08] For all simple graphs G and H, $\mathrm{Z}(G \times H) \leq \min\{\mathrm{Z}(G)|H|,\ \mathrm{Z}(H)|G|\}$.
12. [AIM08] $\mathrm{Z}(G) \geq |G| - 2$ if and only if G does not contain P_4, $P_3 \cup K_2$, Dart, $\ltimes$, or $3K_2$ as an induced subgraph.
13. $\mathrm{Z}(G) = 1$ if and only if G is a path.
14. [Row12] $\mathrm{Z}(G) = 2$ if and only if G is a graph on two parallel paths.
15. [HCY10a] If G is a connected unit interval graph, then $\mathrm{cc}(G) = \mathrm{mr}(G)$ and $\mathrm{Z}(G) = \mathrm{M}(G)$.
16. For $p, q \geq 1$, $\mathrm{Z}(K_{p,q}) = p + q - 2 = \mathrm{M}(K_{p,q})$.
17. For every graph listed in Fact 46.3.30, $\mathrm{Z}(G) = \mathrm{M}(G)$.

Facts about $\mathrm{Z}_+(G)$ and $\mathrm{OS}(G)$

18. Since any zero forcing set is a positive semidefinite zero forcing set, $\mathrm{Z}_+(G) \leq \mathrm{Z}(G)$.
19. For any graph G, $1 \leq \mathrm{Z}_+(G) \leq |G|$, and if G contains at least one edge, $1 \leq \mathrm{Z}_+(G) \leq |G| - 1$.
20. For any graph G that is the disjoint union of connected components $G_i, i = 1, 2, \ldots, k$, $\mathrm{Z}_+(G) = \sum_{i=1}^{k} \mathrm{Z}_+(G_i)$.
21. [BBF10] For any graph G, $\mathrm{M}_+(G) \leq \mathrm{M}_+^{\mathbb{C}}(G) \leq \mathrm{Z}_+(G)$.
22. [MNZ10], [BBF10] For every graph G, $\delta(G) \leq \mathrm{Z}_+(G)$.
23. [EEH13] For any graph G, $\mathrm{T}(G) \leq \mathrm{Z}_+(G)$. For any chronological list of forces of a positive semidefinite zero forcing set, the forcing tree cover is a tree cover.
24. [EEH12] If G is a partial 2-tree (this includes every outerplanar graph), then $\mathrm{Z}_+(G) = \mathrm{M}_+(G)$ $(= \mathrm{T}(G))$.
25. [BDG] Free open-source *Sage* software is available online that computes $\mathrm{Z}_+(G)$.
26. [HHL09] For any graph G, $\mathrm{OS}(G) \leq \mathrm{mr}_+^{\mathbb{C}}(G) \leq \mathrm{mr}_+(G)$.
27. [Mit11] For any graph G, there exists a chordal supergraph H of G such that $\mathrm{OS}(G) = \mathrm{mr}_+(H) = \mathrm{cc}(H)$.
28. [BBF10] $\mathrm{Z}_+(G) + OS(G) = |G|$. Furthermore, for any ordered set S, $V \setminus S$ is a positive semidefinite forcing set for G, and for any positive semidefinite forcing set X for G, there is an order that makes $V \setminus X$ an ordered set for G.
29. [MNZ10], [EEH13] No connected graph G of order greater than one has a unique minimum positive definite zero forcing set. No single vertex is a member of every minimum positive definite zero forcing set for G. For any vertex v of G, there is a minimum positive definite zero forcing set containing v.
30. [MNZ10], [EEH13] Suppose $G_i, i = 1, \ldots, h$ are simple graphs of order at least two, $h \geq 2$, there is a vertex v such that for all $i \neq j$, $G_i \cap G_j = \{v\}$, and $G = \bigcup_{i=1}^{h} G_i$ (v is a cut-vertex of G). Then
$$\mathrm{OS}(G) = \sum_{i=1}^{h} \mathrm{OS}(G_i),$$
$$\mathrm{Z}_+(G) = \left(\sum_{i=1}^{h} \mathrm{Z}_+(G_i)\right) - h + 1.$$

31. [EEH13] For any vertex v and edge e of G, $\mathrm{Z}_+(G) - \mathrm{Z}_+(G - v) \leq 1$ and $-1 \leq \mathrm{Z}_+(G) - \mathrm{Z}_+(G - e) \leq 1$.
32. [BBF10] For all simple graphs G and H,

$$\mathrm{Z}_+(G \times H) \leq \min\{\mathrm{Z}_+(G)|H|,\ \mathrm{Z}_+(H)|G|\},$$

(where $G \times H$ is the Cartesian product of G and H).

33. [MNZ12], [BBF10] Let G be a graph. Then $\mathrm{mr}^{\mathbb{C}}_{+}(G) = 1, 2, |G| - 2, |G| - 1$ if and only if $\mathrm{Z}_+(G) = |G| - 1, |G| - 2, 2, 1$, respectively.
34. [MNZ12] Let G be a graph. If $\mathrm{OS}(G) = |G| - 3$, then $\mathrm{mr}^{\mathbb{C}}_{+}(G) = |G| - 3$, and if $\mathrm{mr}^{\mathbb{C}}_{+}(G) = 3$, then $\mathrm{OS}(G) = 3$.
35. For $1 \leq p \leq q$, $\mathrm{Z}_+(K_{p,q}) = p = \mathrm{M}_+(K_{p,q})$.
36. For every graph listed in Fact 46.3.30, $\mathrm{Z}_+(G) = \mathrm{M}_+(G) = \mathrm{Z}(G) = \mathrm{M}(G)$ and $\mathrm{OS}(G) = \mathrm{mr}_+(G) = \mathrm{mr}(G)$.

Examples:

1. Either pendant vertex of P_n is a zero forcing set for P_n, and so $\mathrm{Z}(P_n) = 1$. Hence $\mathrm{M}(P_n) = 1$. Moreover, the only graph G with $Z(G) = 1$ is $G = P_n$.
2. For $n \geq 2$, $\mathrm{Z}(K_n) = \mathrm{Z}_+(K_n) = n - 1$. The only connected graph G with $\mathrm{Z}(G) = |G| - 1$ is the complete graph.
3. Let T be a tree. Then $\mathrm{Z}_+(T) = 1$ because any one vertex v is a positive semidefinite zero forcing set. Observe that $\mathrm{M}_+(T) = \mathrm{M}^{\mathbb{C}}_{+}(T) = 1$ is an immediate consequence of $\mathrm{Z}_+(T) = 1$.
4. For $n \geq 3$, any two consecutive vertices of C_n form a zero forcing set, and any two vertices form a positive definite zero forcing set. Thus, $\mathrm{Z}(C_n) = \mathrm{Z}_+(C_n) = 2$.
5. (Petersen graph) Consider the initial coloring given for the Petersen graph in Figure 46.6(a). Observe that the 5 black vertices form a zero forcing set for the Petersen graph, and thus the zero forcing number for the Petersen graph is at most 5. On the other hand, the adjacency matrix $\mathcal{A}$ has an eigenvalue with multiplicity five, and so there exists a translate of $\mathcal{A}$ with nullity 5. Thus, the zero forcing number of the Petersen graph (and the maximum nullity) is 5.

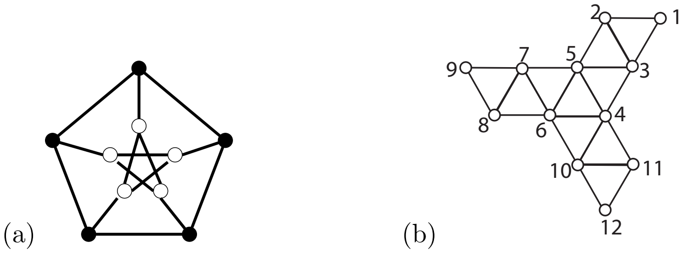

FIGURE 46.6 (a) Initial coloring for the Petersen graph, and (b) the pinwheel on 12 vertices, G_{12}.

6. Let G_{12} be the graph shown in Figure 46.6(b), called the pinwheel on 12 vertices. Note that G_{12} is an outerplanar 2-tree. The set $\{1, 2, 6, 10\}$ is a zero forcing set for G_{12}, so $\mathrm{Z}(G_{12}) \leq 4$. In fact, $\mathrm{Z}(G_{12}) = 4$ [BBF10]. Since $\mathrm{cc}(G_{12}) = 9$, we have $\mathrm{mr}_+(G_{12}) \leq \mathrm{mr}(G_{12}) \leq \mathrm{cc}(G_{12}) = 9$. But since G_{12} is also chordal, equality holds, and hence $\mathrm{M}_+(G_{12}) = \mathrm{M}(G_{12}) = 3$. For an alternate way to determine maximum positive semidefinite nullity, observe that since G_{12} is outerplanar and $\mathrm{T}(G_{12}) = 3$, we deduce that $\mathrm{M}_+(G_{12}) = 3$. Furthermore, G_{12} has $\mathrm{Z}_+(G_{12}) = 3 = \mathrm{M}_+(G_{12})$ because $X = \{4, 5, 6\}$ is a positive semidefinite zero forcing set ($G_{12} - X$ is disconnected, and X is a zero forcing set for $G[\{1, 2, 3, 4, 5, 6\}]$, etc.). Thus, for the pinwheel G_{12} we have $\mathrm{Z}(G_{12}) = 4 > \mathrm{Z}_+(G_{12}) = 3 = \mathrm{M}_+(G_{12}) = \mathrm{M}(G_{12}) = 3$.

7. There are examples of graphs for which Z_+ is not equal to $\mathrm{M}_+^{\mathbb{C}}$. For example, in [MNZ10] it was established that the Möbius ladder on 8 vertices, shown in Figure 46.7 and sometimes denoted by ML_8 or V_8, satisfies $\mathrm{OS}(ML_8) = 4$ and $\mathrm{mr}_+^{\mathbb{C}}(ML_8) = 5$. In this case, it follows that $\mathrm{Z}_+(ML_8) = 4$, and hence $\mathrm{Z}_+(ML_8) > 3 = \mathrm{M}_+^{\mathbb{C}}(ML_8) = \mathrm{M}_+(ML_8)$.

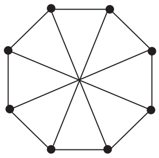

FIGURE 46.7 The graph $ML_8 = V_8$.

Applications:

1. Whether a quantum system is controllable is determined by a Lie algebra associated with the system (see Chapter 87 for definitions and background information on Lie algebras). The Lie algebra rank condition says that a necessary and sufficient condition for complete controllability of a system is that the Lie algebra generated by matrices associated with the set of admissible values for the control is the Lie algebra $u(n)$ of $n \times n$ skew-Hermitian matrices (or the subalgebra of $u(n)$ of matrices having trace 0). In [BDH13] it is shown that if G is a connected graph, $A \in \mathcal{S}_n$, and $Z \subseteq V$ is a zero forcing set of G, then the Lie algebra generated by iA and the matrices $\boldsymbol{i}\mathbf{e}_j\mathbf{e}_j{}^T$ with $j \in Z$ is equal to $u(n)$ and thus the corresponding quantum system is controllable. However, the converse is false, i.e., having the Lie algebra generated by iA and $\{\boldsymbol{i}\mathbf{e}_j\mathbf{e}_j{}^T : j \in Z\}$ being equal to $u(n)$ does not imply that Z is a zero forcing set.

46.5 Colin de Verdière Parameters

Recall that minimum rank is monotone on induced subgraphs (i.e., if $G[W]$ is an induced subgraph of a graph G, then $\mathrm{mr}(G[W]) \le \mathrm{mr}(G)$), and this property can be useful in bounding $\mathrm{mr}(G)$ from below. Unfortunately, maximum nullity is not monotone for induced subgraphs (see Example 1 below). In 1990, Colin de Verdière ([CdV93] in English) introduced the graph parameter μ equal to the maximum nullity among certain generalized Laplacian matrices having a given graph and satisfying the Strong Arnold Hypothesis. The Colin de Verdière number μ was the first of several related parameters that are both minor monotone and bound the maximum nullity from below. In this section we discuss several Colin de Verdière-type parameters and their use for computing the maximum nullity (or equivalently, the minimum rank) of a graph. These parameters are most useful when the graph has a large number of edges (since a matrix with many nonzero entries is more likely to satisfy the Strong Arnold Hypothesis), and least useful for trees, where a convenient method already exists for evaluation of maximum nullity and minimum rank. For bounding maximum nullity, these parameters should be used only for connected graphs (each component should be analyzed separately). Reference [HLS96] provides an excellent introduction to the parameter μ and the Strong Arnold Hypothesis from a linear algebra perspective. All graphs in this section are simple.

Definitions:

Notation: Let G be a simple graph with vertices $\{1, \ldots, n\}$.

A graph parameter ζ is **monotone on induced subgraphs** if for any induced subgraph $G[W]$ of G, $\zeta(G[W]) \le \zeta(G)$.

A **contraction** of an edge in a (simple) graph G is obtained by identifying the two endpoints of the edge (which are adjacent vertices of G) and suppressing any loops or multiple edges that arise in this process.

A **minor** of G arises by performing a series of deletions of edges, deletions of isolated vertices, and/or contraction of edges.

A graph parameter ζ is **minor monotone** if for any minor G' of G, $\zeta(G') \leq \zeta(G)$.

For any graph G, the **Hadwiger number** $\mathrm{h}(G)$ is the maximum size of a clique minor in G.

A real symmetric matrix M satisfies the **Strong Arnold Hypothesis** provided there does not exist a nonzero real symmetric matrix X satisfying:

(i) $MX = \mathbf{0}$,
(ii) $M \circ X = \mathbf{0}$,
(iii) $I \circ X = \mathbf{0}$.

where $\circ$ denotes the Hadamard (entrywise) product and I is the identity matrix.

A matrix $L \in \mathcal{S}(G)$ is a **generalized Laplacian matrix** of G if L is a Z-matrix (i.e., all off-diagonal entries of L are non-positive).

The **Colin de Verdière number** $\mu(G)$ is the maximum nullity among matrices L that satisfy the following:

- L is a generalized Laplacian matrix of G,
- L has exactly one negative eigenvalue (of multiplicity 1),
- L satisfies the Strong Arnold Hypothesis.

The **μ-minimum rank** of G, $\mathrm{mr}_\mu(G)$, is the minimum of the ranks of this set of matrices.

The parameter $\nu(G)$ (also denoted $\nu^{\mathbb{R}}(G)$) is the maximum nullity among matrices A that satisfy the following:

- $A \in \mathcal{S}_+(G)$,
- A satisfies the Strong Arnold Hypothesis.

The **ν-minimum rank** of G, $\mathrm{mr}_\nu(G)$, is the minimum of the ranks of this set of matrices.

The parameter $\xi(G)$ is the maximum nullity among matrices A that satisfy the following:

- $A \in \mathcal{S}(G)$,
- A satisfies the Strong Arnold Hypothesis.

The **ξ-minimum rank** of G, $\mathrm{mr}_\xi(G)$, is the minimum of the ranks of this set of matrices.

Facts:

Additional relevant facts appear in Sections 46.6 and 46.7.
Notation: Let G be a simple graph.

1. $\mathrm{mr}_\mu(G) = |G| - \mu(G)$, $\mathrm{mr}_\nu(G) = |G| - \nu(G)$, and $\mathrm{mr}_\xi(G) = |G| - \xi(G)$.
2. $\mu(G) \leq \xi(G) \leq \mathrm{M}(G)$, $\nu(G) \leq \xi(G)$, and $\nu(G) \leq \mathrm{M}_+(G)$ and these inequalities can be strict (see Example 3 and Facts 10, 11, and 17 below for examples).
3. $\mathrm{mr}_\mu(G) \geq \mathrm{mr}_\xi(G) \geq \mathrm{mr}(G)$, $\mathrm{mr}_\nu(G) \geq \mathrm{mr}_\xi(G)$, and $\mathrm{mr}_\nu(G) \geq \mathrm{mr}_+(G)$ and these inequalities can be strict.
4. A subgraph is a minor. A minor monotone graph parameter is monotone on subgraphs and thus on induced subgraphs.
5. [CdV93], [HLS96] The Strong Arnold Hypothesis is equivalent to the requirement that certain manifolds intersect transversally.
6. [CdV93], [HLS96] The parameter μ is minor monotone.
7. [CdV98] The parameter ν is minor monotone.
8. [BFH05b] The parameter ξ is minor monotone.
9. [LSS89],[LSS00], [Hol08b] $\kappa(G) \leq \nu(G)$.
10. [BFH05b] If G is the disjoint union of components $G_i, i = 1, \ldots, k$ then $\xi(G) = \max_{i=1}^{k} \xi(G_i)$ (whereas $\mathrm{M}(G) = \sum_{i=1}^{k} \mathrm{M}(G_i)$).

11. [Hol02b] If G is the disjoint union of components $G_i, i = 1, \dots, k$ then $\nu(G) = \max_{i=1}^{k} \nu(G_i)$ (whereas $\mathrm{M}_+(G) = \sum_{i=1}^{k} \mathrm{M}_+(G_i)$).
12. [HLS96] If G is the disjoint union of components $G_i, i = 1, \dots, k$ and G has at least one edge, then $\mu(G) = \max_{i=1}^{k} \mu(G_i)$.
13. For a path P_n, $\mu(P_n) = \nu(P_n) = \xi(P_n) = 1$.
14. For $n \geq 2$, $\mu(K_n) = \nu(K_n) = \xi(K_n) = n - 1$
15. [BFH05b], [CdV93], [HLS96], [Pet12] For $p \leq q$ and $q \geq 3$, $\mu(K_{p,q}) = \xi(K_{p,q}) = p + 1$ and $\nu(K_{p,q}) = p$.
16. $\mathrm{h}(G) - 1 \leq \mu(G)$ and $\mathrm{h}(G) - 1 \leq \nu(G)$. These inequalities can be strict (see Examples 4 and 5 below).
17. [BFH05b], [CdV93], [HLS96], [CdV98] If T is a tree that is not a path, then

$$\xi(T) = \mu(T) = 2 \text{ and } \nu(T) = 1.$$

18. [CdV93], [HLS96] μ is used to characterize planarity:
    (a) $\mu(G) \leq 1$ if and only if G is a disjoint union of paths,
    (b) $\mu(G) \leq 2$ if and only if G is outerplanar,
    (c) $\mu(G) \leq 3$ if and only if G is planar.
19. [KLV97][4]
    (a) If $\overline{G}$ is a disjoint union of paths, then $\mu(G) \geq |G| - 3$.
    (b) If $\overline{G}$ is outerplanar, then $\mu(G) \geq |G| - 4$.
    (c) If $\overline{G}$ is planar, then $\mu(G) \geq |G| - 5$.
20. [GB11] $\mu(G) \leq \mathrm{tw}(G) + 1$.
21. [BBF13] $\nu(G) \leq \mathrm{tw}(G) + 1$.
22. [GB11] If G is chordal, then $\mu(G) \leq \omega(G)$ (where ω is the maximum size of a clique subgraph of G).
23. [Gol09] Assume G_1 and G_2 are connected. Then $\mu(G_1 \times G_2) \geq \mu(G_1) + \mathrm{h}(G_2) - 1$, and it is conjectured there that $\mu(G_1 \times G_2) \geq \mu(G_1) + \mu(G_2)$.

Examples:

1. The maximum nullity $\mathrm{M}(\cdot)$ is not, in general, monotone on induced subgraphs. Consider the graph G shown in Figure 46.8. By Fact 46.1.17 we have that $\mathrm{mr}(G) = 4$, so $\mathrm{M}(G) = 2$. Deleting the vertex of degree three produces $K_{1,4}$ and $\mathrm{M}(K_{1,4}) = 3$. In general, the Strong

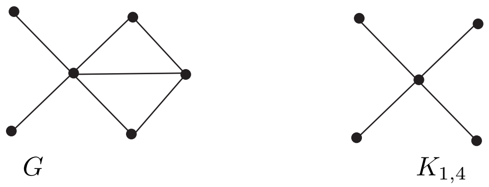

FIGURE 46.8 A graph G for which maximum nullity is not monotone on induced subgraphs

---

[4] The reader is warned that as used in [KLV97], the notation $\nu(G)$ is defined using certain vector representations and is equal to $|G| - \mu(\overline{G}) + 1$ (for $|G| > 2$), not the Colin de Verdière parameter $\nu(G)$ used in this chapter.

Arnold Hypothesis is relevant for minor-monotonicity. Any matrix realizing $\mathrm{M}(K_{1,4}) = 3$ does not satisfy the Strong Arnold Hypothesis: If $A \in \mathcal{S}(K_{1,4})$ and $\operatorname{rank} A = 2$, then

$$A = \begin{bmatrix} x & a & b & c & d \\ a & 0 & 0 & 0 & 0 \\ b & 0 & 0 & 0 & 0 \\ c & 0 & 0 & 0 & 0 \\ d & 0 & 0 & 0 & 0 \end{bmatrix},$$

where a, b, c and d are all nonzero. Then setting

$$X = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{cd}{ab} & \frac{bd}{ac} & \frac{-b-c}{a} \\ 0 & \frac{cd}{ab} & 0 & \frac{-bd-cd}{bc} & 1 \\ 0 & \frac{bd}{ac} & \frac{-bd-cd}{bc} & 0 & 1 \\ 0 & \frac{-b-c}{a} & 1 & 1 & 0 \end{bmatrix},$$

shows that A does not satisfy the Strong Arnold Hypothesis.

2. This example demonstrates the use of minor monotonicity to compute the minimum rank of the graph G shown in Figure 46.9(a). Since $G[\{3, 4, 5, 6\}] = P_4$ is an induced subgraph of G, $3 = \mathrm{mr}(P_4) \leq \mathrm{mr}(G)$. Observe that the graphs shown in Figure 46.9(b),(c) are both minors of G (delete vertex 6 to obtain (b) and then contract on edge $\{1, 5\}$ in (b) to obtain (c)). Hence, $3 = \mathrm{h}(K_4) - 1 = \xi(K_4) \leq \xi(G) \leq M(G)$. Thus, $\mathrm{mr}(G) \leq 6 - 3 = 3$, which implies $\mathrm{mr}(G) = 3$.

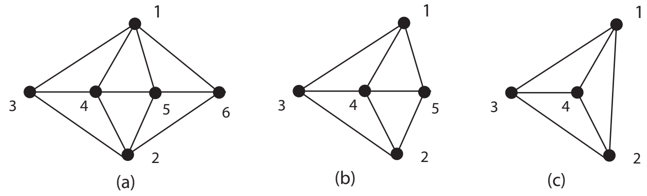

FIGURE 46.9 Using ξ to compute minimum rank.

3. Let G be the graph shown in Figure 46.10(a). Then $\xi(G) = 3$ because the matrix

$$A = \begin{bmatrix} 0 & 1 & 0 & 0 & 1 & 0 & 1 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 2 & 1 & 1 & 0 \\ 1 & 0 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

has nullity 3, $A \in \mathcal{S}(G)$, and A satisfies the Strong Arnold Hypothesis. Since G is outerplanar, $\mu(G) = 2$. In addition, we see that $\nu(G) \leq \mathrm{M}_+(G) \leq \mathrm{Z}_+(G) \leq 2$ because $X = \{1, 4\}$ is a positive semidefinite zero forcing set. Since K_3 is a minor of G, $\nu(G) = \mathrm{M}_+(G) = \mathrm{Z}_+(G) = 2$.
4. The supertriangle T_3 is shown in Figure 46.10(b). Observe that $\mathrm{h}(T_3) = 3$, so $\mathrm{h}(T_3) - 1 = 2$. The clique covering of T_3 by three triangles gives a matrix that satisfies the Strong Arnold Hypothesis, so $\nu(T_3) \geq 3$. Since P_4 is an induced subgraph of T_3, $\mathrm{mr}_+(T_3) \geq 3$, so $\nu(T_3) = 3$.
5. Observe that $\mathrm{h}(K_{2,3}) = 3$, so $\mathrm{h}(K_{2,3}) - 1 = 2$. Since $K_{2,3}$ is planar but not outerplanar, $\mu(K_{2,3}) = 3$.

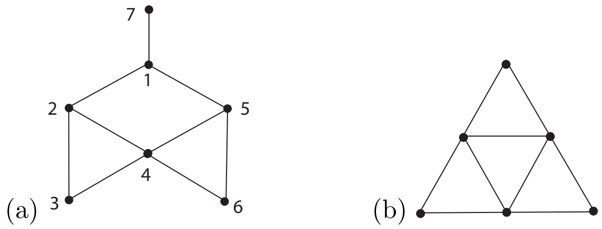

FIGURE 46.10 (a) The graph G for Example 3 and (b) the supertriangle T_3.

46.6 Advanced Topics

All graphs in this section are simple.

Definitions:

Notation: Let G be a simple graph with vertices $\{1, \ldots, n\}$.

For any $n \times n$ real symmetric matrix A, we define the **inertia** of A as the triple $(\pi(A), \nu(A), \delta(A))$, consisting of the number of positive, negative, and zero eigenvalues (counting multiplicity) of A, respectively.

Suppose A is an $n \times n$ real symmetric matrix. A **nonzero** (h, k)**-representation of** A is a $(h + k) \times n$ matrix

$$\begin{bmatrix} P_A \\ N_A \end{bmatrix}$$

with no zero columns such that P_A has h rows, N_A has k rows, and $A = P_A^T P_A - N_A^T N_A$.

A symmetric matrix $A \in \mathbb{R}^{n \times n}$ has **balanced inertia** if $\nu(A) \leq \pi(A) \leq \nu(A) + 1$.

A graph G is **inertia-balanced** if there exists $A \in \mathcal{S}(G)$ that satisfies $\operatorname{rank}(A) = \operatorname{mr}(G)$, and A has balanced inertia.

The **join minimum rank** of G is $\operatorname{jmr}(G) = \operatorname{mr}(G \vee K_1)$.

Let $G = \bigvee_{i=1}^{r} G_i$ be a join of r graphs. Then G is said to be **anomalous** if for each i, $\operatorname{jmr}(G_i) \leqslant 2$ and $K_{3,3,3} = \overline{K}_3 \vee \overline{K}_3 \vee \overline{K}_3$ is a subgraph of G.

A matrix $Q \in \mathbb{R}^{n \times n}$ of order $h + k$ is said to be (h, k)**-unitary** if $Q^T \tilde{I} Q = \tilde{I}$, where

$$\tilde{I} = \begin{bmatrix} I_h & 0 \\ 0 & -I_k \end{bmatrix}.$$

A set S of edges of a graph G (with $|G| > 1$) is a **disconnecting set** if $G - S$ has more than one component.

The **edge connectivity** of G, denoted $\kappa_e(G)$ is the minimum size of a disconnecting set of G.

A real matrix X is **generic** if every square submatrix of X is nonsingular.

The **generic nullity of a nonzero** $n \times n$ **matrix** A is defined by

$$GN(A) = \max\{k : AX = 0, X \text{ is a generic } n \times k \text{ matrix}\}.$$

The **maximum generic nullity of a graph** G is

$$GM(G) = \max\{GN(A) : A \in \mathcal{S}(G)\}.$$

The **average minimum rank** of all (labeled) graphs of order n is defined to be

$$\operatorname{amr}(n) = \frac{\sum_{|G|=n} \operatorname{mr}(G)}{2^{\binom{n}{2}}}.$$

The graph $G(n, p)$ denotes the Erdös-Rényi random graph of order n with edge probability p.

Facts:

Notation: G is a simple graph.

Facts about inertia balanced graphs and joins of graphs

1. [BF07] Trees, K_n, and C_n are all inertia balanced.
2. [BHL09] Not all graphs are inertia balanced.
3. [BF07] $\mathrm{mr}(G) \leq \mathrm{jmr}(G) \leq \mathrm{mr}(G) + 2$.
4. [BF07] Let $G = \bigvee_{i=1}^{r} G_i$, $r > 1$, where each G_i is inertia-balanced. Then G is inertia-balanced, and
$$\mathrm{mr}(G) = \begin{cases} \max_i\{\mathrm{jmr}(G_i)\} & \text{if } G \text{ is not anomalous;} \\ 3 & \text{if } G \text{ is anomalous.} \end{cases}$$
5. [BF07] Let $G = \bigvee_{i=1}^{r} G_i$, $r > 1$, be a connected decomposable graph. Then G is inertia-balanced, and
$$\mathrm{mr}(G) = \begin{cases} \max_i\{\mathrm{jmr}(G_i)\} & \text{if } G \text{ is not anomalous;} \\ 3 & \text{if } G \text{ is anomalous.} \end{cases}$$
6. [BF07] [BBF12] Let G and H be two graphs and let $A \in \mathcal{S}(G)$ and $B \in \mathcal{S}(H)$. There exists an (h, k)-unitary matrix Q such that
$$\begin{bmatrix} P_A \, P'_B \\ N_A N'_B \end{bmatrix}$$
is a nonzero (h, k)-representation of a matrix in $\mathcal{S}(G \vee H)$ with
$$\begin{bmatrix} P'_B \\ N'_B \end{bmatrix} = Q \begin{bmatrix} P_B \\ N_B \end{bmatrix},$$
whenever $h \geq \max\{\pi(A), \pi(B)\}$ and $k \geq \max\{\nu(A), \nu(B)\}$.
7. [BBF12] Let G and H be graphs. If
   (a) G and H each have an edge, or
   (b) either G has an edge and $H = \overline{K_r}$, and $\mathrm{mr}_\nu(G) \geq r$;
   or the same is true with the roles of G and H reversed,

   then
$$\mathrm{mr}_\nu(G \vee H) = \max\{\mathrm{mr}_\nu(G), \mathrm{mr}_\nu(H)\}.$$
   Otherwise,
$$\mathrm{mr}_\nu(G \vee H) = \max\{\mathrm{mr}_\nu(G), \mathrm{mr}_\nu(H)\} + 1.$$

Facts about maximum generic nullity

8. [HS10] If G is connected, then $GM(G) \leq \kappa_e(G)$.
9. [HS10] For any graph G, $\kappa(G) \leq GM(G)$.
10. [HS10] Examples of graphs are known to show that both of the inequalities $GM(G) \leq \kappa_e(G)$ and $\kappa(G) \leq GM(G)$ can be strict.
11. [HS10] As n goes to infinity almost all graphs satisfy
$$\kappa(G) = GM(G) = \kappa_e(G) = \delta(G).$$

Facts about average minimum rank

12. [HHM10] For any n, $\mathrm{amr}(n)$ is equal to the expected value of the minimum rank of $G(n, 1/2)$.

13. [HHM10] For n sufficiently large,
    (a) $0.146907n < \operatorname{amr}(n) < 0.5n + \sqrt{7n \ln n}$, and
    (b) $|\operatorname{mr}(G(n, 1/2)) - \operatorname{amr}(n)| < \sqrt{n \ln \ln n}$ with probability approaching 1 as $n \longrightarrow \infty$.

Facts about relationships between parameters

14. For any graph G, $\delta(G) \leq \operatorname{tw}(G)$.
15. [BBF13] Figure 46.11 describes the relationships between the zero forcing parameters, maximum nullity parameters, and other graph parameters (for graphs that have at least one edge). In Figure 46.11, a line between two parameters q and p where q is below p in the diagram means that for all graphs G, $q(G) \leq p(G)$. Furthermore, it is known in all cases that inequalities represented in Figure 46.11 can be strict (see [BBF13]). The strongest form of the δ conjecture ($\delta(G) \leq \nu(G)$, see Section 46.7) appears as a dashed line of small triangles.

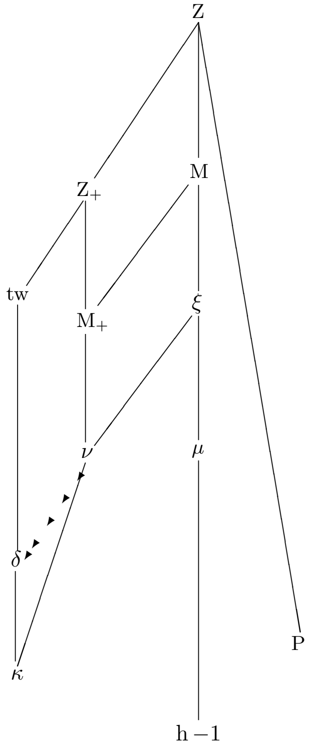

FIGURE 46.11 Relationships between zero forcing parameters, parameters related to maximum nullity, and other graph parameters.

Examples:

1. For the inertia-balanced graph $G = K_{3,3,3} = \overline{K}_3 \vee \overline{K}_3 \vee \overline{K}_3$, we have $3 = \operatorname{mr}(G) \neq \max\{\operatorname{jmr}(\overline{K}_3)\} = 2$.
2. Consider the decomposable G graph in Figure 46.12: Using the recursive formula from Fact 5 we can compute the minimum rank of G as follows:

$$\operatorname{mr}(G) = \max\{\operatorname{jmr}(G_1), \operatorname{jmr}(G_2)\},$$

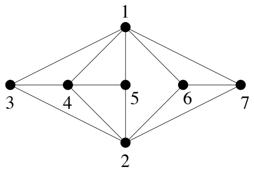

FIGURE 46.12 Decomposable graph G.

where $G_1 = K_1 \cup K_1$ based on vertices 1,2 and $G_2 = P_3 \cup P_2$ based on vertices 3,4,5 and 6,7. It is not difficult to determine that $\text{jmr}(G_1) = \text{mr}(P_3) = 2$ and that $\text{jmr}(G_2) = \text{mr}(P_3) + \text{mr}(P_2) = 3$. Hence by Fact 5, we have that $\text{mr}(G) = 3$.

3. For $n \geq 2$, $GM(K_n) = n - 1$ and if G is obtained from K_n by deleting a single edge, then $GM(G) = n - 2$.

46.7 Conjectures and Open Problems

In this section we present definitions, facts, and examples related to two well-known conjectures, the δ Conjecture and the Graph Complement Conjecture, in that order. To avoid having two facts called Fact 1 in this section, the numbering of facts for the Graph Complement Conjecture begins with the next number after the last δ Conjecture fact, and similarly for examples. A comment about terminology: Throughout this volume, $\delta(v)$ denotes the degree of the vertex v in any graph and $\delta(G)$ denotes the minimum degree over all vertices in the graph G. In this section, the abbreviation δ will mean the minimum degree over all vertices in the graph G. This choice was made here, as δ typically denotes the minimum degree, and the use of δ in this section coincides with current terminology used in works that describe this conjectured inequality involving the minimum degree. All graphs in this section are simple.

δ Conjecture

As mentioned earlier, the 2006 AIM workshop [AIM06] produced many new and interesting directions for investigating the minimum rank of a graph. One such line of study is the so-called δ conjecture, which suggests that the maximum nullity of a graph is bounded below by the minimum degree of a graph. A stronger version of the δ conjecture was made by Maehara in 1987 [LSS89]. Since 2006 these conjectures and an even stronger related version have produced many interesting advances even though these conjectures still remain open.

Definitions:

Notation: G is a simple graph.

The δ **conjecture** [BHS07] is the following inequality relating the maximum nullity of a graph G to the minimum degree $\delta(G)$:

$$\text{M}(G) \geq \delta(G).$$

Equivalently, $\text{mr}(G) \leq |G| - \delta(G)$ holds for all graphs G.

For the δ conjecture and each variant δ_x below, to say **the δ_x conjecture holds for** G means that the inequality in the δ_x conjecture is true for G. The actual δ_x conjecture is that the δ_x conjecture is true for every graph G.

The **positive semidefinite δ conjecture** (or **δ_+ conjecture**) [LSS89, attributed to Maehara] is the following inequality:

$$\text{M}_+(G) \geq \delta(G).$$

Equivalently, $\text{mr}_+(G) \leq |G| - \delta(G)$ holds for all graphs G.

The δ **conjecture for** ν (or δ_ν **conjecture**) [BBF13] is the following inequality:

$$\nu(G) \geq \delta(G).$$

Facts:

1. [LSS89], [Hol08b] For any graph G, $\mathrm{M}_+(G) \geq \nu(G) \geq \kappa(G)$.
2. [BFH08] The δ conjecture is known to hold for many classes of graphs including trees, graphs with $\delta(G) \leq 3$, $\delta(G) \geq |G| - 2$, and bipartite graphs.
3. [BFH08] The δ conjecture is known to hold for any graph G with a cut vertex v provided that it holds for the components of $G - v$.
4. [BFH08] If symmetry is replaced by combinatorial symmetry, then the δ conjecture holds for all graphs.
5. It is shown[5] in Example 1 below that with certain additional conditions, the complement of a bipartite graph satisfies the δ_+ conjecture.
6. At the time of this writing, the δ_+ conjecture is still unresolved for bipartite graphs.
7. [BFH08] The δ conjecture can fail for finite fields such as $\mathbb{Z}_2$; $K_3 \times K_2$ provides an example:
$$\mathrm{M}^{\mathbb{Z}_2}(K_3 \times K_2) = 2 < 3 = \delta(K_3 \times K_2).$$

Examples:

1. Suppose the complement $\overline{G}$ of G is a bipartite graph with bipartition $V(\overline{G}) = U \cup W$, and suppose that every vertex of U is adjacent in G to some vertex in W, and likewise every vertex of W is adjacent in G to some vertex in U. Let $m = |U|$ and $n = |W|$, and assume the vertices in U precede the vertices in W in the ordering used to associate matrices to G. Then a matrix in $\mathcal{S}_+(G)$ has the nonzero pattern $\begin{bmatrix} * & Y \\ Y^T & * \end{bmatrix}$ where $*$ denotes an all-nonzero pattern of appropriate size and Y is an $m \times n$ nonzero pattern with every row and column having a nonzero entry. In [BFH09] it is shown that $\mathrm{mr}_+(G)$ is equal to the minimum rank among matrices having nonzero pattern Y. In [BFH08] it is shown that if r is the minimum number of nonzero entries in a row of Y, then there is a matrix of rank at most $n - r + 1$ having nonzero pattern Y, so $\mathrm{mr}_+(G) \leq n - r + 1$. Observe that $\delta(G) \leq (m-1) + r$, and thus
$$\mathrm{M}_+(G) = |G| - \mathrm{mr}_+(G) \geq n + m - (n - r + 1) = m - 1 + r \geq \delta(G).$$

Graph Complement Conjecture (GCC)

An interesting conjecture that arose from the 2006 AIM workshop [AIM06] has become known as the graph complement conjecture or GCC for short (see [BHS07]). A stronger variant involving the Colin de Verdière number μ had been conjectured previously [KLV97], and several other stronger variants have been conjectured recently. Numerous partial results supporting the conjectures have been obtained. However, it remains unresolved at present.

GCC and its variants are what graph theorists call Nordhaus-Gaddum type problems, in that they involve bounding the sum of a graph parameter evaluated at a graph G and its complement $\overline{G}$. Nordhaus-Gaddum type problems have been studied for many different graph parameters, including chromatic number, independence number, domination number, Hadwiger number, etc. (see, for example, [AH13] or [CN71]).

---

[5] The brief proof is included there because a proof does not appear in the literature.

Definitions:

Notation: G is a simple graph and $\overline{G}$ is the complement of G.

The **Graph Complement Conjecture (GCC)** [BHS07] is the following inequality on the minimum rank of G and its complement:

$$\mathrm{mr}(G) + \mathrm{mr}(\overline{G}) \leq |G| + 2.$$

For GCC and each variant GCC_x below, to say **GCC_x is true for** G (or that G **satisfies GCC_x**) means that the GCC_x inequality is true for G. The actual conjecture GCC_x is that GCC_x is true for every graph G.

The **positive semidefinite Graph Complement Conjecture (GCC_+)** [BBF12] is the following inequality:

$$\mathrm{mr}_+(G) + \mathrm{mr}_+(\overline{G}) \leq |G| + 2.$$

The **Graph Complement Conjecture for ν (GCC_ν)** [BBF12] is the following inequality:

$$\nu(G) + \nu(\overline{G}) \geq |G| - 2.$$

The **Graph Complement Conjecture for ξ (GCC_ξ)** is the following inequality:

$$\xi(G) + \xi(\overline{G}) \geq |G| - 2.$$

The **Graph Complement Conjecture for μ (GCC_μ)** [KLV97] is the following inequality:

$$\mu(G) + \mu(\overline{G}) \geq |G| - 2.$$

GCC for tree-width ($\mathrm{GCC}_{\mathrm{tw}}$) [EEH13] is

$$\mathrm{tw}(G) + \mathrm{tw}(\overline{G}) \geq |G| - 2.$$

Facts:

Notation: G is a simple graph.

8. [BBF12] GCC and GCC_+ have maximum nullity equivalents,
$$\mathrm{M}(G) + \mathrm{M}(\overline{G}) \geq |G| - 2 \qquad \text{and} \qquad \mathrm{M}_+(G) + \mathrm{M}_+(\overline{G}) \geq |G| - 2.$$
9. [BBF12] GCC_ν implies GCC_+, and GCC_+ implies GCC.
10. GCC_ν implies GCC_ξ, GCC_μ implies GCC_ξ, and GCC_ξ implies GCC.
11. [EEH13] $\mathrm{GGC}_{\mathrm{tw}}$ is true for all graphs, and thus $\mathrm{Z}_+(G) + \mathrm{Z}_+(\overline{G}) \geq |G| - 2$ ($\mathrm{GCC}_{\mathrm{Z}_+}$) and $\mathrm{Z}(G) + \mathrm{Z}(\overline{G}) \geq |G| - 2$ ($\mathrm{GCC}_{\mathrm{Z}}$) are true for all graphs.
12. [SH11] GCC_ν is true for graphs of tree-width at most 3.
13. [SH11] If G is a k-connected partial k-tree, then GCC_ν is true for G. In particular, if G is a k-tree, then G satisfies GCC_ν.
14. [BBF12] If G is a graph with $|G| \leq 8$, then G satisfies GCC_ν (and hence GCC_+ and GCC).
15. [BBF12] If G is a graph with $|G| \leq 10$, then G satisfies GCC_ξ (and hence GCC).
16. [Hog08] If $\mathrm{mr}(G) \leq 4$ or $\mathrm{mr}(\overline{G}) \leq 4$, then G satisfies GCC. If $\mathrm{mr}_+(G) \leq 4$ or $\mathrm{mr}_+(\overline{G}) \leq 4$, then G satisfies GCC_+.
17. The following are shown[6] in Example 5 next: If $\nu(G) \geq |G| - 4$ or $\nu(\overline{G}) \geq |G| - 4$, then G satisfies GCC_ν. If $\xi(G) \geq |G| - 4$ or $\xi(\overline{G}) \geq |G| - 4$, then G satisfies GCC_ξ.
18. [KLV97] If $\mu(G) \geq |G| - 6$ or $\mu(\overline{G}) \geq |G| - 6$, then G satisfies GCC_μ (see Example 6 below for explanation).

---

[6] The brief proof is included there because a proof does not appear in the literature.

19. [BBF12] If $\mathrm{mr}(G) \geq |G| - 3$ or $\mathrm{mr}(\overline{G}) \geq |G| - 3$, then G satisfies GCC. If $\mathrm{mr}_+(G) \geq |G| - 3$ or $\mathrm{mr}_+(\overline{G}) \geq |G| - 3$, then G satisfies GCC$_+$. If $\nu(G) \leq 2$ or $\nu(\overline{G}) \leq 2$, then G satisfies GCC$_\nu$.
20. [KLV97], [BBF12] GCC$_\mu$ is true for all planar graphs.
21. [BBF12] If G is decomposable, then G satisfies GCC$_\nu$.
22. [Mit11] If G is chordal, then G satisfies GCC$_\nu$.
23. [BBF12] If G and H are graphs that satisfy GCC$_\nu$, then the join $G \vee H$ and disjoint union $G \cup H$ satisfy GCC$_\nu$.
24. [BBF12] If G and H are graphs such that their inductive cores satisfy GCC, then the join $G \vee H$ and disjoint union $G \cup H$ satisfy GCC (see [BBF12] for the definition of inductive core).
25. If the δ-conjecture (respectively, δ_+-conjecture, δ_ν-conjecture) is true, then GCC (respectively, GCC$_+$, GCC$_\nu$) is true for all regular graphs.
26. If GCC fails for a simple graph G, then at least one of $\mathrm{M}(G) < \mathrm{tw}(G)$ or $\mathrm{M}(\overline{G}) < \mathrm{tw}(\overline{G})$ must hold. See Example 7 for a graph having $\mathrm{M}(\overline{G}) < \mathrm{tw}(\overline{G})$ (however, GCC$_\nu$ does hold for this graph).
27. The natural extension of GCC to minimum degree, $\delta(G) + \delta(\overline{G}) \geq |G| - 2$, is false. See Example 9.
28. The natural extension of GCC to path cover number, $\mathrm{P}(G) + \mathrm{P}(\overline{G}) \geq |G| - 2$, is false. See Example 10.
29. [Kos84] The natural extension of GCC to Hadwiger number, $\mathrm{h}(G) + \mathrm{h}(\overline{G}) \geq |G|$, is false (this is the natural extension because $\mathrm{h}(G) - 1 \leq \nu(G)$). See Example 8.

Examples:

2. $\overline{P_4} = P_4$ and $\mathrm{mr}(P_4) = 3$, so P_4 satisfies GCC with equality (P_4 also satisfies GCC$_+$ and GCC$_\nu$ with equality).
3. For $n \geq 5$, $\overline{C_n} = n - 3$ [AIM08]. Since $\mathrm{M}(C_n) = 2$, $\mathrm{M}(C_n) + \mathrm{M}(\overline{C_n}) = n - 1$ and C_n satisfies GCC. (Since C_n is a 2-connected partial 2-tree, C_n satisfies GCC$_\nu$ by Fact 13.)
4. Let G be a connected strongly regular graph with parameters (n, k, λ, μ) (see Section 39.3). Then the adjacency matrix $\mathcal{A}_G$ of G has exactly three eigenvalues, one of which is k with multiplicity one (see Facts 39.3.13 and 39.3.14). Thus, $\mathcal{A}_G$ has an eigenvalue of multiplicity at least $\lceil \frac{n-1}{2} \rceil$. Since $\overline{G}$ is also strongly regular, $\mathrm{M}(G) + \mathrm{M}(\overline{G}) \geq n - 1$ and GCC is true for G.
5. In this example we show why $\nu(G) \geq |G| - 4$ implies G satisfies GCC$_\nu$, and similarly why $\xi(G) \geq |G| - 4$ implies G satisfies GCC$_\xi$.

   Clearly if $|G| \leq 3$, then G satisfies GCC$_\nu$. Assume $\nu(G) \geq |G| - 4$ and GCC$_\nu$ fails, i.e., $\nu(G) + \nu(\overline{G}) \leq |G| - 3$. Thus, $|G| \geq 4$, $\nu(G) = |G| - 4$ and $\nu(\overline{G}) = 1$; the latter implies each connected component of $\overline{G}$ is a tree [CdV98], so $\overline{G}$ is a forest. (For GCC$_\xi$, the analogous argument shows that $\xi(\overline{G}) = 1$, and this implies each connected component of $\overline{G}$ is a path [BFH05b].) Add edges to $\overline{G}$ to obtain a tree T and observe that $\overline{T}$ is a subgraph of G. Thus, $\nu(G) \geq \nu(\overline{T})$ and it suffices to show $\nu(\overline{T}) \geq |T| - 3$ for every tree of order at least 4, contradicting $\nu(G) = |G| - 4$.

   Let $T = (V, E)$ be a tree of order $n \geq 3$. In the proof of Theorem 3.16 in [AIM08], a faithful orthogonal representation of T is constructed in $\mathbb{R}^3$ for $\overline{T}$ with the additional property that if $i \neq j \in V$, then $\mathbf{v}_i$ and $\mathbf{v}_j$ are linearly independent (call such a representation an *independent faithful orthogonal representation*). Let $B = [\mathbf{v}_1, \ldots, \mathbf{v}_n]$ be an independent faithful orthogonal representation of $\overline{T}$ in $\mathbb{R}^3$. We show by induction on $n = |T|$ that $B^T B$ satisfies the Strong Arnold Hypothesis, and thus $\nu(\overline{T}) \geq |T| - 3$.

   Since every nonsingular matrix trivially satisfies the Strong Arnold Hypothesis, the result is clear for $n = 2$. Assume true for all trees of order at most $n - 1$. Without loss of generality (by renumbering if necessary), assume n is a vertex of degree one in T and $n - 1$ is its neighbor in T. Define $B' = [\mathbf{v}_1, \dots, \mathbf{v}_{n-1}]$, $A = B^T B$, and $A' = B'^T B'$. We can partition $A = \begin{bmatrix} A' & \mathbf{c} \\ \mathbf{c}^T & \alpha \end{bmatrix}$ where $\mathbf{c} = [\gamma_1, \dots, \gamma_{n-2}, 0] \in \mathbb{R}^{n-1}$ and $\alpha \in \mathbb{R}$. Let X be a symmetric matrix satisfying (i) $AX = \mathbf{0}$, (ii) $A \circ X = \mathbf{0}$, and (iii) $I \circ X = \mathbf{0}$. Partition X conformally with A as $X = \begin{bmatrix} X' & \mathbf{z} \\ \mathbf{z}^T & 0 \end{bmatrix}$ where $\mathbf{z} = [0, \dots, 0, \zeta] \in \mathbb{R}^{n-1}$ by (ii) and (iii). By examining the 1,2-block of $AX = 0$, we see that $0 = A'\mathbf{z} = B'^T B'\mathbf{z}$. Thus, $0 = B'\mathbf{z} = \zeta \mathbf{v}_{n-1}$. Since $\mathbf{v}_{n-1} \neq 0$ (all vectors in an independent faithful orthogonal representation are nonzero), $\zeta = 0$, i.e., $\mathbf{z} = 0$. Then by examining the 1,1-block of $AX = 0$, we have $0 = A'X' + \mathbf{c}\mathbf{z}^T = A'X'$. Since $A' = B'^T B'$ and B' is an independent faithful orthogonal representation of $T \backslash n$, A' satisfies the Strong Arnold Hypothesis by the induction assumption. Thus, $X' = 0$, so $X = 0$, and A satisfies the Strong Arnold Hypothesis.

6. In this example we explain why $\mu(G) \geq |G| - 6$ implies G satisfies GCC_μ. Assume $\mu(G) \geq |G| - 6$ and G does not satisfy GCC_μ. Then $\mu(\overline{G}) \leq 3$, so $\overline{G}$ must be planar. Then by results in [KLV97] (see Fact 20), G satisfies GCC_μ, contradicting the hypothesis.
7. [BBF13] The Heawood graph H is shown in Figure 46.13(a); we consider its complement $\overline{H}$. It is well known that H is the incidence graph of the Fano projective plane (the numbering in Figure 46.13(a) follows [BFH09, Figure 4.1] with vertices $1-7$ interpreted as the lines and vertices $8-14$ interpreted as points). Any matrix in $\mathcal{S}(\overline{H})$ has the form $\begin{bmatrix} * & X_F \\ X_F^T & * \end{bmatrix}$ where $*$ indicates every entry is nonzero (except possibly on the diagonal) and X_F is the zero-nonzero pattern of the complement of the incidence pattern in the Fano projective plane. So by [BFH09, Theorem 3.1], $\mathrm{mr}_+(\overline{H}) = \mathrm{mr}(\overline{H})$ is equal to the minimum of the ranks of the (not necessarily symmetric) matrices described by X_F, i.e., $\mathrm{mr}_+(\overline{H}) = \mathrm{mr}(\overline{H}) = 4$, so $\mathrm{M}_+(\overline{H}) = \mathrm{M}(\overline{H}) = 10$. Since $\mathrm{g}(H) = 6$, $\mathrm{tw}(\overline{H}) \geq 14 - 3 = 11$ [BBF13, Theorem A.19] (in fact $\mathrm{tw}(\overline{H}) = 11$). Thus, $\mathrm{M}(\overline{H}) < \mathrm{tw}(\overline{H})$. It is straightforward to verify that the matrix
$$A = \begin{bmatrix} 44 & 26 & -34 & 60 & 78 & 18 & 11 & 1 & 0 & 0 & 0 & 1 & 1 & 1 \\ 26 & 70 & -59 & 129 & 85 & -44 & 3 & 0 & 1 & 0 & 1 & 0 & 1 & 1 \\ -34 & -59 & 54 & -113 & -88 & 25 & -6 & 0 & 0 & 1 & 1 & 1 & 0 & 1 \\ 60 & 129 & -113 & 242 & 173 & -69 & 9 & 0 & 1 & -1 & 0 & -1 & 1 & 0 \\ 78 & 85 & -88 & 173 & 166 & -7 & 17 & 1 & 0 & -1 & -1 & 0 & 1 & 0 \\ 18 & -44 & 25 & -69 & -7 & 62 & 8 & 1 & -1 & 0 & -1 & 1 & 0 & 0 \\ 11 & 3 & -6 & 9 & 17 & 8 & 3 & 1 & 1 & 1 & 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 & 1 & 1 & 1 & 21 & 33 & 34 & 17 & 5 & 4 & 38 \\ 0 & 1 & 0 & 1 & 0 & -1 & 1 & 33 & 54 & 59 & 45 & 24 & 19 & 78 \\ 0 & 0 & 1 & -1 & -1 & 0 & 1 & 34 & 59 & 70 & 77 & 52 & 41 & 111 \\ 0 & 1 & 1 & 0 & -1 & -1 & 0 & 17 & 45 & 77 & 178 & 150 & 118 & 195 \\ 1 & 0 & 1 & -1 & 0 & 1 & 0 & 5 & 24 & 52 & 150 & 131 & 103 & 155 \\ 1 & 1 & 0 & 1 & 1 & 0 & 0 & 4 & 19 & 41 & 118 & 103 & 81 & 122 \\ 1 & 1 & 1 & 0 & 0 & 0 & 1 & 38 & 78 & 111 & 195 & 155 & 122 & 233 \end{bmatrix}$$
satisfies the Strong Arnold Hypothesis, $\operatorname{rank} A = 4$, and $A \in \mathcal{S}(\overline{H})$, so $\nu(\overline{H}) \geq 10 = |\overline{H}| - 4$. Thus, $\overline{H}$ satisfies GCC_ν by Fact 17.
8. [BBF12] The icosahedral graph G_{12} shown in Figure 46.13(b) has order 12, is 5-regular, and is planar. Thus, G_{12} cannot have a K_5 minor. So in order for G_{12} to satisfy $\mathrm{h}(G_{12}) + \mathrm{h}(\overline{G_{12}}) \geq |G_{12}|$, $\overline{G_{12}}$ would need to have a K_8 minor. To obtain a minor, we delete a (possibly empty) subset of vertices, delete a (possibly empty) subset of edges, and (possibly) perform edge contractions. The contractions induce a partition of the subset of vertices that are not deleted. Thus, it is impossible to have a K_8 minor of $\overline{G_{12}}$, since for any minor that has 8 vertices, we must partition a subset of the 12 vertices of $\overline{G_{12}}$ into 8 sets (associated with the 8 vertices of the minor), requiring that there be a set with only one vertex of $\overline{G_{12}}$, hence a vertex

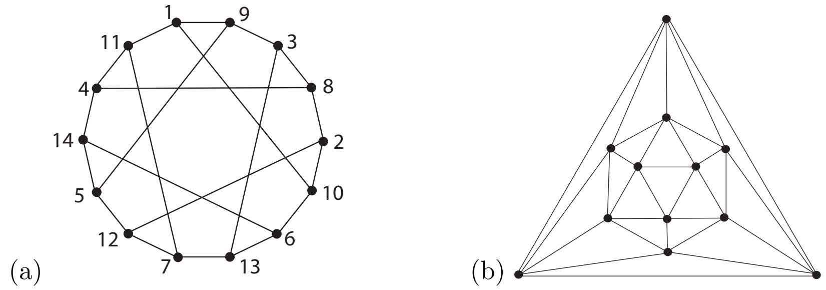

FIGURE 46.13 (a) The Heawood graph H and (b) the icosahedral graph G_{12}.

of degree at most 6 in the minor, because $\overline{G_{12}}$ is 6-regular. Note that $\kappa(G_{12}) = 5$ and $\kappa(\overline{G_{12}}) = 6$, so by Fact 46.5.9, $\nu(G_{12}) + \nu(\overline{G_{12}}) \geq 11 > |G_{12}| - 2$. So G_{12} satisfies GCC$_\nu$ and hence GCC and GCC$_+$.

9. A graph G and its complement $\overline{G}$ are shown in Figure 46.14. For this graph, $\delta(G) = 1 = \delta(\overline{G})$ and $|G| = 5$, so $\delta(G) + \delta(\overline{G}) < |G| - 2$.

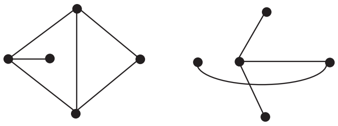

FIGURE 46.14 A graph and its complement.

10. For the path on six vertices, $\mathrm{P}(P_6) = 1$ and $\mathrm{P}(\overline{P_6}) = 2$, so $\mathrm{P}(P_6) + \mathrm{P}(\overline{P_6}) < |P_6| - 2$.

46.8 Minimum Rank without Symmetry

The previous sections present a relatively complete description of the state of knowledge of the topics covered at the time of this writing (2012). By contrast, this section is a brief overview that is not comprehensive.

The families of matrices discussed in the previous sections have had off-diagonal nonzero patterns described by edges of simple undirected graphs, and the matrices have been symmetric (or sometimes Hermitian in the case of minimum positive semidefinite rank). In this section we give a brief overview of the more limited work that has been done on the minimum rank problem for matrices without symmetry that are described by more general patterns of nonzero entries, sometimes eliminating the requirement of positional symmetry by using directed graphs, allowing the pattern to (more fully) constrain the diagonal, and including sign patterns in addition to nonzero patterns.

A **nonzero pattern** is a matrix (not necessarily square) whose entries are elements of $\{*, 0\}$, where $*$ denotes a nonzero entry. A square nonzero pattern can be naturally associated with a digraph (see Chapter 40 for definitions and properties of digraphs, which are directed graphs that allow loops but not multiple edges). A **sign pattern** is a matrix (not necessarily square) having entries in $\{+, -, 0\}$ (see Chapter 42 for definitions and properties of sign patterns). The definitions of minimum rank and maximum nullity are extended in the natural way to a nonzero pattern or sign pattern. Definitions of related parameters such as zero forcing number and path cover number have also been extended to patterns — see Example 1 next, [BFH09], and [Hog11]. A ***t*-triangle** of an $m \times n$ nonzero pattern Y is a $t \times t$ subpattern that is permutation similar to a pattern that is upper triangular with all diagonal entries nonzero. The **triangle number** of pattern Y, denoted $\text{tri}(Y)$, is the maximum size of a triangle in Y. The triangle number and t-triangles have been used as a lower bound for minimum rank in both the symmetric and asymmetric minimum rank problems, see e.g., [BHL04], [CJ06], [JL08]; triangle number is generally more useful in the asymmetric case.

The minimum rank of full sign patterns has important applications to communication complexity in computer science (a sign pattern is **full** if all entries are nonzero), and some progress on minimum rank of full sign patterns has been obtained through work on communication complexity. See Application 1 for a discussion of the connection between minimum rank and communication complexity.

For a simple (undirected) graph G, the **Haemers minimum rank** $\eta(G)$ is the smallest rank of any (not necessarily symmetric) matrix (over any field) having all diagonal entries nonzero and having zero in every position that corresponds to a nonedge of G [Hae81]; facts about η can be found in Section 39.5, an more recent results can be found in [Tim12].

Facts:

1. It is straightforward to determine the minimum rank of any tree pattern by computing a related parameter such as triangle number or zero forcing number, but techniques vary with the type of pattern. For a survey of all types of trees and ditrees, see [Hog10]. For the original work on nonezero patterns, see [BFH09]. For the original work on trees with loops and positionally symmetric tree sign patterns, see [DHH06]. For tree sign patterns in general, see [Hog11].
2. [For02] Let X be a $m \times n$ full sign pattern and let M_X be the $m \times n$ matrix obtained from X by replacing $+$ by 1 and $-$ by -1. Then

$$\text{mr}(X) \geq \frac{\sqrt{mn}}{\|M_X\|_2},$$

where $\|M_X\|_2$ is the spectral norm of M_X.

Examples:

1. Let Γ be a digraph. Vertex v is an *out-neighbor* of u if (u, v) is an arc of Γ, and we say that Γ *requires nonsingularity* if every matrix having the nonzero pattern of entries described by Γ is nonsingular. The zero forcing number $\text{Z}(\Gamma)$ is the minimum number of black vertices needed to color all the vertices black using the following *color change rule*: If exactly one out-neighbor v of u is white, then change the color of v to black (the possibility that $u = v$ is permitted). The extension of the definition of path cover number requires a fundamental change in the definition: The *path cover number* $\text{P}(\Gamma)$ of Γ is the minimum number of vertex disjoint paths whose deletion leaves a digraph that requires nonsingularity (or the empty set) [BFH09]. In [BFH09] it is shown that for a tree digraph T, $\text{mr}(T) = \text{tri}(T)$ and $\text{M}(T) = \text{Z}(T) = \text{P}(T)$. Here we use the latter to compute $\text{M}(T)$ and hence $\text{mr}(T)$ for the tree digraph shown in Figure 46.15. Observe that the black vertices $\{1, 13\}$ are a zero forcing set for T, with the chronological list of forces $1 \to 2, 2 \to 3, 13 \to 12, 12 \to 4, 11 \to 11, 5 \to 6, 8 \to 7, 9 \to 9, 6 \to 5, 7 \to 8, 4 \to 10$. Similarly, the paths $(1, 2, 3), (13, 12, 4, 10)$ are a path cover because $T[\{5, 6, 7, 8, 9\}]$ and $T[\{11\}]$ both require nonsingulararity. In fact, both of these are minimal, so $\text{M}(T) = 2$ and $\text{mr}(T) = 11$.
2. An $n \times n$ *Hadamard matrix* is a ± 1-matrix H such that $H^T H = nI_n$ (see Chapter 44). For an $n \times n$ Hadamard matrix H, $\frac{\sqrt{n^2}}{\|H\|_2} = \sqrt{n}$, so $\text{mr}(\text{sgn}(H)) \geq \sqrt{n}$ [For02]. For the 4×4

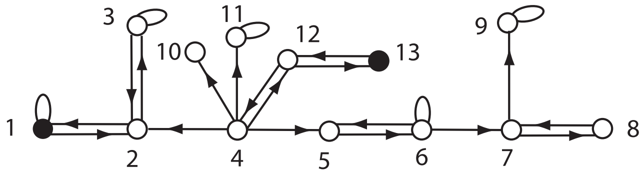

FIGURE 46.15 A tree digraph T.

Hadamard matrix

$$H = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & -1 & 1 \end{bmatrix},$$

it is shown in [Hog11] using results from [BCS94] that $\text{mr}(\text{sgn}(H)) = 3 > 2 = \sqrt{4}$.

Applications:

1. In a simple model of communication, described in [CCM00], there are two processors A and B, each of which receives its own input (a string of bits that are 0 or 1), and the goal is to compute a value that is a function of both inputs. The computation function can be described by a $\{0,1\}$-matrix M with rows indexed by the possible inputs of A, columns indexed by the possible inputs for B, and the entry representing the value computed. A *(deterministic) protocol* tells the processors how to exchange information to enable this computation. The *(deterministic) communication complexity* $c(M)$ associated to the $\{0,1\}$ function matrix M is the minimum number of bits that must be transmitted in any protocol associated with M. Melhorn and Schmidt [MS82] showed that $\log_2 \text{rank}\, M \leq c(M) \leq \text{rank}\, M$ [CCM00].

   Communication complexity is also studied from a probabilistic point of view; this approach is described in [Lok09] and [DS12]. An *unbounded error probabilistic protocol* tells the processors how to exchange information to enable computation that will be accurate with probability $> \frac{1}{2}$. The *unbounded error probabilistic communication complexity* upp-cc(M) associated to the function matrix M is the minimum number of bits that must be transmitted in any unbounded error probabilistic protocol associated with M. When studying upp-cc, it is common to use a $\{+1,-1\}$-matrix. A $\{0,1\}$-matrix M can be converted to a $\{+1,-1\}$-matrix by replacing entry m_{ij} by $(-1)^{m_{ij}}$, or equivalently, using $J - 2M$, where J is the all ones matrix. If M is an $m \times n$ $\{+1,-1\}$-matrix, then sgn(M) is a full sign pattern. For a $\{+1,-1\}$-matrix M, the *sign rank* of M is sign-rank(M) = mr(sgn(M)). Paturi and Simon [PS84], [Lok09, p. 106] showed that

$$\log_2 \text{sign-rank}(M) \leq \text{upp-cc}(M) \leq \log_2 \text{sign-rank}(M) + 1.$$

   Thus, the computation of sign-rank(M) = mr(sgn(M)) is of interest in the study of communication complexity. A more thorough introduction to communication complexity and its connections to sign-rank and minimum rank can be found in Deaett and Srinivasan's recent survey [DS12] or Lokam's book [Lok09].

There are many different ways to associate a matrix with a graph (an introduction of which can be found in Chapter 39 on matrices and graphs). The focus of spectral graph theory is to examine the eigenvalues (or spectrum) of such a matrix and use them to determine structural properties of the graph; or conversely, given a structural property of the graph determine the nature of the eigenvalues of the matrix.

Some of the different matrices we can use for a graph G include the adjacency matrix $\mathcal{A}_G$, the (combinatorial) Laplacian matrix L_G, the signless Laplacian matrix $|L_G|$, and the normalized Laplacian matrix $\mathcal{L}_G$. The eigenvalues of these different matrices can be used to find out different information about the graph. No one matrix is best because each matrix has its own limitations in that there is some property which the matrix cannot always determine (this shows the importance of understanding all the different matrices).

In the table below we summarize the four matrices and four different structural properties of a graph and indicate which properties can be determined by the eigenvalues. A "No" answer indicates the existence of two non-isomorphic graphs which have the same spectrum but differ in the indicated structure.

Matrix	Bipartite	# Components	# Bipartite Components	# Edges
Adjacency — $\mathcal{A}_G$	Yes	No	No	Yes
(combinatorial) Laplacian — L_G	No	Yes	No	Yes
Signless Laplacian — $\lvert L_G\rvert$	No	No	Yes	Yes
Normalized Laplacian — $\mathcal{L}_G$	Yes	Yes	Yes	No

In this chapter we will introduce the normalized Laplacian and give some basic properties of this matrix and some additional applications of the eigenvalues of graphs. This chapter will focus more on analytic aspects, whereas Chapter 39 focused more on the algebraic aspects. Both sides are important to spectral graph theory and powerful when used correctly.

In addition to Chapter 39 and the references contained therein, there are a number of excellent books [Chu97, Van11] and surveys [HLW06, KS06] that can be consulted.

47.1 The Normalized Laplacian Matrix

In this section we introduce the normalized Laplacian matrix alluded to in the introduction. This has intimate ties to random walks and so has many useful properties; unfortunately, it also is poor at counting certain structures (i.e., edges).

Definitions:

A **weighted graph** G is a graph with vertices $v_1, v_2, \ldots, v_n$ and a **weight function**, w, satisfying $w(v_i, v_j) = w(v_j, v_i)$ (symmetric) and $w(v_i, v_j) \geq 0$ (nonnegative). In this setting, edges correspond to when $w(v_i, v_j) > 0$ and non-edges when $w(v_i, v_j) = 0$; note that we allow loops but do not allow multiple edges (opting instead to modify the weight).

A **simple graph** is a weighted graph where $w(v_i, v_j) \in \{0, 1\}$ and $w(v_i, v_i) = 0$ for all v_i.

The **degree** of a vertex v_i in a weighted graph is $d_i = \sum_{v_j} w(v_i, v_j)$. A vertex is **isolated** if $d_i = 0$.

Given a subset X of the vertices the **volume of** X is $\text{vol}(X) = \sum_{v_i \in X} d_i$.

We let $\text{vol}(G)$ denote the sum of all the degrees.

Given subsets X and Y of the vertices (not necessarily disjoint), $e(X, Y) = \sum_{x \in X, y \in Y} w(x, y)$.

The **adjacency matrix** of a weighted graph, $\mathcal{A}_G$, is the real symmetric $n \times n$ matrix with entries $(\mathcal{A}_G)_{i,j} = w(v_i, v_j)$.

The **diagonal degree matrix** of a weighted graph, D_G, is the diagonal matrix with $(D_G)_{i,i} = d_i$.

The **(combinatorial) Laplacian** of a weighted graph, L_G, is defined as $L_G = D_G - \mathcal{A}_G$.

The **signless Laplacian** of a weighted graph, $|L_G|$, is defined as $|L_G| = D_G + \mathcal{A}_G$.

The **normalized Laplacian matrix** of a weighted graph, $\mathcal{L}_G$, is the symmetric $n \times n$ matrix with entries defined as follows:

$$(\mathcal{L}_G)_{i,j} = \begin{cases} 1 - \frac{w(v_i, v_i)}{d_i} & \text{if } i = j \text{ and } d_i \neq 0 \\ -\frac{w(v_i, v_j)}{\sqrt{d_i d_j}} & \text{if } i \neq j \text{ and } w(v_i, v_j) > 0 \\ 0 & \text{otherwise} \end{cases}$$

Facts:

If no reference is given, the results are elementary or can be found in [Chu97].

1. If the weighted graph G has no isolated vertices, then $\mathcal{L}_G = D_G^{-1/2} L_G D_G^{-1/2}$.
2. If the weighted graph G has each vertex of degree $k > 0$, then $\mathcal{L}_G = I - \frac{1}{k}\mathcal{A}_G = \frac{1}{k} L_G$. In particular, if α is an eigenvalue of $\mathcal{A}_G$, then $1 - \frac{1}{k}\alpha$ is an eigenvalue of $\mathcal{L}_G$.
3. [But08, Sect. 1.5] Let δ and Δ denote the minimum and maximum degrees of a weighted graph G without isolated vertices, respectively. Further, let $\phi_0 \leq \phi_1 \leq \cdots \leq \phi_{n-1}$, $q_0 \leq q_1 \leq \cdots \leq q_{n-1}$, and $\lambda_0 \leq \lambda_1 \leq \cdots \leq \lambda_{n-1}$ denote the eigenvalues of L_G, $|L_G|$, and $\mathcal{L}_G$, respectively. Then the following holds for $0 \leq i \leq n-1$:[1]
    (a) $\dfrac{1}{\Delta}\phi_i \leq \lambda_i \leq \dfrac{1}{\delta}\phi_i$
    (b) $\dfrac{1}{\Delta}q_{n-1-i} \leq 2 - \lambda_i \leq \dfrac{1}{\delta}q_{n-1-i}$
    (c) $2\delta \leq \phi_i + q_{n-1-i} \leq 2\Delta$

---

[1] Only the proof of the first item is found in [But08, Sect. 1.5]; the second item has an identical proof and the third item is an easy combination of the first two.

4. The eigenvalues of $\mathcal{L}_G$ for a weighted graph G are real numbers satisfying $0 = \lambda_0 \leq \lambda_1 \leq \cdots \leq \lambda_{n-1} \leq 2$. Further, the multiplicity of 0 as an eigenvalue is the number of connected components of G. In particular, G is connected if and only if $\lambda_1 > 0$. The multiplicity of 2 as an eigenvalue is the number of bipartite connected components of G with at least two vertices.
5. A weighted graph is bipartite with no isolated vertices if and only if the spectrum of $\mathcal{L}_G$ is symmetric around 1.
6. For $n \geq 2$ the eigenvalues of the normalized Laplacian of the complete simple graph are 0 and $\frac{n}{n-1}$ (with multiplicities 1 and $n-1$, respectively); for $p+q=n$ the eigenvalues of the simple graph $K_{p,q}$ are 0, 1, and 2 (with multiplicities 1, $n-2$, and 1, respectively). In particular, all complete bipartite simple graphs on n vertices are cospectral.
7. For a simple graph without isolated vertices and $n \geq 2$ vertices, then $\lambda_1 = \frac{n}{n-1}$ if and only if the graph is the complete graph on n vertices; if the graph is not the complete graph, then $\lambda_1 \leq 1$. Further, if G is a simple graph with no isolated vertices, then $\lambda_{n-1} \geq \frac{n}{n-1}$.
8. If the weighted graph G has a set of two or more nonadjacent vertices with the same neighbors and corresponding edge weights, then 1 is an eigenvalue of $\mathcal{L}_G$ and 0 is an eigenvalue of $\mathcal{A}_G$. If the weighted graph G has a set of two or more adjacent vertices with degree d and the same (closed) neighborhood and corresponding edge weights, then $\frac{d+1}{d}$ is an eigenvalue of $\mathcal{L}_G$ and -1 is an eigenvalue of $\mathcal{A}_G$.
9. Let $\mathbf{1}$ denote the vector of all 1s. Then for a connected weighted graph G with eigenvalues $\lambda_0 \leq \lambda_1 \leq \cdots \lambda_{n-1}$ for $\mathcal{L}_G$ the following hold:
   (a) [But08, Sect. 1.6] $\lambda_{n-1} - \lambda_1 \geq \dfrac{2}{n-1}\sqrt{(n-1)\mathbf{1}^T D_G^{-1}\mathcal{A}_G D_G^{-1}\mathbf{1} - n}$.

   (b) [But08, Sect. 1.6] $\sqrt{\dfrac{\lambda_{n-1}}{\lambda_1}} + \sqrt{\dfrac{\lambda_1}{\lambda_{n-1}}} \geq 2\sqrt{(1-\frac{1}{n})(1+\frac{1}{n}\mathbf{1}^T D_G^{-1}\mathcal{A}_G D_G^{-1}\mathbf{1})}$.

   (c) [But08, Sect. 5.6.2] If $X, Y \subseteq V$ and $e(X,Y) = 0$ (i.e., no edges joining X and Y), then
   $$\frac{\mathrm{vol}(X)\,\mathrm{vol}(Y)}{\mathrm{vol}(\overline{X})\,\mathrm{vol}(\overline{Y})} \leq \left(\frac{\lambda_{n-1}-\lambda_1}{\lambda_{n-1}+\lambda_1}\right)^2.$$
10. Let D be the diameter of the weighted graph G.
    (a) The matrix $\mathcal{L}_G$ has at least $D+1$ distinct eigenvalues.

    (b) $\lambda_1 \geq \dfrac{1}{D\,\mathrm{vol}(G)}$.

    (c) [Gro05] If Δ is the maximum degree of the graph, then $\lambda_1 \geq \dfrac{1}{(\Delta+1)\Delta^{\lceil D/2 \rceil - 1}}$.

    (d) If Δ is the maximum degree of the graph, then
    $$\lambda_1 \leq 1 - 2\frac{\sqrt{\Delta-1}}{\Delta}\left(1-\frac{2}{D}\right) + \frac{2}{D}.$$
11. [Kir07] Suppose G a simple graph other than the complete graph. Let X and Y be subsets of the vertices of G with $X \neq Y$ and $X \neq \overline{Y}$, and let $d(X,Y)$ denote the minimum distance between some vertex in X and some vertex in Y. Then
    $$d(X,Y) \leq \max\left\{ \left\lceil \frac{\log\sqrt{\frac{\mathrm{vol}(\overline{X})\,\mathrm{vol}(\overline{Y})}{\mathrm{vol}(X)\,\mathrm{vol}(Y)}}}{\log\frac{\lambda_{n-1}+\lambda_1}{\lambda_{n-1}-\lambda_1}} \right\rceil, 2 \right\}.$$

12. [Chu97, Theorem 8.3] Recall $\mathcal{L}_G(k)$ denotes the sub-matrix of $\mathcal{L}_G$ with the kth row and column removed. For any $1 \leq k \leq n$, the number of spanning trees in a simple graph G is $\det\big(\mathcal{L}_G(k)\big)\prod\limits_{i\neq k} d_i$.

Examples:

1. The eigenvalues of the normalized Laplacian of the path on n vertices are $1-\cos\dfrac{\pi k}{n-1}$ for $k = 0, 1, \ldots, n-1$.
2. The eigenvalues of the normalized Laplacian of the n-cube on 2^n vertices are $\frac{2k}{n}$ (with multiplicity $\binom{n}{k}$) for $k = 0, 1, \ldots, n$.
3. [BG11] The two pairs of simple graphs shown in Figure 47.1 have the same spectra for the normalized Laplacian. These pairs show that the spectrum of the normalized Laplacian cannot determine the number of edges, cannot determine if a graph is regular, and cannot always distinguish a graph from its subgraph.

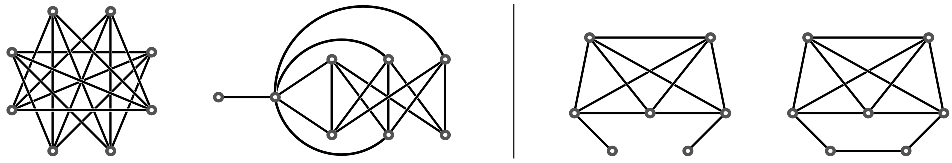

FIGURE 47.1 Two examples of pairs of graphs which are cospectral with respect to $\mathcal{L}_G$.

4. Consider the paw graph shown in Figure 47.2. The normalized Laplcian for this graph is

$$\mathcal{L}_G = \begin{bmatrix} 1 & -\frac{1}{\sqrt{3}} & 0 & 0 \\ -\frac{1}{\sqrt{3}} & 1 & -\frac{1}{\sqrt{6}} & -\frac{1}{\sqrt{6}} \\ 0 & -\frac{1}{\sqrt{6}} & 1 & -\frac{1}{2} \\ 0 & -\frac{1}{\sqrt{6}} & -\frac{1}{2} & 1 \end{bmatrix}$$

This graph has three spanning trees and

$$\det\big(\mathcal{L}_G(1)\big)\prod_{i\neq 1} d_i = \frac{1}{4}\cdot 12 = 3; \qquad \det\big(\mathcal{L}_G(2)\big)\prod_{i\neq 2} d_i = \frac{3}{4}\cdot 4 = 3.$$

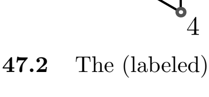

FIGURE 47.2 The (labeled) paw graph.

47.2 Random Walks

Random walks on graphs have a variety of applications from mixing and searching to finding cuts and so on. One of the main tools to help understand random walks comes from spectral graph theory. This material is closely related to Markov chains (see Chapter 72) and stochastic matrices (see Section 10.4).

Definitions:

A **probability distribution** on a weighted graph G is an assignment of nonnegative values to the vertices which sum to 1, i.e., a function f with $f(v) \geq 0$ and $\sum_{v \in V} f(v) = 1$. For convenience we will treat f as a row vector.

A **random walk** on a weighted graph consists of starting at a vertex (usually chosen from some initial probability distribution) and then taking a specified number of steps. Each step in the random walk consists of moving from a current vertex to an adjacent vertex where the probability of using an edge is proportional to the weight of that edge.

Given an initial probability distribution $f^{(0)}$, then a **probability distribution of a random walk at time** t, denoted $f^{(t)}$, is the probability distribution reflecting the likelihood of being at some given vertex given that a random walk started with the initial distribution $f^{(0)}$ and took t steps.

A **stationary distribution** of a random walk is a probability distribution π where the distribution is unchanged after one step of the random walk.

A random walk is **ergodic** if it converges to a unique stationary distribution.

A **lazy random walk** with parameter p is a random walk where at each time step we either stay at the current vertex (with probability p) or take one step of the random walk (with probability $1 - p$).

If G has no isolated vertices, the **probability transition matrix** $\mathcal{P}_G$ of a random walk (also known as the **walk transition matrix**) is the matrix with entries defined as follows:

$$(\mathcal{P}_G)_{i,j} = \begin{cases} \frac{w(v_i, v_j)}{d_i} & \text{if } v_i \text{ is adjacent to } v_j; \\ 0 & \text{otherwise.} \end{cases}$$

Facts:

The graphs on which we will consider random walks will be weighted graphs.

1. Given a probability distribution $f^{(i)}$, then
$$f^{(i+1)}(v) = \sum_u f^{(i)}(u) \frac{w(u,v)}{d_u}.$$
2. The probability distribution of a random walk after taking t steps is given by $f^{(t)} = f^{(0)} \mathcal{P}_G^t$. A stationary distribution satisfies $\pi = \pi \mathcal{P}_G$ (i.e., corresponds to a left eigenvector of $\mathcal{P}_G$ for the eigenvalue 1).
3. If the graph G has no isolated vertices, then $\mathcal{P}_G = D_G^{-1/2}(I - \mathcal{L}_G) D_G^{1/2}$, where D_G is the diagonal degree matrix. In particular, when G has no isolated vertices, then $I - \mathcal{L}_G$ and $\mathcal{P}_G$ are cospectral.
4. A lazy random walk is equivalent to taking a random walk on the graph where we either add a loop of weight $pd_i/(1-p)$ or if a loop is already present by increasing the weight of the loop by $pd_i/(1-p)$.
5. [Chu97, Sect. 1.5] If G is connected and not bipartite, then the random walk on the graph is ergodic. (For directed graphs, the condition of being bipartite is replaced by being aperiodic.) In particular, for any initial probability distribution $f^{(0)}$ we have
$$\lim_{t \to \infty} f^{(0)} \mathcal{P}_G^t = \pi = \frac{\mathbf{1}^T D_G}{\mathrm{vol}(G)},$$
where $\mathbf{1}$ is the all 1s vector and D_G is the diagonal degree matrix. If G is connected, then the lazy random walk on the graph is ergodic.

6. [Chu97, Sect. 1.5] If $0 = \lambda_0 < \lambda_1 \le \cdots \le \lambda_{n-1} < 2$ are the eigenvalues of $\mathcal{L}_G$ and we let $\widehat{\lambda} = \max\{1 - \lambda_1, \lambda_{n-1} - 1\}$, then
$$\|f^{(0)}\mathcal{P}_G^t - \pi\| \le \widehat{\lambda}^t \frac{\max_x \sqrt{d_x}}{\min_y \sqrt{d_y}}.$$

Examples:

1. [DGM90] Let G be the n-cube graph and let $N = \frac{1}{4}n\log n + cn$. Then for f being the probability distribution with initial weight all at some vertex
$$\left\|f\mathcal{P}_G^N - \frac{1}{2^n}\mathbf{1}^T\right\| \approx \frac{2}{\sqrt{\pi}}\int_0^{e^{-2c}/\sqrt{8}} e^{-t^2}\,dt.$$
This bound is much better than the spectral bound in Fact 6 applied to the cube graph, thus showing some limitations of spectral techniques.

47.3 Graphs with Shared Eigenvalues

Cospectral graphs have the same eigenvalues including multiplicities and help us understand weaknesses in identifying structures only using the spectrum. A graph can also share some of its eigenvalues with a smaller related graph.

Definitions:

An **equitable partition** of the vertices of a simple graph G is a partition $V = V_1 \cup V_2 \cup \cdots \cup V_k$ such that for each $v \in V_i$ the number of adjacent vertices in V_j does not depend on v. This includes the situation with $i = j$. In a weighted graph, this is similarly defined but now we need the sum of the weights from $v \in V_i$ to vertices in V_j to be independent of v.

An **automorphism** of a weighted graph G is a mapping $\pi : V(G) \to V(G)$ (i.e., a relabeling of the vertices) such that for each $u, v \in V(G)$ we have $w(u,v) = w\big(\pi(u), \pi(v)\big)$.

A weighted graph G is a **cover** of a weighted graph H if there is a surjective map $\pi : V(G) \to V(H)$ which preserves edge weights so that for each vertex $v \in V(G)$ the restriction of π to the neighborhood of v is a bijection.

Let G be a simple graph with $V = C_1 \cup C_2 \cup \cdots \cup C_k \cup E$ where the graph restricted to $C_1 \cup \cdots \cup C_k$ forms an equitable partition and for each $v \in E$ the number of neighbors of v in C_i is either 0, $\frac{1}{2}|C_i|$ or $|C_i|$. **Godsil-McKay switching** on one of the C_i is the operation taking all of the vertices $v \in E$ which have $\frac{1}{2}|C_i|$ neighbors in C_i and replacing edges by non-edges and vice versa between E and C_i.

A **distance transitive graph** is a graph where whenever the distance between x and y equals the distance between z and w, then there is an automorphism that sends x to z and y to w.

The **join** of two simple graphs G_1 and G_2 is formed by taking disjoint copies of G_1 and G_2 and adding an edge between each vertex of G_1 and each vertex of G_2.

Facts:

1. An automorphism of a weighted graph produces an equitable partition by grouping vertices into orbits.
2. [BH12, Sect. 6.4] If the weighted graph G is a cover of the weighted graph H, then the eigenvalues of $\mathcal{A}_H$ (L_H, $|L_H|$, and $\mathcal{L}_H$, respectively), counting multiplicity, are also eigenvalues of $\mathcal{A}_G$ (L_G, $|L_G|$, and $\mathcal{L}_G$, respectively).

3. [GR01, Sect. 9.3] Given an equitable partition $V = V_1 \cup \cdots \cup V_k$ of a weighted graph G we can form a matrix $\mathcal{B}$ by letting $\mathcal{B}_{ij} = e(u, V_j)$ where $u \in V_i$ (the matrix $\mathcal{B}$ need not be symmetric and so can be interpreted as the adjacency matrix of a weighted directed graph). Then the eigenvalues of $\mathcal{B}$ are also eigenvalues of $\mathcal{A}_G$ (including multiplicity).
4. Given an equitable partition $V = V_1 \cup \cdots \cup V_k$ of a weighted graph G we can form a new graph H with vertices $v_1, \ldots, v_k$ and edge weights $w(v_i, v_j) = e(V_i, V_j)$. Then the eigenvalues of $\mathcal{L}_H$ are also eigenvalues of $\mathcal{L}_G$ (including multiplicity).[2]
5. [Chu97, Theorem 7.11] The eigenvalues for the normalized Laplacian (not counting multiplicity) of a weighted distance transitive graph of diameter D are the eigenvalues of a normalized Laplacian for a weighted path on $D + 1$ vertices. In particular, such a graph has precisely $D + 1$ distinct eigenvalues.
6. [BH12, Sect. 1.8.3] Let G be a simple graph and let G' be a graph related to G under Godsil-McKay switching. Then G and G' are cospectral with respect to $\mathcal{A}_G$.
7. [Cav10, Sect. 2.5] Let G be a simple graph and let G' be a graph related to G under Godsil-McKay switching. If the degrees of G and G' agree, then G and G' are cospectral with respect to $\mathcal{L}_G$.
8. [But08, Sect. 2.3] Let G_1 be a weighted graph on n vertices with each vertex of degree r and G_2 be a weighted graph on m vertices with each vertex of degree s and let G be the join of G_1 and G_2.
   (a) If $0 = \lambda_0^{(1)} \le \lambda_1^{(1)} \le \cdots \le \lambda_{n-1}^{(1)}$ and $0 = \lambda_0^{(2)} \le \lambda_1^{(2)} \le \cdots \le \lambda_{m-1}^{(2)}$ are the eigenvalues of $\mathcal{L}_{G_1}$ and $\mathcal{L}_{G_2}$, respectively, then the eigenvalues for $\mathcal{L}_G$ are

   $$0, \frac{m + r\lambda_1^{(1)}}{m+r}, \ldots, \frac{m + r\lambda_{n-1}^{(1)}}{m+r}, \frac{n + s\lambda_1^{(2)}}{n+s}, \ldots, \frac{n + s\lambda_{m-1}^{(2)}}{n+s}, 2 - \frac{r}{m+r} - \frac{s}{n+s}.$$

   (b) If $\alpha_0^{(1)} \le \alpha_1^{(1)} \le \cdots \le \alpha_{n-1}^{(1)} = r$ and $\alpha_0^{(2)} \le \alpha_1^{(2)} \le \cdots \le \alpha_{m-1}^{(2)} = s$ are the eigenvalues of $\mathcal{A}_{G_1}$ and $\mathcal{A}_{G_2}$, respectively, then the eigenvalues for $\mathcal{A}_G$ are

   $$\alpha_0^{(1)}, \ldots, \alpha_{n-2}^{(1)}, \alpha_0^{(2)}, \ldots, \alpha_{m-2}^{(2)}, \frac{r + s \pm \sqrt{(r-s)^2 + 4mn}}{2}.$$

9. [But08, Sect. 4.6.1] Let G be a bipartite simple graph with no isolated vertices where the vertices are partitioned into $V = V_1 \cup V_2$ with $|V_1| = p \le |V_2| = q$. Let the graphs G_1 and G_2 be formed as follows (in the notation below we let V_i' denote a copy of V_i):

   $$\begin{aligned} V(G_1) &= V_1 \cup V_1' \cup V_2 \\ E(G_1) &= \big\{\{v_1, v_2\}, \{v_1', v_2\} \mid \{v_1, v_2\} \in E(G)\big\} \\ V(G_2) &= V_1 \cup V_2 \cup V_2' \\ E(G_2) &= \big\{\{v_1, v_2\}, \{v_1, v_2'\} \mid \{v_1, v_2\} \in E(G)\big\} \end{aligned}$$

   Then the spectrum of $\mathcal{L}_{G_1}$ and $\mathcal{L}_{G_2}$ differ by $q - p$ eigenvalues of 1; the spectrum of $\mathcal{A}_{G_1}$ and $\mathcal{A}_{G_2}$ differ by $q - p$ eigenvalues of 0. In particular if $q = p$, the graphs G_1 and G_2 are cospectral both with respect to the adjacency matrix and the normalized Laplacian matrix.

---

[2] See Example 1 for a proof.

Examples:

1. Fact 4 shares similarities with Fact 3. However, where in Fact 3 the "weight" function from the equitable partition is generally not symmetric, in Fact 4 the resulting weight function will always be symmetric. The two results can be proved in a similar way. Since Fact 4 has not previously appeared we give a proof for completeness. Before we begin we note without loss of generality that we may assume there are no isolated vertices.
   Let S be the $n \times k$ matrix defined by $S = D_G^{1/2}\widehat{S}D_H^{-1/2}$ where $\widehat{S}_{ij} = 1$ if $v_i \in V_j$ and 0 otherwise. In particular, $S_{ij} = \sqrt{d_i/\operatorname{vol}(V_j)} = \sqrt{1/|V_j|}$ if $v_i \in V_j$; so the columns of S are orthonormal.
   We have
   $$\mathcal{L}_G S = D_G^{-1/2}(D_G - \mathcal{A}_G)D_G^{-1/2}D_G^{1/2}\widehat{S}D_H^{-1/2} = D_G^{-1/2}(D_G - \mathcal{A}_G)\widehat{S}D_H^{-1/2}.$$
   This gives
   $$\begin{aligned}\big(\mathcal{L}_G S\big)_{ij} &= \begin{cases} \frac{1}{\sqrt{d_i}}\big(d_i - \sum_{v_k \in V_j} w(v_i,v_k)\big)\frac{1}{\sqrt{\operatorname{vol}(V_j)}} & \text{if } v_i \in V_j \\ -\frac{1}{\sqrt{d_i}}\sum_{v_k \in V_j} w(v_i,v_k)\frac{1}{\sqrt{\operatorname{vol}(V_j)}} & \text{if } v_i \in V_\ell \neq V_j \end{cases} \\ &= \begin{cases} \frac{1}{\sqrt{|V_j|}}\big(1 - \frac{e(V_j,V_j)}{\operatorname{vol}(V_j)}\big) & \text{if } v_i \in V_j \\ \frac{1}{\sqrt{|V_\ell|}}\big(-\frac{e(V_\ell,V_j)}{\sqrt{\operatorname{vol}(V_\ell)\operatorname{vol}(V_j)}}\big) & \text{if } v_i \in V_\ell \neq V_j \end{cases} \\ &= \frac{1}{\sqrt{|V_\ell|}}\big(\mathcal{L}_H\big)_{\ell j} \qquad (\text{where } v_i \in V_\ell) \\ &= (S\mathcal{L}_H)_{ij}.\end{aligned}$$
   In going from the first to the second line we used that we have an equitable partition and so for $v_i \in V_\ell$ we have $d_i = \operatorname{vol}(V_\ell)/|V_\ell|$ and also $\sum_{v_k \in V_j} w(v_i,v_k) = e(V_\ell,V_j)/|V_\ell|$, the rest is simplifying. We can conclude that $\mathcal{L}_G S = S\mathcal{L}_H$.
   Let T be an $n \times (n-k)$ matrix so that the matrix $(S\ T)$ is invertible (i.e., the matrix formed by first putting in the columns of S followed by the columns of T). For some matrices B and C we have
   $$\mathcal{L}_G(S\ T) = (S\ T)\begin{pmatrix} \mathcal{L}_H & B \\ O & C \end{pmatrix}.$$
   Since $(S\ T)$ is invertible, it follows that the eigenvalues of $\mathcal{L}_H$, including multiplicity, are eigenvalues of $\mathcal{L}_G$.
2. As an example of Fact 2, for $p \geq 3$ the cycle graph C_{pq} is a cover of C_p by the map $\pi(v_i) = v_{(i \mod p)}$. So the eigenvalues of the cycle graph C_p are also eigenvalues of C_{pq}. The collection of pre-images of vertices $u \in C_p$ under the map π form an equitable partition of C_{pq}.
3. As an example of Fact 6, two graphs related under Godsil-McKay switching are shown in Figure 47.3. (The central vertex corresponds to E and the outer cycle corresponds to a single set C.)
4. [But08, Sect. 2.3.1] As an example of Fact 8, the wheel graph on $n+1$ vertices is formed by taking the join of an isolated vertex with a cycle on n vertices. So the eigenvalues of the wheel graph for the normalized Laplacian are:
   $$\Big\{0, \underbrace{1 - \frac{2}{3}\cos\frac{2\pi k}{n}}_{k=1,\ldots,n-1}, \frac{4}{3}\Big\}.$$

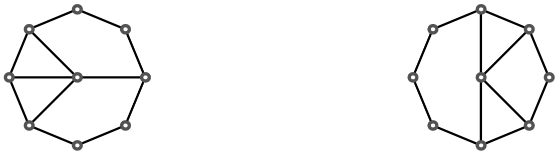

FIGURE 47.3 Two graphs related by Godsil-McKay switching.

5. [But08, Sect. 4.6.1] As an example of Fact 9, the graphs shown in Figure 47.4 are cospectral by duplicating different sides of bipartite graphs.

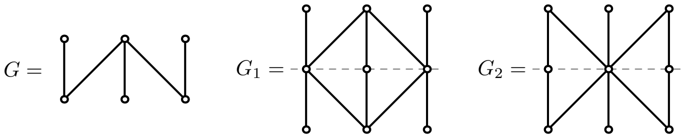

FIGURE 47.4 An example of constructing cospectral graphs by duplicating the two different sides of the bipartite graph.

47.4 Interlacing Eigenvalues

Graphs can be related to one another via some small perturbation such as removal of edges or vertices. The result of such a small perturbation changes the eigenvalues; however, the different spectra are still closely related and often interlace. This can allow us to make conclusions about the eigenvalues of a graph when some small structure is removed (or added). In particular if a graph has an eigenvalue with high multiplicity, then removing a small enough substructure results in a graph with the same eigenvalue.

Definitions:

A **subgraph** of a weighted graph G is a weighted graph H on a subset of the vertices of G and satisfying $w_H(v_i, v_j) \leq w_G(v_i, v_j)$ for all vertices (with the convention that $w_H(v_i, v_j) = 0$ if v_i or v_j is not a vertex in H). If H is a subgraph of G, then $G - H$ is the weighted graph with weight function $w_{G-H}(v_i, v_j) = w_G(v_i, v_j) - w_H(v_i, v_j)$.

A weighted graph G is a **weak cover** of the weighted graph H if there is some mapping of the vertices $\pi : V(G) \to V(H)$ so that for all $v_i, v_j \in V(H)$:

$$w_H(v_i, v_j) = \sum_{\substack{x \in \pi^{-1}(v_i) \\ y \in \pi^{-1}(v_j)}} w_G(x, y).$$

Facts:

1. [BH12, Sect. 3.2] Let G be a weighted graph with vertex v. If $\alpha_1 \leq \alpha_2 \leq \cdots \leq \alpha_n$ are the eigenvalues of $\mathcal{A}_G$ and $\widehat{\alpha}_1 \leq \widehat{\alpha}_2 \leq \cdots \leq \widehat{\alpha}_{n-1}$ are the eigenvalues of A_{G-v}, then

$$\alpha_i \leq \widehat{\alpha}_i \leq \alpha_{i+1}.$$

2. [BH12, Sect. 3.2] Let G be a weighted graph with edge e. If $0 = \theta_1 \leq \theta_2 \leq \cdots \leq \theta_n$ are the eigenvalues of L_G and $0 = \widehat{\theta}_1 \leq \widehat{\theta}_2 \leq \cdots \leq \widehat{\theta}_n$ are the eigenvalues of L_{G-e},

then

$$\theta_{i-1} \le \widehat{\theta}_i \le \theta_i.$$

3. [Lot07] Let G be a simple graph and with vertex v. If $0 = \theta_1 \le \theta_2 \le \cdots \le \theta_n$ are the eigenvalues of L_G and $0 = \widehat{\theta}_1 \le \widehat{\theta}_2 \le \cdots \le \widehat{\theta}_{n-1}$ are the eigenvalues of L_{G-v}, then

$$\theta_i - 1 \le \widehat{\theta}_i \le \theta_{i+1}.$$

4. [But07] Let G be a weighted graph and let H be a subgraph of G where H has t vertices none of which are isolated. If $\lambda_0 \le \lambda_1 \le \cdots \le \lambda_{n-1}$ are the eigenvalues of $\mathcal{L}_G$ and $\widehat{\lambda}_0 \le \widehat{\lambda}_1 \le \cdots \le \widehat{\lambda}_{n-1}$ are the eigenvalues of $\mathcal{L}_{G-H}$, then

$$\lambda_{k-t+1} \le \widehat{\lambda}_k \le \begin{cases} \lambda_{k+t-1} & \text{if } H \text{ is bipartite} \\ \lambda_{k+t} & \text{otherwise} \end{cases}$$

where $\lambda_{-t+1} = \cdots = \lambda_{-1} = 0$ and $\lambda_n = \cdots = \lambda_{n+t-1} = 2$.

5. [But07] Suppose the weighted graph G is a weak cover of the weighted graph H with n and m vertices, respectively, and let $\lambda_0 \le \cdots \le \lambda_{n-1}$ be the eigenvalues of $\mathcal{L}_G$ and $\widehat{\lambda}_0 \le \cdots \le \widehat{\lambda}_{m-1}$ be the eigenvalues of $\mathcal{L}_H$. Then for $k = 0, 1, \ldots, m-1$ we have

$$\lambda_k \le \lambda_k \le \lambda_{k+(n-m)}.$$

Examples:

1. As an illustration of Fact 4, if G is a simple graph on n vertices and more than $n/2$ of the vertices have degree $n-1$, then $\frac{n}{n-1}$ is an eigenvalue of the normalized Laplacian of G.
2. An example of a graph and a weak covering is shown in Figure 47.5.

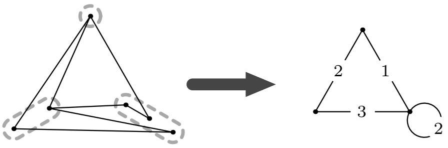

FIGURE 47.5 An example of a graph G (on left) which is a weak cover of a graph H (on right).

47.5 Isoperimetric Problems

One of the most useful ways to understand a graph is to understand how to cut it into smaller graphs. In this section we will look at some of the connections between cuts and the spectrum of graphs. This section is closely related to Chapter 48 on algebraic connectivity.

Definitions:

Notation: G denotes a weighted graph.

Given subsets S and T of the vertices we let $E(S,T) = \{\text{edges with one end in } S \text{ and one end in } T\}$. By convention, if $S \cap T \ne \emptyset$, then an edge with both ends in $S \cap T$ will appear twice in $E(S,T)$.

The **edge boundary** of a subset of the vertices is $\partial S = E(S, \overline{S})$, i.e., the minimal set of edges needed to be removed which disconnects S from the rest of the graph.

For a graph that is not the complete graph, the **vertex boundary**, denoted δS, is the minimal set of vertices outside of S whose removal disconnects S from the rest of the graph.

The **Cheeger constant** of a set $S \subseteq V(G)$, denoted $h_G(S)$ is

$$h_G(S) = \frac{|\partial S|}{\operatorname{vol}(S)}.$$

The **Cheeger constant of the graph**, denoted h_G, is given by the following:

$$h_G = \min_{S \subset V} \left(\frac{|\partial S|}{\min\{\operatorname{vol}(S), \operatorname{vol}(\overline{S})\}} \right) = \min_{\substack{S \subset V \\ \operatorname{vol}(S) \le \frac{1}{2} \operatorname{vol}(G)}} \{h_G(S)\}.$$

(Roughly, this gives a measure of how well we can find a small edge-cut to break the graph into two large pieces.) Similarly,

$$g_G = \min_{S \subset V} \left(\frac{|\delta S|}{\min\{\operatorname{vol}(S), \operatorname{vol}(\overline{S})\}} \right).$$

The **isoperimetric number** of a simple graph is defined as

$$h'_G = \min_{S \subset V} \left(\frac{|\partial S|}{\min\{|S|, |\overline{S}|\}} \right).$$

Facts:

1. If the simple graph is k-regular, then $h_G = \frac{1}{k} h'_G$.
2. [Chu97, Sects. 2.3 and 2.4] Let the weighted graph G be connected but not the complete graph and let $0 = \lambda_0 < \lambda_1 \le \cdots \le \lambda_{n-1}$ be the eigenvalues of $\mathcal{L}_G$, let $0 = \phi_0 < \phi_1 \le \cdots \le \phi_{n-1}$ be the eigenvalues of L_G, and let Δ denote the maximum degree of G. Then the following hold:
   (a) $\frac{1}{2} h_G^2 \le 1 - \sqrt{1 - h_G^2} < \lambda_1 \le 2h_G$.
   (b) $\frac{1}{2\Delta} (h'_G)^2 < \phi_1 \le 2h'_G$.
   (c) $\frac{g_G^2}{4\Delta + 2\Delta g_G^2} \le \lambda_1$.
3. [Chu97, Sect. 2.3] Let $\mathbf{x}$ be the eigenvector associated with eigenvalue λ_1 of $\mathcal{L}_G$ for the weighted graph G. Further suppose that the vertices are ordered such that $\mathbf{x}(v_1) \le \mathbf{x}(v_2) \le \cdots \le \mathbf{x}(v_n)$. Let

   $$\alpha = \min_{1 \le i \le n-1} \left(\frac{e\big(\{v_1, \dots, v_i\}, \{v_{i+1}, \dots, v_n\}\big)}{\min\left(\sum_{j \le i} d_j, \sum_{j > i} d_j\right)} \right).$$

   Then $1 - \sqrt{1 - h_G^2} \le \alpha \le \lambda_1$.
4. [But08, Sect. 5.6.1] Let G be a weighted graph with no isolated vertices and let $0 = \lambda_0 \le \lambda_1 \le \cdots \le \lambda_{n-1}$ be the eigenvalues of $\mathcal{L}_G$. Then for every partitioning of the vertices into $N_1 \cup \cdots \cup N_m$

   $$\sum_{i=0}^{m-1} \lambda_i \le \sum_{i=0}^{m-1} \frac{e(N_i, \overline{N_i})}{\operatorname{vol}(N_i)} = \sum_{i=0}^{m-1} h_G(N_i) \le \sum_{i=0}^{m-1} \lambda_{n-1-i}.$$

Examples:

1. The Cheeger constant of the (simple) path on n vertices is $1/(n-1)$ for n even and $1/(n-2)$ for n odd. The Cheeger constant for the n-cube is $2/n$. These show that the inequalities relating the Cheeger constants and λ_1 are best possible up to a constant.
2. The use of eigenvectors to find good cuts, as alluded to in Fact 3, is the basis of spectral clustering and spectral cuts.

47.6 Quasirandom Graphs

Random graphs have been shown to have many useful and interesting properties. It is of interest to know if a particular graph has some of these properties; this has led to the theory of quasirandom graphs, which give a way to certify that a graph has random-like properties through an examination of the eigenvalues or other properties. This is also connected to what are known as pseudorandom graphs.

Definitions:

A **graph property** $P = P(\varepsilon)$ is a property that a graph might satisfy involving some tolerance $\varepsilon > 0$. By $P \Rightarrow Q$ we mean that for each $\varepsilon > 0$ there is a $\delta > 0$ so that if G satisfies the property $P(\delta)$, then G must also satisfy the property $Q(\varepsilon)$. Two graph properties P and Q are equivalent if $P \Rightarrow Q$ and $Q \Rightarrow P$.

The **discrepancy of a graph**, denoted $\operatorname{disc}(G)$, is the minimal α so that for all $X, Y \subseteq V$ we have

$$\left| e(X,Y) - \frac{\operatorname{vol}(X)\operatorname{vol}(Y)}{\operatorname{vol}(G)} \right| \le \alpha\sqrt{\operatorname{vol}(X)\operatorname{vol}(Y)}.$$

(Roughly this is a measurement of how randomly edges are placed.)

The **square product** of two graphs $G = \big(V(G), E(G)\big)$ and $H = \big(V(H), E(H)\big)$, denoted $G\square H$, is the graph with vertex set $V(G\square H) = V(G) \times V(H) = \{(x,y) \mid x \in V(G), y \in V(H)\}$ and edge set

$$E(G\square H) = \big\{\{(x_i,y_i),(x_j,y_j)\} \mid \text{if exactly one of } (x_i,x_j) \text{ and } (y_i,y_j) \text{ is an edge}\big\}.$$

(The square product of two graphs is not the same as the Cartesian product, which in some sources also uses the "□" notation.)

Facts:

1. [Chu97, CGW89] The following properties are all equivalent for simple graphs and are known as quasirandom graph properties.
   (a) P_1: Let $0 \le \lambda_1 \le \lambda_2 \le \cdots \le \lambda_{n-1}$ be the eigenvalues of $\mathcal{L}_G$. Then we have $\max\{|1-\lambda_1|, |\lambda_{n-1}-1|\} \le \varepsilon$ and all but εn vertices have degree $(1/2 \pm \varepsilon)n$.
   (b) P_2: For each $S \subseteq V$, the number of edges with both ends in S is $\frac{1}{4}|S|^2 \pm \varepsilon n^2$.
   (c) P_3: For each $S \subseteq V$ with $|S| = \lfloor n/2 \rfloor$, the number of edges with both ends in S is $(\frac{1}{16} \pm \varepsilon)n^2$.
   (d) P_4: For $u \in V$ let N_u denote the neighbors of u. Then

$$\sum_{u,v} \left| N_u \cap N_v - \frac{n}{4} \right| \le \varepsilon n^2.$$

(e) P_5: The number of edges in G is $\geq (1-\varepsilon)n^2/4$ and the number of occurrences of C_4 (the cycle on 4 vertices) in G as a labeled subgraph is $(1\pm\varepsilon)n^4/16$.

(f) $P_6(s)$ for $s \geq 4$: For *all* graphs H on s vertices, the number of labeled induced subgraphs of G isomorphic to H is $(1\pm\varepsilon)n^s 2^{-\binom{s}{2}}$.

2. [CG91] If G and H are simple quasirandom graphs, then $G\Box H$ is a simple quasirandom graph.
3. [Chu04] Let $0 \leq \phi_1 \leq \phi_2 \leq \cdots \leq \phi_{n-1}$ be the eigenvalues of L_G for a simple graph G. Further suppose that the graph has average degree d and that $|d-\phi_i| \leq \theta$ for $i \neq 0$. Then for all $X, Y \subseteq V$
$$\left|e(X,Y) - \frac{d}{n}|X||Y|\right| \leq \frac{\theta}{n}\sqrt{|X|(n-|X|)|Y|(n-|Y|)}.$$
4. [But06] Let $0 \leq \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_{n-1}$ be the eigenvalues of $\mathcal{L}_G$ for a weighted graph G. Then
$$\operatorname{disc}(G) \leq \max\{|1-\lambda_1|, |\lambda_{n-1}-1|\} \leq 150\operatorname{disc}(G)\big(1-8\log\operatorname{disc}(G)\big).$$
In particular, $\operatorname{disc}(G)$ is small if and only if $\max\{|1-\lambda_1|, |\lambda_{n-1}-1|\}$ is small.

Examples:

1. The graph $P_3\Box P_3$ is shown in Figure 47.6.

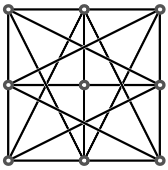

FIGURE 47.6 The graph $P_3\Box P_3$.

2. [CGW89] For a prime $p \equiv 1 \pmod 4$ construct the graph G with vertices $0, 1, \ldots, p-1$ and an edge joins vertex i with vertex j if and only if $i-j$ is a quadratic residue modulo p. This is the Paley graph and is known to be an example of a quasirandom graph family, which satisfies the above properties with $\varepsilon \to 0$ as $p \to \infty$.
3. [CG91] Let G be the graph with vertices indexed by the subsets of $\{1, 2, \ldots, n\}$ and two vertices X and Y are adjacent if and only if $\big|X \cap Y\big| \equiv 0 \pmod 2$. Then G is quasirandom and this family satisfies the above properties with $\varepsilon \to 0$ as $n \to \infty$.

48.1 Algebraic Connectivity for Simple Graphs: Basic Theory

Let G be a simple graph on $n \geq 2$ vertices with Laplacian matrix L_G, and label the eigenvalues of L_G as $0 = \mu_1 \leq \mu_2 \leq \ldots \leq \mu_n$. Throughout this chapter, we consider only Laplacian matrices for graphs on at least two vertices. Henceforth, we use the term *graph* to refer to a simple graph.

Definitions:

The **algebraic connectivity of** G, denoted $\alpha(G)$, is given by $\alpha(G) = \mu_2$.

A **Fiedler vector** is an eigenvector of L_G corresponding to $\alpha(G)$.

The **support** of a vector is the collection of indices corresponding to its nonzero entries.

Given graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, their **Cartesian product**, $G_1 \times G_2$, is the graph with vertex set $V_1 \times V_2$, with vertices (u_1, u_2) and (w_1, w_2) adjacent if and only if either u_1 is adjacent to w_1 in G_1 and $u_2 = w_2$, or u_2 is adjacent to w_2 in G_2 and $u_1 = w_1$.

The symbol $G \dot{\cup} H$ denotes the union of the vertex–disjoint graphs G and H.

Facts:

1. [Fie89] Let G be a graph of order n with Laplacian matrix L_G. Then $\alpha(G) = \min\{\sum_{i<j,\{i,j\}\in E}(x_i - x_j)^2 | \sum_{1\leq i\leq n} {x_i}^2 = 1, \sum_{1\leq i\leq n} x_i = 0\} = \min\{x^T L_G x | x^T x = 1, x^T \mathbf{1} = 0\}$.
2. [Fie73] The algebraic connectivity of a graph is nonnegative, and is equal to 0 if and only if the graph is disconnected.
3. [Fie73] Let G be a connected graph on n vertices with vertex connectivity $\kappa(G)$, and suppose that $G \neq K_n$. Then $\alpha(G) \leq \kappa(G)$. (See Fact 14 for a discussion of the equality case.)

4. [Fie73] Suppose that G is a graph on n vertices, and let $\overline{G}$ denote the complement of G. Then $\alpha(\overline{G}) = n - \mu_n$, where μ_n denotes the largest Laplacian eigenvalue for G.
5. ([GR01], p. 280) If G is a graph on $n \geq 2$ vertices that is regular of degree k, then denoting the eigenvalues of $\mathcal{A}_G$ by $\lambda_1 \leq \ldots \leq \lambda_n$, we have $\alpha(G) = k - \lambda_{n-1}$.
6. [Mer94] Suppose that G_1 and G_2 are two graphs on n_1 and n_2 vertices, respectively, with $n_1, n_2 \geq 2$. Then $\alpha(G_1 + G_2) = \min\{\alpha(G_1) + n_2, \alpha(G_2) + n_1\}$. Similarly, if H is a graph on $k \geq 2$ vertices, then $\alpha(H + K_1) = \alpha(H) + 1$.
7. [Fie73] Suppose that G_1 and G_2 are graphs, each of which has at least two vertices. Then $\alpha(G_1 \times G_2) = \min\{\alpha(G_1), \alpha(G_2)\}$.
8. [Fie73] Suppose that the graph $\hat{G}$ is formed from the graph G by adding an edge not already present in G. Then $\alpha(G) \leq \alpha(\hat{G})$.
9. [FK98] Let G and H be graphs, and suppose that the graph $\hat{G}$ is formed from $G \dot{\cup} H$ as follows: Fix a vertex v of G and a subset S of the vertex set for H, and for each $w \in S$, add in the edge between v and w. Then $\alpha(\hat{G}) \leq \alpha(G)$.
10. [Fie73] Let G be a graph, and suppose that the graph $\hat{G}$ is formed from G by deleting a collection of k vertices and all edges incident with them. Then $\alpha(\hat{G}) \geq \alpha(G) - k$.
11. [Kir10] Let G be a graph, and suppose that the graph $\hat{G}$ is formed from G by deleting a vertex v and all edges incident with v. Then $\alpha(\hat{G}) = \alpha(G) - 1$ if and only if there is a Fiedler vector for G whose support is a subset of the set of neighbors of v.
12. [GMS90] Let G be a graph on $n \geq 3$ vertices and suppose that the edge e of G is not on any 3-cycles. Form $\hat{G}$ from G by deleting e and identifying the two vertices incident with it. Then $\alpha(\hat{G}) \geq \alpha(G)$.
13. [Fie73] If G is a graph on n vertices, then $\alpha(G) \leq n$. Equality holds if and only if $G = K_n$.
14. [KMNS02] Let G be a connected graph on n vertices with vertex connectivity $\kappa(G)$, and suppose that $G \neq K_n$. Then $\alpha(G) = \kappa(G)$ if and only if G can be written as $G = G_1 + G_2$, where G_1 is disconnected, G_2 has $\kappa(G)$ vertices, and $\alpha(G_2) \geq 2\kappa(G) - n$.
15. [Fie89] If G is a connected graph on n vertices with edge connectivity $\kappa_e(G)$, then $2(1 - \cos(\frac{\pi}{n}))\kappa_e(G) \leq \alpha(G)$. Equality holds if and only if $G = P_n$.
16. [Kir10] Let G be a connected graph on $n \geq 3$ vertices, and suppose that the graph $\hat{G}$ is formed from G by deleting a vertex v and all edges incident with v. Then $\alpha(\hat{G}) \leq \alpha(G) + n - 2$. Equality holds if and only if $G = (K_{n-2} \dot{\cup} K_1) + K_1$ and v is a pendent vertex in G.

Examples:

1. ([GK69], p. 138) For $n \geq 2$, the algebraic connectivity of the path P_n is $2(1 - \cos(\frac{\pi}{n}))$, and it is a simple eigenvalue of the corresponding Laplacian matrix.
2. The following can be deduced from basic results on circulant matrices. If $n \geq 3$, the algebraic connectivity of the cycle C_n is $2(1 - \cos(\frac{2\pi}{n}))$, and it is an eigenvalue of multiplicity 2 of the corresponding Laplacian matrix.
3. The algebraic connectivity of K_n is n, and it is an eigenvalue of multiplicity $n - 1$ of the corresponding Laplacian matrix.
4. If $m \leq n$ and $2 \leq n$, then $\alpha(K_{m,n}) = m$. If $1 \leq m < n$, then m is an eigenvalue of multiplicity $n - 1$ of the corresponding Laplacian matrix, while if $2 \leq m = n$, then m is an eigenvalue of multiplicity $2m - 2$ of the corresponding Laplacian matrix.
5. The algebraic connectivity of the Petersen graph is 2, and it is an eigenvalue of multiplicity 5 of the corresponding Laplacian matrix.
6. The algebraic connectivity of the ladder on 6 vertices, shown in Figure 48.1, is 1.
7. Graphs with large algebraic connectivity arise in the study of the class of so-called expander graphs. (See Section 39.5 or [Alo86] for definitions and discussion.)
8. A Fiedler vector for a graph provides a heuristic for partitioning its vertex set so that the

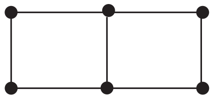

FIGURE 48.1 The ladder on 6 vertices.

number of edges between the two parts is small (see [Moh92] for a discussion), and that heuristic has applications to sparse matrix computations (see [PSL90]).

9. For a connected graph G, the asymptotic rate of convergence of a certain distributed linear consensus protocol for G is given by $\alpha(G)$ (see [SM03]).

48.2 Algebraic Connectivity for Simple Graphs: Further Results

The term *graph* means *simple graph* in this section.

Definitions:

Let $G = (V, E)$ be a graph, and let $X, V\backslash X$ be a nontrivial partitioning of V. The corresponding **edge cut** is the set E_X of edges of G that have one end point in X and the other end point in $V\backslash X$.

Suppose that G_1 and G_2 are graphs. A graph H is formed by **appending** G_2 **at vertex** v **of** G_1 if H is constructed from $G_1\dot{\cup}G_2$ by adding an edge between v and a vertex of G_2.

Suppose that $g, n \in \mathbb{N}$ with $n > g \geq 3$. The graph $C_{n,g}$ is formed by appending the cycle C_g at a pendent vertex of the path P_{n-g}.

Suppose that $g, n \in \mathbb{N}$ with $n > g \geq 3$. Let $D_{g,n-g}$ denote the graph formed from the cycle C_g by appending $n - g$ isolated vertices at a single vertex of that cycle.

For a connected graph G, a vertex v is a **cut-vertex** if $G - v$, the graph formed from G by deleting the vertex v and all edges incident with it, is disconnected.

A graph is **unicyclic** if it contains precisely one cycle.

A graph is **planar** if it can be drawn on a plane so that no pairs of edges cross.

Let S_k be a sphere with k handles. A graph has **genus** k if it can be embedded on S_k but not on S_{k-1}.

Facts:

1. [Moh91] If G is a connected graph on n vertices with diameter d, then $\alpha(G) \geq \frac{4}{dn}$.
2. [AM85] If G is a connected graph on n vertices with diameter d and maximum degree Δ, then $d \leq 2\lceil\sqrt{\frac{2\Delta}{\alpha(G)}}log_2 n\rceil$.
3. [Moh91] If G is a connected graph on n vertices with diameter d and maximum degree Δ, then $d \leq 2\lceil\frac{\Delta+\alpha(G)}{4\alpha(G)}ln(n-1)\rceil$.
4. [Moh92] Let $G = (V, E)$ be a graph, let $X, V\backslash X$ be a nontrivial partitioning of its vertex set, and let E_X denote the corresponding edge cut. Then $\alpha(G) \leq \frac{|V||E_X|}{|X||V\backslash X|}$ and [FKP03a] if $\alpha(G) = \frac{|V||E_X|}{|X||V\backslash X|}$, then necessarily there are integers d_1, d_2 such that:
   (a) Each vertex in X is adjacent to precisely d_1 vertices in $V\backslash X$.
   (b) Each vertex in $V\backslash X$ is adjacent to precisely d_2 vertices in X.
   (c) $|X|d_1 = |V\backslash X|d_2$.
   (d) $\alpha(G) = d_1 + d_2$.
5. [Moh89] Let $G = (V, E)$ be a graph on at least four vertices, with maximum degree Δ.

Then $\frac{\alpha(G)}{2} \leq \Phi(G) \leq \sqrt{\alpha(G)(2\Delta - \alpha(G))}$, where $\Phi(G)$ is the isoperimetric number of G. (See Section 39.5.)

6. [Guo08] If $g \geq 3$, then among all connected graphs on n vertices with girth g, the algebraic connectivity is uniquely minimized by $C_{n,g}$.
7. [Kir00] Let G be a graph on n vertices, and suppose that G has k cut-vertices, where $2 \leq k \leq \frac{n}{2}$. Then $\alpha(G) \leq \frac{2(n-k)}{n-k+2+\sqrt{(n-k)^2+4}}$. For each such k and n, there is a graph on n vertices with k cut-vertices such that equality is attained in the upper bound on α.
8. [Kir01] Suppose that $n \geq 5$ and $\frac{n}{2} < k$, and let G be a graph on n vertices with k cut-vertices. Let $q = \lfloor \frac{k}{n-k} \rfloor$ and $l = k - (n-k)q$.
   (a) If $l = 1$, then $\alpha(G) \leq 2(1 - \cos(\frac{\pi}{2q+3}))$.
   (b) If $l = 0$, let θ_0 be the unique element of $\left[\frac{\pi}{2q+3}, \frac{\pi}{2q+1}\right]$ such that $(n-k-1)\cos((2q+1)\theta_0/2) + \cos((2q+3)\theta_0/2) = 0$. Then $\alpha(G) \leq 2(1 - \cos(\theta_0))$.
   (c) If $2 \leq l$, let θ_0 be the unique element of $\left[\frac{\pi}{2q+5}, \frac{\pi}{2q+3}\right]$ such that $(n-k-1)\cos((2q+3)\theta_0/2) + \cos((2q+5)\theta_0/2) = 0$. Then $\alpha(G) \leq 2(1 - \cos(\theta_0))$.

   For each k and n with $\frac{n}{2} < k$, there is a graph on n vertices with k cut-vertices such that equality is attained in the corresponding upper bound on α.
9. [FK98] Over the class of unicyclic graphs on n vertices having girth 3, the algebraic connectivity is uniquely maximized by $D_{3,n-3}$.
10. [FKP03b] Over the class of unicyclic graphs on n vertices having girth 4, the algebraic connectivity is uniquely maximized by $D_{4,n-4}$.
11. [FKP03b] Fix $g \geq 5$. There is an N such that if $n > N$, then over the class of unicyclic graphs on n vertices having girth g, the algebraic connectivity is uniquely maximized by $D_{g,n-g}$.
12. [Kir03] For each real number $r \geq 0$, there is a sequence of graphs G_k with distinct algebraic connectivities, such that $\alpha(G_k)$ converges monotonically to r as $k \to \infty$.
13. [Mol06] If G is a planar graph, then $\alpha(G) \leq 4$. Equality holds if and only if G is either K_4 or $K_{2,2,2}$.
14. [Mol06] Let G be a graph of genus $k \geq 1$, and set $p_k = \left\lfloor \frac{7+\sqrt{1+48k}}{2} \right\rfloor$. If G is the complete graph on the largest number of vertices that can be embedded in S_k, then $\alpha(G) = p_k$. Otherwise, $\alpha(G) \leq p_k - 1$.
15. [Kir10] Let G be a connected graph on $n \geq 3$ vertices, and suppose that the graph $\hat{G}$ is formed from G by deleting a vertex v and all edges incident with v. Then $\frac{\alpha(\hat{G})}{\alpha(G)} \leq n-1$. Equality holds if and only if $G = (K_{n-2} \dot{\cup} K_1) + K_1$ and v is a pendent vertex in G.
16. [Kir10] Let G be a connected graph on $n \geq 3$ vertices, and suppose that the graph $\hat{G}$ is formed from G by deleting a vertex v and all edges incident with v. Suppose that v is not a cut–vertex. Then $\frac{\alpha(\hat{G})}{\alpha(G)} \geq \frac{2-2\cos(\frac{\pi}{n-1})}{3-2\cos(\frac{\pi}{n-1})}$. If $G = P_{n-1} + K_1$ and v is the vertex of degree $n-1$ of G, then equality holds in the lower bound on $\frac{\alpha(\hat{G})}{\alpha(G)}$.
17. [KOJ11] Let G be a noncomplete graph on n vertices, and let H be a connected subgraph of $\overline{G}$ on p vertices. Then $0 \leq \alpha(G \cup H) - \alpha(H) \leq p$. We have $\alpha(G \cup H) - \alpha(H) = p$ if and only if $G \cup H = K_n$ and H is a join of two graphs. In the case that G is connected, we have $\alpha(G \cup H) - \alpha(H) = 0$ if and only if there is a Fiedler vector for G whose entries are constant on the vertices of H.
18. [Kim10] Let G be a noncomplete graph on n vertices. Denote the eigenvalues of the corresponding Laplacian matrix by $\mu_1 \leq \mu_2 \leq \ldots \leq \mu_n$, and suppose that $\mu_2 < \mu_3$. Let $\epsilon > 0$ be given. There is a bisection algorithm for identifying an edge $e_0 \in \overline{G}$ such that $\alpha(G \cup e_0) > \max\{\alpha(G \cup e) | e \in \overline{G}\} - \epsilon$. Denoting the number of edges in $\overline{G}$ by m, the computational complexity of the algorithm is $O(4mn\log_2(\frac{\mu_3-\mu_2}{\epsilon}) + \frac{4n^3}{3})$.

19. [Mos08] The following decision problem is NP–hard. Given a noncomplete graph G, a number $t > 0$ and a $k \in \mathbb{N}$, is there a subset A consisting of edges of $\overline{G}$ such that $|A| \leq k$ and $\alpha(G \cup A) \geq t$?

Examples:

1. The graph $C_{6,3}$ is shown in Figure 48.2; its algebraic connectivity is approximately 0.3249.

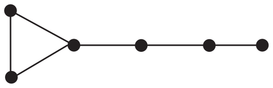

FIGURE 48.2 The graph $C_{6,3}$.

2. The graph $D_{4,3}$ is shown in Figure 48.3; its algebraic connectivity is approximately 0.7269.

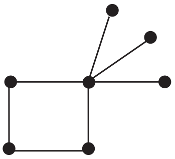

FIGURE 48.3 The graph $D_{4,3}$.

3. [FK98] The algebraic connectivity of $D_{3,n-3}$ is 1, and it is an eigenvalue of multiplicity $n-3$ of the corresponding Laplacian matrix.
4. Consider the graph G pictured in Figure 48.4. Its algebraic connectivity is 2, so that from Fact 5 above, we deduce that $1 \leq \Phi(G) \leq 2\sqrt{2}$. It turns out that the value of $\Phi(G)$ is $\frac{3}{2}$.

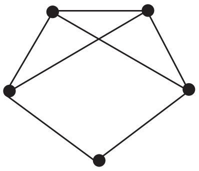

FIGURE 48.4 The graph G for Example 4.

5. [Mol06] The graph $K_{3,3,3}$ has genus 1 and algebraic connectivity $p_1 - 1 = 6$, while the graph $K_{4,4,4}$ has genus 3 and algebraic connectivity $p_3 - 1 = 8$. In particular, for these examples, equality holds in the upper bound in Fact 14 above.

48.3 Algebraic Connectivity for Trees

The term *graph* means *simple graph* in this section.

Definitions:

Let T be a tree, and let $\mathbf{y}$ be a Fiedler vector for T. A **characteristic vertex** of T is a vertex i satisfying one of the following conditions:

I $y_i = 0$, and vertex i is adjacent to a vertex j such that $y_j \neq 0$.

II There is a vertex j adjacent to vertex i such that $y_i y_j < 0$.

A tree is called **type I** if it has a single characteristic vertex, and **type II** if it has two characteristic vertices.

Let T be a tree and suppose that v is a vertex of T. The **bottleneck matrix** of a branch of T at v is the inverse of the principal submatrix of the Laplacian matrix corresponding to the vertices of that branch.

A branch at vertex v is called a **Perron branch at** v if the Perron value of the corresponding bottleneck matrix is maximal among all branches at v.

Suppose that T is a type I tree with characteristic vertex i. A branch at i is called an **active branch** if, for some Fiedler vector $\mathbf{y}$, the entries in $\mathbf{y}$ corresponding to the vertices in the branch are nonzero.

Suppose that $n \geq d+1$. Denote by $P(n,d)$ the tree constructed as follows: Begin with the path P_{d+1}, on vertices $1, \ldots, d+1$, labeled so that vertices 1 and $d+1$ are pendent, while for each $i = 2, \ldots, d$, vertex i is adjacent to vertices $i-1$ and $i+1$, then append $n-d-1$ isolated vertices at vertex $\lfloor \frac{d}{2} \rfloor + 1$ of that path.

Let $T(k,l,d)$ be the tree on $n = d+k+l$ vertices constructed from the path P_d by appending k isolated vertices at one end vertex of P_d, and appending l isolated vertices at the other end vertex of P_d.

A **caterpillar** is a tree with the property that if all pendent vertices and their incident edges are removed, what remains is a path.

Facts:

1. The bottleneck matrix for a branch is the inverse of an irreducible M-matrix, and so is entrywise positive (see Section 10.5 or [KNS96]).
2. [Fie89] If T is a tree on n vertices, then $2(1-\cos(\frac{\pi}{n})) \leq \alpha(T)$; equality holds if and only if $G = P_n$.
3. [Mer87] If T is a tree on $n \geq 3$ vertices, then $\alpha(G) \leq 1$; equality holds if and only if $G = K_{1,n-1}$.
4. [GMS90] If T is a tree with diameter d, then $\alpha(T) \leq 2(1 - cos(\frac{\pi}{d+1}))$.
5. [Fie75b] Let T be a tree on vertices labeled $1, \ldots, n$, and suppose that $\mathbf{y}$ is a Fiedler vector of T. Then exactly one of two cases can occur.
   (a) There are no zero entries in $\mathbf{y}$. Then T contains a unique edge $\{i,j\}$ such that $y_j < 0 < y_i$. As we move along any path in T that starts at i and does not contain j, the corresponding entries in $\mathbf{y}$ are positive and increasing. As we move along any path in T that starts at j and does not contain i, the corresponding entries in $\mathbf{y}$ are negative and decreasing. In this case, T is type II.
   (b) The vector $\mathbf{y}$ has at least one zero entry. Then there is a unique vertex i of T such that $y_i = 0$ and i is adjacent to a vertex j such that $y_j \neq 0$. As we move along any path in T that starts at vertex i, the corresponding entries in $\mathbf{y}$ are either increasing, decreasing, or identically zero. In this case, T is type I.
6. [KNS96] Let T be a tree and $\mathbf{y}$ be a Fiedler vector for T. Let P be a path in T that starts at a characteristic vertex i of T, and does not contain any other characteristic vertices of T. If, as we move along P away from i the entries of $\mathbf{y}$ are increasing, then they are also concave down. If, as we move along P away from i the entries of $\mathbf{y}$ are decreasing, then they are also concave up.
7. [Mer87] Let T be a tree. Then each Fiedler vector for T identifies the same vertex (or vertices) as the characteristic vertex (or vertices). Consequently, the type of the tree is independent of the particular choice of the Fiedler vector.
8. [Fie75a] If T is a type II tree, then $\alpha(T)$ is a simple eigenvalue.
9. [KNS96] A tree T is type I if and only if at some vertex i, there are two or more Perron branches. In that case, i is the characteristic vertex of T, $\alpha(T)$ is the reciprocal of the Perron value of the bottleneck matrix of a Perron branch at i, and [KF98] the multiplicity of $\alpha(T)$ is one less than the number of Perron branches at i.

10. [KNS96] A tree T is type II if and only if there is a unique Perron branch at every vertex. In this case, the characteristic vertices of T are the unique adjacent vertices i, j such that the Perron branch at vertex i is the branch containing vertex j, and the Perron branch at vertex j is the branch containing vertex i. Letting B_i and B_j denote the bottleneck matrices for the Perron branches at vertices i and j, respectively, $\exists! \gamma \in (0,1)$ such that $\rho(B_i - \gamma J) = \rho(B_j - (1-\gamma)J)$, and the common Perron value for these matrices is $1/\alpha(T)$.
11. The following is a consequence of results in [GM87] and [KNS96]. Suppose that T is a type I tree with characteristic vertex i; then a branch at i is an active branch if and only if it is a Perron branch at i.
12. [FK98] Among all trees on n vertices with diameter d, the algebraic connectivity is maximized by $P(n,d)$.
13. [FK98] Let T be a tree on n vertices with diameter d. Then

$$\alpha(T) \geq \alpha(T(\lceil \tfrac{n-d+1}{2} \rceil, \lfloor \tfrac{n-d+1}{2} \rfloor, d-1)),$$

with equality holding if and only if $T = T(\lceil \frac{n-d+1}{2} \rceil, \lfloor \frac{n-d+1}{2} \rfloor, d-1)$.
14. [BL09] Suppose that T is a tree having minimum algebraic connectivity over the class of trees with a given degree sequence. Then T is a caterpillar. Further, if $\mathbf{y}$ is a Fiedler vector for T, then letting P denote the path induced by the nonpendent vertices of T whose corresponding entries in $\mathbf{y}$ are nonnegative, it is the case that the degree sequence of the vertices on P is monotone, with a minimum at the characteristic vertex on P.

Examples:

1. [GM90] The algebraic connectivity of $T(k,l,2)$ is the smallest root of the polynomial $x^3 - (k+l+4)x^2 + (2k+2l+kl+5)x - (k+l+2)$.
2. Let T be the tree constructed as follows: At a single vertex v, append $k \geq 2$ copies of the path P_2 and $l \geq 0$ pendent vertices. For each branch at v consisting of a path on two vertices, the bottleneck matrix can be written as $\begin{bmatrix} 2 & 1 \\ 1 & 1 \end{bmatrix}$, which has Perron value $\frac{3+\sqrt{5}}{2}$, while each branch at v consisting of a single vertex has bottleneck matrix equal to $[1]$. Then $\alpha(T) = \frac{3-\sqrt{5}}{2}$, and is an eigenvalue of multiplicity $k-1$ of the corresponding Laplacian matrix. In particular, T is a type I tree with characteristic vertex v.
3. [FK98] If $d \geq 4$ is even, $\alpha(P(n,d)) = 2(1 - \cos(\frac{\pi}{d+1}))$, and is a simple eigenvalue of the corresponding Laplacian matrix.
4. Consider the tree $T(2,2,2)$ shown in Figure 48.5. At both of its nonpendent vertices, the bottleneck matrix for the corresponding Perron component can be written as $\begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 1 \end{bmatrix}$. It follows that $1/\alpha(T) = \rho\left(\begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 1 \end{bmatrix} - 1/2J\right) = (5+\sqrt{17})/4$. Hence, the algebraic connectivity for $T(2,2,2)$ is $(5-\sqrt{17})/2$, and it is a type II tree, with the two nonpendent vertices as the characteristic vertices. $[\frac{3+\sqrt{17}}{4}, \frac{3+\sqrt{17}}{4}, 1, -\frac{3+\sqrt{17}}{4}, -\frac{3+\sqrt{17}}{4}, -1]^T$ is a Fiedler vector.
5. [GM87] Consider the tree T shown in Figure 48.6; this is a type I tree with characteristic vertex v. The numbers above the vertices are the vertex numbers and the numbers below are (to four decimal places) the entries in a Fiedler vector for T. The bottleneck matrix for the

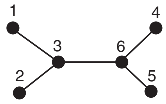

FIGURE 48.5 The tree $T(2,2,2)$.

branch at v on 5 vertices can be written as $\begin{bmatrix} 3 & 1 & 2 & 1 & 1 \\ 1 & 3 & 1 & 2 & 1 \\ 2 & 1 & 2 & 1 & 1 \\ 1 & 2 & 1 & 2 & 1 \\ 1 & 1 & 1 & 1 & 1 \end{bmatrix}$, while that for the branch at v on 4 vertices can be written as $\begin{bmatrix} 3 & 2 & 2 & 1 \\ 2 & 3 & 2 & 1 \\ 2 & 2 & 2 & 1 \\ 1 & 1 & 1 & 1 \end{bmatrix}$. The algebraic connectivity is the smallest root of the polynomial $x^3 - 6x^2 + 8x - 1$, and is approximately 0.1392.

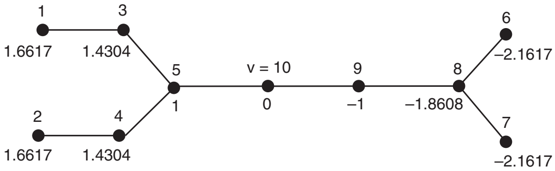

FIGURE 48.6 The tree T in Example 5.

48.4 Fiedler Vectors and Algebraic Connectivity for Weighted Graphs

The term *graph* means *simple graph* in this section.

Definitions:

Let $G = (V, E)$ be a graph on $n \geq 2$ vertices, and suppose that for each edge $e \in E$ we have an associated positive number $w(e)$.

- Then $w(e)$ is the **weight** of e.
- The function $w : E \to \mathbb{R}^+$ is a **weight function** on G.
- The graph G, together with the function $w : E \to \mathbb{R}^+$, is a **weighted graph**, and is denoted G_w.

The **Laplacian matrix** $L(G_w)$ for the weighted graph G_w is the $n \times n$ matrix $L(G_w) = [l_{i,j}]$ such that $l_{i,j} = 0$ if vertices i and j are distinct and not adjacent in G, $l_{i,j} = -w(e)$ if $e = \{i, j\} \in E$, and $l_{i,i} = \sum w(e)$, where the sum is taken over all edges e incident with vertex i.

Throughout this chapter, we only consider Laplacian matrices for weighted graphs on at least two vertices. The notation $L(G_w)$ for the Laplacian matrix of the weighted graph G_w should not be confused with the notation for the line graph introduced in Section 39.2.

Let G_w be a weighted graph on n vertices, and denote the eigenvalues of $L(G_w)$ by $0 = \mu_1 \leq \mu_2 \leq \ldots \leq \mu_n$. The **algebraic connectivity of** G_w is μ_2 and is denoted $\alpha(G_w)$.

Let G_w be a weighted graph. A **Fiedler vector for** G_w is an eigenvector of $L(G_w)$ corresponding to the eigenvalue $\alpha(G_w)$.

Let G_w be a weighted graph and $\mathbf{y}$ be a Fiedler vector for G_w. For each vertex i of G_w, the **valuation of** i is equal to the corresponding entry in $\mathbf{y}$. A vertex is **valuated positively, negatively,** or **zero** accordingly, as the corresponding entry in $\mathbf{y}$ is positive, negative, or zero.

Facts:

1. [Fie75b] Let G_w be a weighted graph and let $\mathbf{y}$ be a Fiedler vector for G_w. Then exactly one of the following holds.
   (a) Case A—There is a single block B_0 in G_w containing both positively valuated vertices and negatively valuated vertices. For every other block of G_w, the vertices are either all valuated positively or all valuated negatively or all valuated zero. Along any path in G that starts at a vertex $k \in B_0$, contains just one vertex in B_0, and contains at most two cut-vertices from each block, the valuations of the cut-vertices form an increasing sequence, a decreasing sequence, or an all zero sequence, according as $y_k > 0, y_k < 0$, or $y_k = 0$, respectively. In the case where $y_k = 0$, then each vertex on that path is valuated zero.
   (b) Case B — No block in G_w has both positively and negatively valuated vertices. Then there is a unique vertex i of G_w having zero valuation that is adjacent to a vertex j with nonzero valuation. The vertex i is a cut-vertex. Each block of G_w contains (with the exception of i) only vertices of positive valuation, or only vertices of negative valuation, or only vertices of zero valuation. Along any path that starts at vertex i and contains at most two cut-vertices from each block, the valuations of the cut-vertices form an increasing sequence, a decreasing sequence, or an all zero sequence. Any path in G_w that contains both positively and negatively valuated vertices must pass through vertex i.
2. [KF98] Let G_w be a weighted graph. If case A holds for some Fiedler vector, then case A holds for every Fiedler vector and, moreover, every Fiedler vector identifies the same block of G_w having vertices of both positive and negative valuations. Similarly, if case B holds for some Fiedler vector, then case B holds for every Fiedler vector and, moreover, every vector identifies the same vertex i that is valuated zero and is adjacent to a vertex with nonzero valuation.
3. [KF98] Suppose that for a weighted graph G_w, case A holds, and let B_0 be the unique block of G_w containing both positively and negatively valuated vertices. Fix an edge $e \in B_0$, and let $\hat{w}$ be the weighting of G formed from w by replacing $w(e)$ by t, where $0 < t < w(e)$. Then for the weighted graph $G_{\hat{w}}$, case A also holds, and B_0 is still the block of G containing both positively and negatively valuated vertices. Similarly, if $B_0 - e$ is a block of $G - e$, then case A still holds for the weighting $\hat{w}$ of $G - e$ arising from setting $\hat{w}(f) = w(f)$ for each $f \in E \backslash \{e\}$, and $B_0 - e$ is still the block containing both positively and negatively valuated vertices.
4. [KF98] Suppose that G is a graph, that w is weight function on G, and consider the weighted graph G_w. Suppose that B is a block of G_w that is valuated all nonnegatively or all nonpositively by some Fiedler vector. Let $\hat{G}_w$ be the weighted graph formed from G_w by either adding a weighted edge to B, or raising the weight of an existing edge in B, and denote the modified block by $\hat{B}$. Then every Fiedler vector for $\hat{G}_w$ valuates the vertices of $\hat{B}$ all nonnegatively, or all nonpositively.
5. [FN02] Suppose that G_w is a weighted graph on n vertices with Laplacian matrix $L(G_w)$. For each nonempty subset U of the vertex set V, let $L(G_w)[U]$ denote the principal submatrix of $L(G_w)$ on the rows and columns corresponding to the vertices in U, and let $\tau(L(G_w)[U])$ denote its smallest eigenvalue. Then $\alpha(G_w) \geq \min\{\max\{\tau(L(G_w)[U]), \tau(L(G_w)[V \setminus U])\} | U \subset V, 0 < |U| \leq [\frac{n}{2}]\}$.
6. [KN04] Suppose that $G = (V, E)$ is a graph, that w is a weight function on G, and consider the weighted graph G_w. Fix an edge $e = \{i, j\} \in E$. For each $t \geq w(e)$, let

w_t be the weight function on G constructed from w by setting the weight of the edge e to t.

(a) If some Fiedler vector $\mathbf{y}$ for G_w has the property that $y_i = y_j$, then for any $t \geq w(e), \alpha(G_{w_t}) = \alpha(G_w)$. In particular, if $\alpha(G_w)$ is an eigenvalue of multiplicity at least two, then $\alpha(G_{w_t}) = \alpha(G_w)$ for all $t \geq w(e)$.

(b) If $\alpha(G_w)$ is a simple eigenvalue, then $\exists t_0 > 0$ such that for each $t \in [0, t_0), \alpha(G_{w_t})$ is a twice differentiable function of t, with $0 \leq \frac{d\alpha(G_{w_t})}{dt} \leq 2$ and $\frac{d^2\alpha(G_{w_t})}{dt^2} \leq 0$. Further, let $\mathbf{y}(t)$ denote a Fiedler vector for G_{w_t} of norm 1 that is analytic for $t \in [0, t_0)$; then $|(\mathbf{y}(t))_i - (\mathbf{y}(t))_j|$ is nonincreasing for $t \in [0, t_0)$.

Examples:

1. Consider the weighting of K_n in which each edge has weight 1. Then any vector that is orthogonal to $\mathbf{1}_n$ is a Fiedler vector.
2. Consider the weighting of $K_{1,n-1}$ in which edge has weight 1. If i and j are pendent vertices of $K_{1,n-1}$, then $\mathbf{e}_i - \mathbf{e}_j$ is a Fiedler vector.
3. Consider the weighting of the path P_n in which each edge has weight 1, and label the vertices of P_n so that vertices 1 and n are pendent, while for each $i = 2, \ldots, n-1$, vertex i is adjacent to vertices $i-1$ and $i+1$. Then the vector $\mathbf{y}$ with $y_i = cos((2i-1)\pi/(2n))$ is a Fiedler vector.
4. Suppose that $a, b > 0$, and let T_w be the weighting of the path P_4 arising by assigning the pendent edges weight a, and the nonpendent edge weight b. The corresponding Laplacian matrix can be written as $\begin{bmatrix} a & 0 & -a & 0 \\ 0 & a & 0 & -a \\ -a & 0 & a+b & -b \\ 0 & -a & -b & a+b \end{bmatrix}$, which has eigenvalues $0, a+b \pm \sqrt{a^2+b^2}$, and $2a$. In particular, $\alpha(T_w) = a+b-\sqrt{a^2+b^2}$, with corresponding Fiedler vector $\begin{bmatrix} a \\ -a \\ \sqrt{a^2+b^2}-b \\ b-\sqrt{a^2+b^2} \end{bmatrix}$.
5. Figure 48.7 shows a weighted graph G_w, where the parameters a, b, c are the weights of the edges, and where the vertices are labeled $1, \ldots, 4$, as indicated in the figure. The corresponding Laplacian matrix is $L(G_w) = \begin{bmatrix} b & 0 & 0 & -b \\ 0 & a+c & -c & -a \\ 0 & -c & a+c & -a \\ -b & -a & -a & 2a+b \end{bmatrix}$. The eigenvalues of $L(G_w)$ are $0, a+2c$, and $\frac{3a+2b\pm\sqrt{9a^2-4ab+4b^2}}{2}$, so that $\alpha(G_w) = \min\{a+2c, \frac{3a+2b-\sqrt{9a^2-4ab+4b^2}}{2}\}$. If $\alpha(G_w) = a+2c$, then $\begin{bmatrix} 0 \\ 1 \\ -1 \\ 0 \end{bmatrix}$ is a Fiedler vector for G_w, while if $\alpha(G_w) = \frac{3a+2b-\sqrt{9a^2-4ab+4b^2}}{2}$, then $\begin{bmatrix} \frac{3a+\sqrt{9a^2-4ab+4b^2}}{2} \\ -\frac{a+2b+\sqrt{9a^2-4ab+4b^2}}{4} \\ -\frac{a+2b+\sqrt{9a^2-4ab+4b^2}}{4} \\ b-a \end{bmatrix}$ is a Fiedler vector for G_w.

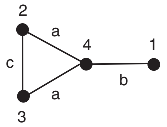

FIGURE 48.7 The weighted graph G_w in Example 5.

48.5 Absolute Algebraic Connectivity for Simple Graphs

The term *graph* means *simple graph* in this section.

Definitions:

Let $G = (V, E)$ be a graph on $n \geq 2$ vertices. Let W denote the set of all nonnegative weightings of G with the property that for each weighting w, we have $\sum_{e \in E} w_e = |E|$ (observe that here we relax the restriction that each edge weight be positive, and allow zero weights).

The **absolute algebraic connectivity of** G is denoted by $\hat{\alpha}(G)$, and is given by $\hat{\alpha}(G) = \max\{\alpha(G_w)|w \in W\}$.

Let $T = (V, E)$ be a tree. For each vertex u of T, define $S(u) = \sum_{k \in V}(d(u,k))^2$.

Facts:

1. [Fie90] For a graph $G, \hat{\alpha}(G) = 0$ if and only if G is disconnected.
2. [GHW08] Let G be a graph on vertices $1, \ldots, n$ with edge set E. The optimization problem of finding $\max\{\alpha(G_w)|w \in W\}$ is equivalent to the following optimization problem:
   maximize $\sum_{i=1}^{n} ||v_i||^2$ subject to $v_i \in \mathbb{R}^n, i = 1, \ldots, n, \sum_{i=1}^{n} v_i = 0$, and $||v_i - v_j|| \leq 1$ whenever $\{i, j\} \in E$.
3. [Fie90] If G is a graph and Ω is its automorphism group, then $\hat{\alpha}(G) = \max\{\alpha(G_w)|w \in W_0\}$, where W_0 is the subclass of W consisting of weightings for which equivalent edges in Ω have the same weight.
4. [KP02] If G is a graph with m edges, and H is the graph formed from G by adding an edge not already present in G, then $\frac{m+1}{m}\hat{\alpha}(G) \leq \hat{\alpha}(H)$.
5. [Fie90] Let T be a tree on n vertices. Then one of the following two cases occurs:
   (a) There is a vertex v of T such that for any vertex $k \neq v, S(v) \leq S(k) - n$. In this case, $\hat{\alpha}(T) = \frac{n-1}{S(v)}$.
   (b) There is an edge $\{u, v\}$ of T such that $|S(u) - S(v)| < n$. In this case, $\hat{\alpha}(T) = \frac{4n(n-1)}{4nS(u)-(n+S(u)-S(v))^2}$.

   Weightings of trees that yield the maximum value $\hat{\alpha}$ are also discussed in [Fie90].
6. [Fie93] If T is a tree on $n \geq 3$ vertices, then $\frac{12}{n(n+1)} \leq \hat{\alpha}(T) \leq 1$. Equality holds in the lower bound if $T = P_n$, and equality holds in the upper bound if $T = K_{1,n-1}$.
7. [KP02] Suppose that G is a graph on $n \geq 7$ vertices that has a cut-vertex. Then $\hat{\alpha}(G) \leq \left(\frac{n^2-3n+4}{n-3}\right)\left(1 - \frac{4}{2(n-1)-(n-3)\sqrt{2(n-2)/(n-1)}}\right)$. Further, the upper bound is attained by the graph formed by appending a pendent vertex at a vertex of K_{n-1}; a weighting of that graph that yields the maximum value $\hat{\alpha}$ is also given in [KP02].

Examples:

1. The absolute algebraic connectivity of K_n is n.
2. If $m \leq n$ and $2 \leq n$, then $\hat{\alpha}(K_{m,n}) = m$.
3. [KP02] Let e be an edge of K_n. Then $\hat{\alpha}(K_n - e) = \frac{(n-2)(n^2-n-2)}{n^2-3n+4}$.

4. Consider the tree $P(9, 5)$ shown in Figure 48.8; we have $S(v) = 22$, and $S(v) \le S(k) - 9$ for any vertex $k \ne v$, so that the first case of Fact 5 holds. Hence, $\hat{\alpha}(P(9, 5)) = \frac{4}{11}$.

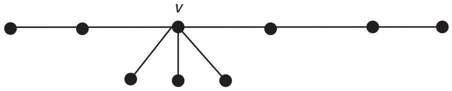

FIGURE 48.8 The tree $P(9, 5)$.

5. Consider the tree $T(2, 3, 4)$ pictured in Figure 48.9. We have $S(u) = 41$ and $S(v) = 36$, so that the second case of Fact 5 holds. Hence, $\hat{\alpha}(T(2, 3, 4)) = \frac{9}{40}$.

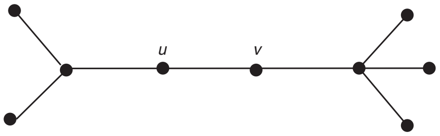

FIGURE 48.9 The tree $T(2, 3, 4)$.

48.6 Generalized Laplacians and Multiplicity

The term *graph* means *simple graph* in this section.

Definitions:

Let $G = (V, E)$ be a graph on $n \ge 2$ vertices. A **generalized Laplacian** of G is a symmetric $n \times n$ matrix M with the property that for each $i \ne j, m_{i,j} < 0$ if $\{i, j\} \in E$ and $m_{i,j} = 0$ if $\{i, j\} \notin E$.

We only consider generalized Laplacian matrices for graphs on at least two vertices.

For any symmetric matrix B, let $\tau(B)$ denote its smallest eigenvalue, let $\mu(B)$ denote its second smallest eigenvalue, and let $\lambda(B)$ denote its largest eigenvalue.

Let G be a graph, and let v be a vertex of G. Suppose that M is a generalized Laplacian matrix for G. Let $C_1, \ldots, C_k$ denote the components of $G - v$; a component C_j is called a **Perron component at** v if $\tau(M[C_j])$ is minimal among all $\tau(M[C_i]), i = 1, \ldots, k$.

Facts:

1. [BKP01] Let G be a connected graph and let v be a cut-vertex of G. Suppose that M is a generalized Laplacian matrix for G. If there are $p \ge 2$ Perron components at v, say $C_1, \ldots, C_p$, then $\mu(M) = \tau(M[C_1])$. Further, $\mu(M)$ is an eigenvalue of M of multiplicity $p - 1$.
2. [BKP01] Let G be a connected graph, and let v be a cut-vertex of G. Let M be a generalized Laplacian matrix for G. Suppose that there is a unique Perron component A_0 at v; denote the other connected components at v by $B_1, \ldots, B_k$, and set $A_1 = G \backslash A_0$. Let $\mathbf{z}$ be an eigenvector of M corresponding to $\tau(M)$, and let $\mathbf{z_0}, \mathbf{z_1}$ be the subvectors of $\mathbf{z}$ corresponding to the vertices in A_0, A_1, respectively. For each $i = 1, \ldots, k$, denote the principal submatrix of M corresponding to the vertices of B_i by $M[B_i]$. Let $S = (M[B_1])^{-1} \oplus \ldots \oplus (M[B_k])^{-1} \oplus [0]$, and let M_0 denote the principal submatrix of M corresponding to the vertices of A_0. There is a unique $\gamma > 0$ such that $\lambda(M_0^{-1} - \gamma \mathbf{z_0} \mathbf{z_0}^T) = \lambda(S + \gamma \mathbf{z_1} \mathbf{z_1}^T) = 1/\mu(M)$. Further, the multiplicity of $\mu(M)$ as an eigenvalue of M coincides with the multiplicity of $1/\mu(M)$ as an eigenvalue of $M_0^{-1} - \gamma \mathbf{z_0} \mathbf{z_0}^T$.

Examples:

1. Consider the generalized Laplacian matrix $M = \begin{bmatrix} 0 & -1 & -1 & -1 & -2 \\ -1 & 3 & -1 & 0 & 0 \\ -1 & -1 & 3 & 0 & 0 \\ -1 & 0 & 0 & 2 & 0 \\ -2 & 0 & 0 & 0 & 2 \end{bmatrix}$. There are three Perron components at vertex 1, induced by the vertex sets $\{2,3\}, \{4\}$, and $\{5\}$. We have $\mu(M) = 2$, which is an eigenvalue of multiplicity two.
2. Consider the generalized Laplacian matrix $M = \begin{bmatrix} -3 & -1 & -1 & -1 & -2 \\ -1 & 2 & -1 & 0 & 0 \\ -1 & -1 & 2 & 0 & 0 \\ -1 & 0 & 0 & 2 & 0 \\ -2 & 0 & 0 & 0 & 2 \end{bmatrix}$. The unique Perron component at vertex 1 is induced by the vertex set $\{2,3\}$. We have $\mu(M) = \frac{-3+\sqrt{29}}{2}$, which is a simple eigenvalue.

A partial matrix is a rectangular array of numbers in which some entries are specified while others are free to be chosen. A completion of a partial matrix is a specific choice of values for the unspecified entries. A matrix completion problem asks whether a partial matrix (or family of partial matrices with a given pattern of specified entries) has a completion of a specific type, such as a positive definite matrix. In some cases, a “best” completion is sought.

Matrix completion problems arise in applications whenever a full set of data is not available, but it is known that the full matrix of data must have certain properties. Such applications include molecular biology and chemistry (see Chapter 66), seismic reconstruction problems, mathematical programming, and data transmission, coding, and image enhancement problems in electrical and computer engineering.

A matrix completion problem for a family of partial matrices with a given pattern of specified entries is usually studied by means of graphs or digraphs. If a pattern of specified entries does not always allow completion to the desired type of matrix, conditions on the entries that will allow such completion are sought. A question of finding the “best completion” often involves optimization techniques. Matrix completion results are usually constructive, with the result established by giving a specific construction for a completion.

In this chapter, we focus on completion problems involving classes of matrices that generalize the positive definite matrices, and emphasize graph theoretic techniques that allow completion of families of matrices. This chapter is organized by class of matrices, with the symmetric classes first.

Organizing the information by classes of matrices provides easy access to results about a particular class, but obscures techniques that apply to the matrix completion problems of many classes and relationships between completion problems for different classes. For information on these subjects, see for example [FJT00], [Hog01], and [Hog03a].

49.1 Introduction

All matrices and partial matrices discussed in Sections 49.1 – 49.12 are square (in Section 49.13 matrices and partial matrices may be rectangular). Graphs allow loops but do not allow multiple edges. Definitions and terminology about graphs and digraphs given in Chapters 39, 40, and 41 are used here. However, the association between matrices and digraphs is different from the association in those chapters, where an arc is associated with a nonzero entry, whereas here an arc is associated with a specified entry.

Definitions:

A **partial matrix** is a square array in which some entries are specified and others are not. An unspecified entry is denoted by ? or by x_{ij}. An ordinary matrix is considered a partial matrix, as is a matrix with no specified entries.

A **completion** of a partial matrix is a choice of values for the unspecified entries.

A partial matrix B is **combinatorially symmetric** (also called **positionally symmetric**) if b_{ij} specified implies b_{ji} specified.

Let B be an $n \times n$ partial matrix. The **digraph** of B, $\mathcal{D}(B) = (V, E)$, has vertices $V = \{1, \dots, n\}$, and for each i and j in V, the arc $(i, j) \in E$ exactly when b_{ij} is specified.

Let B be an $n \times n$ combinatorially symmetric partial matrix. The **graph** of B, $\mathcal{G}(B) = (V, E)$, has vertices $V = \{1, \dots, n\}$, and for each i and j in V, the edge $\{i, j\} \in E$ exactly when b_{ij} is specified.

A partial matrix B **specifies** a graph (or digraph) G if $\mathcal{G}(B) = G$ (or $\mathcal{D}(B) = G$).

A vertex v of a connected graph or digraph G is a **cut-vertex** if $G - v$ is disconnected.

A connected graph or digraph is **nonseparable** if it does not have a cut-vertex.

A **block** of a graph or digraph is a maximal nonseparable sub(di)graph. This use of "block" is for graphs and digraphs and differs from "block" in a block matrix.

A graph (respectively, digraph) is a **clique** if every vertex has a loop and for any two distinct vertices u, v, the edge $\{u, v\}$ is present (respectively, both arcs $(u, v), (v, u)$ are present).

A graph or digraph is **block-clique** (also called **1-chordal**) if every block is a clique.

A digraph $G = (V, E)$ is **symmetric** if $(i, j) \in E$ implies $(j, i) \in E$ for all $i, j \in V$.

A digraph $G = (V, E)$ is **asymmetric** if $(i, j) \in E$ implies $(j, i) \notin E$ for all distinct $i, j \in V$.

A digraph (respectively, graph) G has the X**-completion property** (where X is a type of matrix) if every partial X-matrix B such that $\mathcal{D}(B) = G$ (respectively, $\mathcal{G}(B) = G$) can be completed to an X-matrix. In the literature, the phrase "has X-completion" is sometimes used for "has the X-completion property."

A class X is **closed under permutation similarity** if whenever A is an X-matrix and P is a permutation matrix, then $P^T AP$ is an X-matrix.

A class X is **hereditary** (or **closed under taking principal submatrices**) if whenever A is an X-matrix and $\alpha \subseteq \{1, \dots, n\}$, then $A[\alpha]$ is an X-matrix.

A class X is **closed under matrix direct sums** if whenever $A_1, A_2, \dots, A_k$ are X-matrices, then $A_1 \oplus A_2 \oplus \cdots \oplus A_k$ is an X-matrix.

Note: Many matrix terms, such as size, entry, submatrix, etc., are applied in the obvious way to partial matrices.

Facts:

Let Y be one of the following classes of matrices: positive (semi)definite matrices, Euclidean distance matrices, (symmetric) M-matrices, (symmetric) M_0-matrices, (symmetric) inverse M-matrices, completely positive matrices, doubly nonnegative matrices, doubly negative matrices, (strictly) copositive matrices, P-matrices, P_0-matrices, $P_{0,1}$-matrices, nonnegative P-matrices, nonnegative P_0-matrices, nonnegative $P_{0,1}$-matrices, positive P-matrices, entry (weakly) sign symmetric P-matrices, entry (weakly) sign symmetric P_0-matrices, entry (weakly) sign symmetric $P_{0,1}$-matrices; this includes all classes discussed in this chapter except Q-matrices, totally nonnegative matrices, totally positive matrices, and totally nonpositive matrices. (The definitions of these classes can be found in the relevant sections.)

Proofs of the facts below can be found in [Hog01] for most of the classes discussed, and the proofs given there apply to all the classes Y listed above. Most of these facts are also in the original papers discussing the completion problem for a specific class; those references are listed in the section devoted to the class. In the literature, when it is assumed that a partial matrix B has every diagonal entry specified (equivalently, every vertex of the graph $\mathcal{G}(B)$ or digraph $\mathcal{D}(B)$ has a loop), it is customary to suppress all the loops and treat $\mathcal{G}(B)$ or $\mathcal{D}(B)$ as a simple graph or digraph. That is not done in this chapter because of the danger of confusion. Also, in some references, such as [Hog01], a mark is used to indicate a specified vertex instead of a loop. This has no effect on the results (but requires translation of the notation). If X is a symmetric class of matrices, then there is no loss of generality in assuming every partial matrix is combinatorially symmetric and this assumption is standard practice.

1. If B is a combinatorially symmetric partial matrix, then $\mathcal{D}(B)$ is a symmetric digraph and $\mathcal{G}(B)$ is the graph associated with $\mathcal{D}(B)$. Combinatorially symmetric partial matrices are usually studied by means of graphs rather than digraphs, and it is understood that the graph represents the associated symmetric digraph.
2. Each of the classes Y (listed at the beginning of the facts) is closed under permutation similarity, as is the class of Q-matrices. The classes of totally positive matrices, totally nonnegative matrices, and totally nonpositive matrices are not closed under permutation similarity.
3. Applying a permutation similarity to a partial matrix B corresponds to renumbering the vertices of the digraph $\mathcal{D}(B)$ (or graph $\mathcal{G}(B)$ if B is combinatorially symmetric).
4. Renumbering the vertices of a graph or digraph does not affect whether it has the X-completion property for a property X that is closed under permutation similarity. It is therefore customary to use unlabeled (di)graph diagrams for the classes that are closed under permutation similarity, including the classes Y and the class of Q-matrices. This fact is not true for the classes of totally positive matrices, totally nonnegative matrices, and totally nonpositive matrices, and so we use labeled graphs and digraphs for these classes of matrices.
5. Each of the classes Y, as well as the classes of totally positive matrices, totally nonnegative matrices, and totally nonpositive matrices, is hereditary. The class of Q-matrices, however, is not hereditary.
6. Let B be a partial matrix and $\alpha \subseteq \{1, \ldots, n\}$. The digraph of the principal submatrix $B[\alpha]$ is isomorphic to the subdigraph of $\mathcal{D}(B)$ induced by α (and is customarily identified with it). The same is true for the graph if B is combinatorially symmetric.
7. If X is a hereditary class and a graph or digraph G has the X-completion property, then every induced subgraph or induced subdigraph of G has the X-completion

property. Classes X to which this applies include the classes Y and totally positive matrices, totally nonnegative matrices, and totally nonpositive matrices. This fact is not true of the class of Q-matrices.

8. Each of the classes Y (except the class of positive P-matrices) as well as the classes of Q-matrices and totally nonnegative matrices, is closed under matrix direct sums. This fact is not true for the classes of positive P-matrices, totally positive matrices, and totally nonpositive matrices.
9. Let B be a partial matrix such that all specified entries are contained in diagonal blocks $B_1, B_2, \ldots, B_k$. The connected components of $\mathcal{D}(B)$ are isomorphic to the $\mathcal{D}(B_i),\ i = 1, \ldots, k$. The same is true for $\mathcal{G}(B)$ if B is combinatorially symmetric.
10. Suppose X is a class closed under direct sums or the class of positive P-matrices. If every connected component of a graph or digraph G has the X-completion property, then G has the X-completion property. Classes X to which this applies include the classes Y as well as the classes of Q-matrices and totally nonnegative matrices. This fact is not true for the classes of totally positive matrices and totally nonpositive matrices.
11. If X is one of the classes Y or totally nonnegative matrices, then a graph or digraph G has the X-completion property if and only if every connected component of G has the X-completion property. This fact is not true of the classes of Q-matrices, totally positive matrices, and totally nonpositive matrices.
12. A block-clique graph is chordal.
13. A block-clique digraph is symmetric.

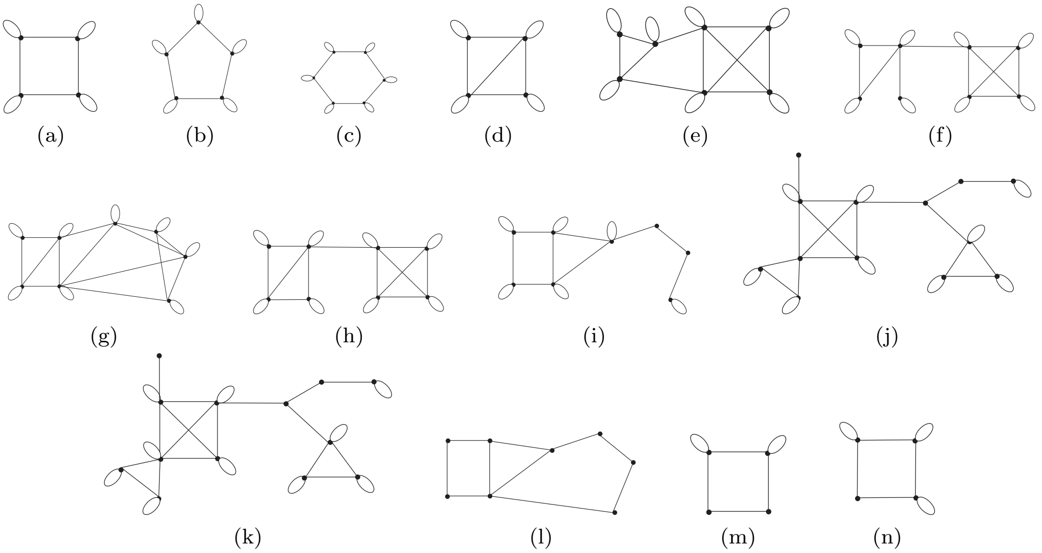

FIGURE 49.1 Graphs.

Examples:

1. Graphs (a) through (n) in Figure 49.1 will be used in examples in this and the following sections.
2. The graph in Figure 49.1f is block-clique, and this is the only block-clique graph in Figure 49.1.

3. The matrix $\begin{bmatrix} 1 & 3 & ? & 0 \\ -1 & 1 & -7 & ? \\ ? & -7 & 1 & 2 \\ 8 & ? & 0 & 1 \end{bmatrix}$ is a partial matrix specifying the graph in Figure 49.1a with vertices numbered 1, 2, 3, 4 clockwise from upper left (or any other numbering around the cycle in order).
4. Digraphs (a) through (r) in Figure 49.2 will be used in examples in the following sections. Note that when both arcs (i, j) and (j, i) are present, the arrows are omitted.

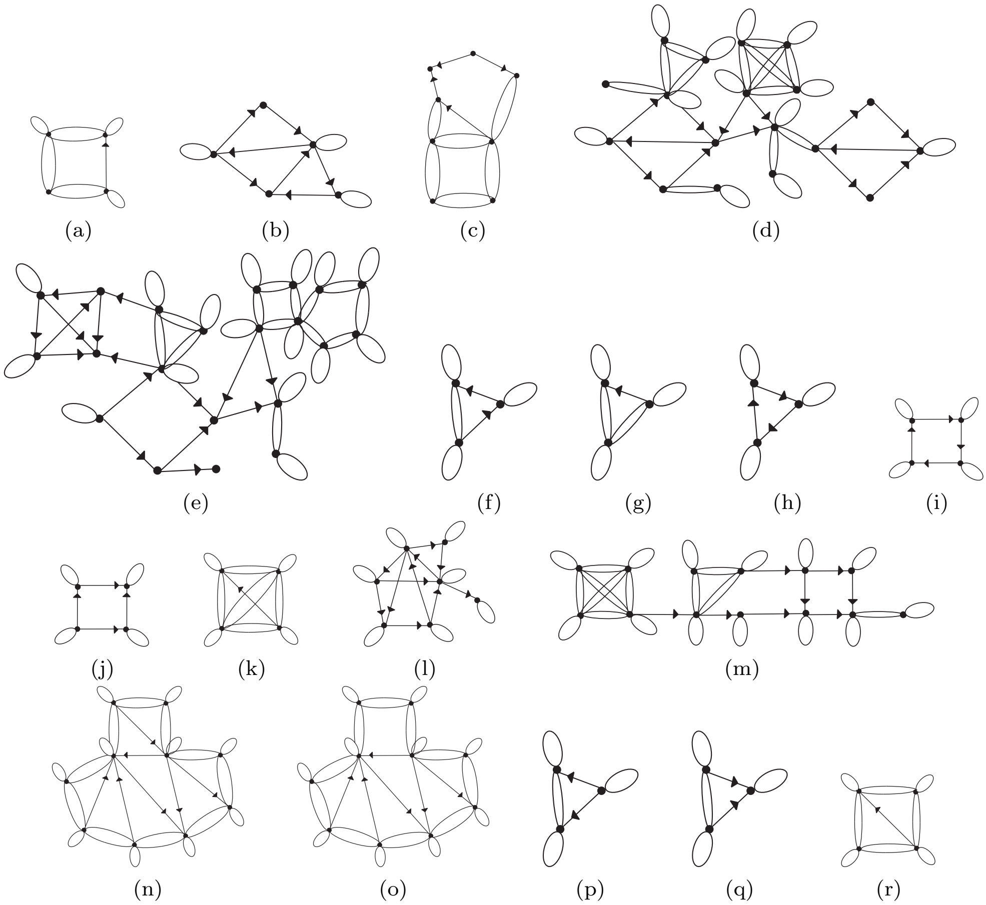

FIGURE 49.2 Digraphs.

5. None of the digraphs in Figure 49.2 are symmetric. (We diagram a symmetric digraph by its associated graph.) The digraphs in Figures 49.2b, 49.2h, 49.2i, 49.2j, and 49.2l are asymmetric.

49.2 Positive Definite and Positive Semidefinite Matrices

In this section, all matrices are real or complex.

Definitions:

The matrix A is **positive definite** (respectively, **positive semidefinite**) if A is Hermitian and for all nonzero $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{x}^* A\mathbf{x} > 0$ (respectively, $\mathbf{x}^* A\mathbf{x} \geq 0$).

The partial matrix B is a **partial positive definite matrix** (respectively, **partial positive semidefinite matrix**) if every fully specified principal submatrix of B is a positive definite matrix (respectively, positive semidefinite matrix), and whenever b_{ij} is specified then so is b_{ji} and $b_{ji} = \overline{b_{ij}}$.

Facts:

1. A Hermitian matrix A is positive definite (respectively, positive semidefinite) if and only if it is positive stable (respectively, positive semistable) if and only if all principal minors are positive (respectively, nonnegative). There are many additional characterizations. (See Sections 9.4 and 9.5 for more information.)
2. The classes of positive definite and positive semidefinite matrices are closed under permutation similarity. The classes of positive definite and positive semidefinite matrices are hereditary classes that are closed under matrix direct sums.
   (a) If a graph G has the positive definite (respectively, positive semidefinite) completion property, then every induced subgraph of G has the positive definite (respectively, positive semidefinite) completion property.
   (b) A graph G has the positive definite (respectively, positive semidefinite) completion property if and only if every connected component of G has the positive definite (respectively, positive semidefinite) completion property.
3. [GJS84] A graph that has a loop at every vertex has the positive definite (positive semidefinite) completion property if and only if it is chordal. (For information on how to construct such a completion, see [GJS84] and [DG81].)
4. [GJS84] A graph has the positive definite completion property if and only if the subgraph induced by the vertices with loops has the positive definite completion property.
5. [Hog01] A graph G has the positive semidefinite completion property if and only if for each connected component H of G, either H has a loop at every vertex and is chordal, or H has no loops.
6. [GJS84] If B is a partial positive definite matrix with all diagonal entries specified such that $\mathcal{G}(B)$ is chordal, then there is a unique positive definite completion A of B that maximizes the determinant, and this completion has the property that whenever the i,j-entry of B is unspecified, the i,j-entry of A^{-1} is zero.
7. [Fie66] Let B be a $n \times n$ real partial positive semidefinite matrix such that every diagonal entry is specified and $\mathcal{G}(B)$ with loops suppressed is a cycle. If any diagonal entry is 0, then B can be completed to a real positive semidefinite matrix. If every diagonal entry is nonzero, there is a positive diagonal matrix D such that every diagonal entry of $C = DBD$ is equal to 1. Let the specified off-diagonal entries of C be denoted $c_1, \ldots, c_n$. Then C (and, hence, B) can be completed to a real positive semidefinite matrix if and only if the following *cycle conditions* are satisfied:

$$2 \max_{1 \le k \le n} \arccos|c_k| \le \Sigma_{k=1}^{n} \arccos|c_k| \qquad \text{for } c_1 \ldots c_n > 0,$$

$$\Sigma_{k=1}^{n} \arccos|c_k| \ge \pi \qquad \text{for } c_1 \ldots c_n \le 0.$$

   (See [BJL96] for additional information.)

Examples:

The graphs for the examples can be found in Figure 49.1.

1. The graphs in Figures 49.1d, 49.1f, and 49.1h have both the positive definite and positive semidefinite completion properties by Fact 3.
2. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1e, and 49.1g have neither the positive definite nor the positive semidefinite completion property by Fact 3.

3. The graphs in Figures 49.1j, 49.1k, 49.1l, 49.1m, and 49.1n have the positive definite completion property by Facts 4 and 3.
4. The graph in Figure 49.1i does not have the positive definite completion property by Facts 4 and 3.
5. The graph in Figure 49.1l has the positive semidefinite completion property by Fact 5.
6. The graphs in Figures 49.1i, 49.1j, 49.1k, 49.1m, and 49.1n do not have the positive semidefinite completion property by Fact 5.
7. The partial matrix $B = \begin{bmatrix} 1 & .3 & ? & ? & -.1 \\ .3 & 1 & 1 & ? & ? \\ ? & 1 & 1 & .2 & ? \\ ? & ? & .2 & 1 & 1 \\ -.1 & ? & ? & 1 & 1 \end{bmatrix}$ can be completed to a positive semidefinite matrix by Fact 7 because because

$$\Sigma_{k=1}^{n} \arccos |c_k| = 4.10617 \geq \pi.$$

49.3 Euclidean Distance Matrices

In this section, all matrices are real.

Definitions:

The matrix $A = [a_{ij}]$ is a **Euclidean distance matrix** if there exist vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \mathbb{R}^d$ (for some $d \geq 1$) such that $a_{ij} = \|\mathbf{x}_i - \mathbf{x}_j\|_2$ for all $i, j = 1, \ldots, n$.

The partial matrix B is a **partial Euclidean distance matrix** if every diagonal entry is specified and equal to 0, every fully specified principal submatrix of B is a Euclidean distance matrix, and whenever b_{ij} is specified then so is b_{ji} and $b_{ji} = b_{ij}$.

Facts:

1. Every Euclidean distance matrix has all diagonal elements equal to 0. There is no loss of generality by considering only a graph that has loops at every vertex, and requiring all diagonal entries of partial Euclidean distance matrices to be 0.
2. The class of Euclidean distance matrices is closed under permutation similarity. The class of Euclidean distance matrices is a hereditary class that is closed under matrix direct sums.
    (a) If a graph G has the Euclidean distance completion property, then every induced subgraph of G has the Euclidean distance completion property.
    (b) A graph G has the Euclidean distance completion property if and only if every connected component of G has the Euclidean distance completion property.
3. [Lau98] A graph with a loop at every vertex has the Euclidean distance completion property if and only if it is chordal.
4. [Lau98] A graph with a loop at every vertex has the Euclidean distance completion property if and only if it has the positive semidefinite completion property. There is a method for transforming the Euclidean distance completion problem into the positive semidefinite completion problem via the Schoenberg transform that provides additional information about conditions on entries that are sufficient to guarantee completion.

Examples:

The graphs for the examples can be found in Figure 49.1.

1. The graphs in Figures 49.1d, 49.1f, and 49.1h have the Euclidean distance completion property by Fact 3.
2. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1e, and 49.1g do not have the Euclidean distance completion property by Fact 3.

49.4 Completely Positive and Doubly Nonnegative Matrices

In this section, all matrices are real.

Definitions:

The matrix A is a **completely positive matrix** if $A = CC^T$ for some nonnegative $n \times m$ matrix C.

A matrix is a **doubly nonnegative matrix** if it is positive semidefinite and every entry is nonnegative.

The partial matrix B is a **partial completely positive matrix** (respectively, **partial doubly nonnegative matrix**) if every fully specified principal submatrix of B is a completely positive matrix (respectively, doubly nonnegative matrix), and whenever b_{ij} is specified then so is b_{ji} and $b_{ji} = b_{ij}$, and all specified off-diagonal entries are nonnegative.

Facts:

1. A completely positive matrix is doubly nonnegative.
2. The classes of completely positive and doubly nonnegative matrices are closed under permutation similarity. The classes of completely positive and doubly nonnegative matrices are hereditary classes that are closed under matrix direct sums.
   (a) If a graph G has the completely positive (respectively, doubly nonnegative) completion property, then every induced subgraph of G has the completely positive (respectively, doubly nonnegative) completion property.
   (b) A graph G has the completely positive (respectively, doubly nonnegative) completion property if and only if every connected component of G has the completely positive (respectively, doubly nonnegative) completion property.
3. [DJ98] A graph that has a loop at every vertex has the completely positive completion property (respectively, doubly nonnegative completion property) if and only if it is block-clique.
4. [Hog02] A graph G has the completely positive completion property (respectively, doubly nonnegative completion property) if and only if for every connected component H of G, H is block-clique, or H has no loops.
5. A graph has the completely positive completion property if and only if it has the doubly nonnegative completion property.
6. [DJK00] A partial matrix that satisfies the conditions of Fact 49.2.7 can be completed to a CP- (respectively, DN-) matrix.

Examples:

The graphs for the examples can be found in Figure 49.1.

1. The graph in Figure 49.1f has both the completely positive completion property and the doubly nonnegative completion property by Fact 3.
2. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1d, 49.1e, 49.1g, and 49.1h have neither the completely positive completion property nor the doubly nonnegative completion property by Fact 3.

3. The graph in Figure 49.1l has both the completely positive completion property and the doubly nonnegative completion property by Fact 4.
4. The graphs in Figures 49.1i, 49.1j, 49.1k, 49.1m, and 49.1n have neither the completely positive completion property nor the doubly nonnegative completion property by Fact 4.

49.5 Doubly Negative Matrices

Given that the doubly negative matrix completion was studied in [MTU05], we use that terminology here, but observe that the results could equivalently be stated for doubly positive matrices (positive definite entry-wise positive matrices). In this section, all matrices are real.

Definitions:

The matrix A is **negative definite** if A is Hermitian and for all $\mathbf{x} \neq 0$, $\mathbf{x}^*A\mathbf{x} < 0$.

The symmetric matrix A is **doubly negative** if it is negative definite and all its entries are negative.

The partial matrix B is a **partial doubly negative matrix** if every fully specified principal submatrix of B is a doubly negative matrix, all its specified entries are negative, and whenever b_{ij} is specified then so is b_{ji} and $b_{ji} = b_{ij}$.

Facts:

1. The matrix A is a doubly negative matrix if and only if $-A$ is a positive definite matrix and entry-wise positive.
2. [MTU05] Doubly negative matrices are invariant under left and right multiplication by a positive or negative diagonal matrix. Therefore, every diagonal entry can be assumed to be equal to -1.
3. The class of doubly negative matrices is closed under permutation similarity. The class of doubly negative matrices is a hereditary class that is closed under matrix direct sums.
   (a) If a graph G has the doubly negative completion property, then every induced subgraph of G has the doubly negative completion property.
   (b) A graph G has the doubly negative completion property if and only if every connected component of G has the doubly negative completion property.
4. [MTU05] Let G be block-clique. Then any partial doubly nonnegative matrix, the graph of whose specified entries is G, can be completed to a doubly nonnegative matrix. (For information on how to construct such a completion, see [MTU05].)
5. [MTU05] Let C be a partial doubly negative matrix such that every diagonal entry is -1 and $\mathcal{G}(C)$ with loops suppressed is a cycle. Let the specified off-diagonal entries of C be denoted $-c_1, \ldots, -c_n$. Then C can be completed to a doubly negative matrix if $0 < c_1, c_2, \ldots, c_{n-1}, c_n < 1$ and c_n lies in the interval $(c_1c_2 \ldots c_{n-1}-\epsilon, c_1c_2 \ldots c_{n-1}+\epsilon)$ where
$$\epsilon = \max_{j\in\{1,\ldots,n-2\}} \left\{ \left(\prod_{i=1, i\neq j, j+1}^{n-1} c_i \right) (1-c_j^2)^{1/2}(1-c_{j+1}^2)^{1/2} \right\}.$$

Examples:

1. The graph in Figure 49.1f has the doubly negative completion property by Fact 4.
2. [MTU05] The double triangle in Figure 49.1d does not have the doubly negative-completion

property because $B = \begin{bmatrix} -1 & -0.45 & -0.016 & ? \\ -0.45 & -1 & -0.9 & -0.01 \\ -0.016 & -0.9 & -1 & -0.2 \\ ? & -0.01 & -0.2 & -1 \end{bmatrix}$ cannot be completed to a doubly negative-matrix (setting the ? to $-c$ produces $\det A = -0.0282 - 0.1469c - 0.19c^2 < 0$, but the product of four negative eigenvalues must be positive). This implies the graphs in Figures 49.1g and 49.1h do not have the doubly negative-completion property by Fact 3a.

49.6 Copositive and Strictly Copositive Matrices

In this section, all matrices are real.

Definitions:

The symmetric matrix A is **strictly copositive** if $\mathbf{x}^T A\mathbf{x} > 0$ for all $\mathbf{x} \geq 0$ and $\mathbf{x} \neq 0$; A is **copositive** if $\mathbf{x}^T A\mathbf{x} \geq 0$ for all $\mathbf{x} \geq 0$.

The partial matrix B is a **partial strictly copositive matrix** (respectively, **partial copositive matrix**) if every fully specified principal submatrix of B is a strictly copositive matrix (respectively, copositive matrix) and whenever b_{ij} is specified then so is b_{ji} and $b_{ji} = b_{ij}$.

Facts:

1. If A is copositive (respectively, strictly copositive), then so is $A+M$ for any symmetric nonnegative matrix M.
2. The classes of copositive and strictly copositive matrices are closed under permutation similarity. The classes of copositive and strictly copositive matrices are hereditary classes that are closed under matrix direct sums.
   (a) If a graph G has the copositive (respectively, strictly copositive) completion property, then every induced subgraph of G has the copositive (respectively, strictly copositive) completion property.
   (b) A graph G has the copositive (respectively, strictly copositive) completion property if and only if every connected component of G has the copositive (respectively, strictly copositive) completion property.
3. [HJR05] Every partial strictly copositive matrix can be completed to a strictly copositive matrix using the method described in Facts 5 and 6.
4. [HJR05] Every partial copositive matrix that has every diagonal entry specified can be completed to a copositive matrix using the completion described in Fact 5 below. There exists a partial copositive matrix with an unspecified diagonal entry that cannot be completed to a copositive matrix (see Example 2).
5. [HJR05] Let B be a partial copositive matrix with every diagonal entry specified. For each pair of unspecified off-diagonal entries, set $x_{ij} = x_{ji} = \sqrt{b_{ii}b_{jj}}$. The resulting matrix is copositive, and is strictly copositive if B is a partial strictly copositive matrix.
6. [Hog07] Any completion found by Algorithm 1 (of a partial strictly copositive matrix omitting only one diagonal entry) is a strictly copositive matrix. If B is a partial strictly copositive matrix that omits more than one diagonal entry, values for these entries can be chosen one at a time using Algorithm 1 (using the largest value obtained by considering all principal submatrices completed by the choice of that diagonal entry) to obtain a partial strictly copositive matrix with specified diagonal that agrees with B on every specified entry of B.

Algorithm 1: Completing one unspecified diagonal entry

Let $B = \begin{bmatrix} x_{11} & \mathbf{b}^T \\ \mathbf{b} & B_1 \end{bmatrix}$ be a partial strictly copositive $n \times n$ matrix having all entries except the 1,1-entry specified. Let $\|\cdot\|$ be a vector norm.

Complete B by choosing a value for x_{11} as follows:

1. $\beta = \min_{\mathbf{y} \in \mathbb{R}^{n-1}, \mathbf{y} \geq 0, \|\mathbf{y}\|=1} \mathbf{b}^T\mathbf{y}$.
2. $\gamma = \min_{\mathbf{y} \in \mathbb{R}^{n-1}, \mathbf{y} \geq 0, \|\mathbf{y}\|=1} \mathbf{y}^T B_1 \mathbf{y}$.
3. $x_{11} > \frac{\beta^2}{\gamma}$.

7. [HJR05], [Hog07] Every graph has the strictly copositive completion property.
8. [HJR05], [Hog07] A graph has the copositive completion property if and only if for each connected component H of G, either H has a loop at every vertex, or H has no loops.

Examples:

1. The partial matrix $B = \begin{bmatrix} x_{11} & -5 & 1 & x_{14} & x_{15} & x_{16} \\ -5 & 1 & -2 & x_{24} & x_{25} & 1 \\ 1 & -2 & 5 & 1 & -1 & -1 \\ x_{14} & x_{24} & 1 & 1 & x_{45} & 1 \\ x_{15} & x_{25} & -1 & x_{45} & x_{55} & x_{56} \\ x_{16} & 1 & -1 & 1 & x_{56} & 3 \end{bmatrix}$ is a partial strictly copositive matrix. We use the methods in Facts 5 and 6 to complete B to a strictly copositive matrix: Select index 5. The only principal submatrix completed by a choice of b_{55} is $B[\{3,5\}]$. Any value that makes $x_{55}b_{33} > b_{35}^2$ will work; we choose $x_{55} = 1$.

   Select index 1. The only principal submatrices completed by a choice of b_{11} are principal submatrices of $B[\{1,2,3\}] = \begin{bmatrix} x_{11} & \mathbf{b}^T \\ \mathbf{b} & B[\{2,3\}] \end{bmatrix}$. Apply Algorithm 1 (using $\|\cdot\|_1$):

   1. $\beta = \min_{\|\mathbf{y}\|_1=1} \mathbf{b}^T\mathbf{y} = -5$.
   2. $\gamma = \min_{\|\mathbf{y}\|_1=1} \mathbf{y}^T B[\{2,3\}]\mathbf{y} = \frac{1}{10}$.
   3. Choose $b_{11} = 256$ $(> \frac{\beta^2}{\gamma})$.

   Then by Fact 5, $\begin{bmatrix} 256 & -5 & 1 & 16 & 16 & 16\sqrt{3} \\ -5 & 1 & -2 & 1 & 1 & 1 \\ 1 & -2 & 5 & 1 & -1 & -1 \\ 16 & 1 & 1 & 1 & 1 & 1 \\ 16 & 1 & -1 & 1 & 1 & \sqrt{3} \\ 16\sqrt{3} & 1 & -1 & 1 & \sqrt{3} & 3 \end{bmatrix}$ is a strictly copositive matrix that completes B.
2. $B = \begin{bmatrix} x_{11} & -1 \\ -1 & 0 \end{bmatrix}$ is a partial copositive matrix that cannot be completed to a copositive matrix because once x_{11} is chosen (clearly $x_{11} > 0$), then $\mathbf{v} = [\frac{1}{x_{11}}, 1]^T$ results in $\mathbf{v}^T B\mathbf{v} = -\frac{1}{x_{11}} < 0$.
3. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1d, 49.1e, 49.1f, 49.1g, 49.1h, and 49.1l have the copositive completion property by Fact 8, and these are the only graphs in Figure 49.1 that have the copositive completion property.

49.7 M- and M_0-Matrices

In this section, all matrices are real.

Definitions:

The matrix A is an **M-matrix** (respectively, **M_0-matrix**) if there exist a nonnegative matrix P and a real number $s > \rho(P)$ (respectively, $s \geq \rho(P)$) such that $A = sI - P$.

The partial matrix B is a **partial M-matrix** (respectively, **partial M_0-matrix**) if every fully specified principal submatrix of B is an M-matrix (respectively, M_0-matrix) and every specified off-diagonal entry of B is nonpositive.

If B is a partial matrix that includes all diagonal entries, the **zero completion** of B, denoted B_0, is obtained by setting all unspecified (off-diagonal) entries to 0.

Facts:

1. For a Z-matrix A (i.e., every off-diagonal entry of A is nonpositive), the following are equivalent:
   (a) A is an M-matrix.
   (b) Every principal minor of A is positive.
   (c) Every leading principal minor of A is positive.
   (d) A is positive stable.
   (e) A^{-1} is nonnegative.

   The analogs of the first three conditions are equivalent to A being an M_0-matrix. See Section 10.5 for more information about M- and M_0-matrices.
2. The classes of M- and M_0-matrices are closed under permutation similarity. The classes of M- and M_0-matrices are hereditary classes that are closed under matrix direct sums.
   (a) If a digraph G has the M- (respectively, M_0-) completion property, then every induced subdigraph of G has the M- (respectively, M_0-) completion property.
   (b) A digraph G has the M- (respectively, M_0-) completion property if and only if every connected component of G has the M- (respectively, M_0-) completion property.
3. [JS96], [Hog01] A partial M- (M_0-) matrix B that includes all diagonal entries can be completed to an M- (M_0-) matrix if and only if the zero completion B_0 is an M- (M_0-) matrix.
4. [Hog98b], [Hog01] A digraph G with a loop at every vertex has the M- (M_0-) completion property if and only if every strongly connected induced subdigraph of G is a clique.
5. [Hog98b], [Hog01] A digraph G has the M-completion property if and only if the subdigraph induced by the vertices of G that have loops has M-completion.
6. [Hog01] A digraph G has the M_0-completion property if and only if for every strongly connected induced subdigraph H of G, either H is a clique or H has no loops.
7. [Hog02] Symmetric M- and M_0-matrices and partial matrices are defined in the obvious way. A graph has the symmetric M-completion property if and only if every connected component of the subgraph induced by the vertices with loops is a clique. A graph has the symmetric M_0-completion property if and only if every connected component is either a clique or has no loops.

Examples:

The graphs and digraphs for the examples can be found in Figures 49.1 and 49.2.

1. Even if the digraph of a partial M-matrix does not have the M-matrix completion property, such a matrix may still have an M-matrix completion. By Fact 3 it is easy to determine whether there is an M-completion. For example, complete the partial M-matrix $B = \begin{bmatrix} 1 & ? & ? & -2 \\ -0.5 & 2 & ? & ? \\ ? & -1 & 1 & ? \\ ? & ? & -1 & 1 \end{bmatrix}$ to B_0 by setting every unspecified entry to 0. To determine whether B_0 is an M-matrix, compute the leading principal minors: $\det B_0[\{1\}] = 1, \det B_0[\{1,2\}] = 2, \det B_0[\{1,2,3\}] = 2, \det B_0 = 1$. If we change the values of entries we can obtain a partial M-matrix that does not have an M-matrix completion, e.g., $C = \begin{bmatrix} 1 & ? & ? & -2 \\ -2.5 & 2 & ? & ? \\ ? & -1 & 1 & ? \\ ? & ? & -1 & 1 \end{bmatrix}$. Then $\det C_0 = -3$ so by Fact 3, C cannot be completed to an M-matrix. Note $\mathcal{D}(B) = \mathcal{D}(C)$ is the digraph in Figure 49.2i, which does not have the M-matrix completion property by Fact 4.
2. The digraphs in Figures 49.2j, 49.2m, 49.2p, and 49.2q have the M- and M_0-completion properties by Fact 4.
3. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1d, 49.1e, 49.1f, 49.1g, and 49.1h and the digraphs in Figures 49.2f, 49.2g, 49.2h, 49.2i, 49.2k, 49.2l, 49.2n, 49.2o, and 49.2r have neither the M-completion property nor the M_0-completion property by Fact 4.
4. The graphs in Figures 49.1j, 49.1l, and 49.1m and the digraphs in Figures 49.2a, 49.2b, 49.2c, and 49.2d have the M-completion property by Facts 4 and 5. Of these (di)graphs, only those in Figures 49.1l and 49.2c have the M_0 completion property, by Fact 6.
5. The graphs in Figures 49.1i, 49.1k, and 49.1n and the digraph in Figure 49.2e do not have the M-completion property (respectively, the M_0-completion property) by Facts 4 and 5 (respectively, Fact 6).

49.8 Inverse M-Matrices

In this section, all matrices are real.

Definitions:

The matrix A is an **inverse M-matrix** if A is the inverse of an M-matrix.

The partial matrix B is a **partial inverse M-matrix** if every fully specified principal submatrix of B is an inverse M-matrix and every specified entry of B is nonnegative.

A digraph is **cycle-clique** if the induced subdigraph of every cycle is a clique.

An **alternate path to a single arc** in a digraph G is a path of length greater than 1 between vertices i and j such that the arc (i,j) is in G.

A digraph G is **path-clique** if the induced subdigraph of every alternate path to a single arc is a clique.

A digraph is **homogeneous** if it is either symmetric or asymmetric.

A **simple cycle** in a digraph is a cycle such that the subdigraph induced by the vertices of the cycle is the cycle and possibly some loops.

Facts:

1. A matrix A is an inverse M-matrix if and only if all entries of A are nonnegative and all off-diagonal entries of A^{-1} are nonpositive. There are many equivalent characterizations of inverse M-matrices; see Section 10.5 for more information.

2. The class of inverse M-matrices is closed under permutation similarity. The class of inverse M-matrices is a hereditary class that is closed under matrix direct sums.
   (a) If a digraph G has the inverse M-completion property, then every induced subdigraph of G has the inverse M-completion property.
   (b) A digraph G has the inverse M-completion property if and only if every connected component of G has the inverse M-completion property.
3. [JS96] Let $B = \begin{bmatrix} B_{11} & \mathbf{b}_{12} & ? \\ \mathbf{b}_{21}^T & b_{22} & \mathbf{b}_{23}^T \\ ? & \mathbf{b}_{32} & B_{33} \end{bmatrix}$ be an $n \times n$ partial inverse M matrix, where B_{11} and B_{33} are square matrices of size k and $n-k-1$, and all entries of the submatrices shown are specified. Then $A = \begin{bmatrix} B_{11} & \mathbf{b}_{12} & \mathbf{b}_{12}b_{22}^{-1}\mathbf{b}_{23}^T \\ \mathbf{b}_{21}^T & b_{22} & \mathbf{b}_{23}^T \\ \mathbf{b}_{32}b_{22}^{-1}\mathbf{b}_{21}^T & \mathbf{b}_{32} & B_{33} \end{bmatrix}$ is the unique inverse M-completion of B such that A^{-1} has zeros in all the positions where B has unspecified entries. This method can be used to complete a partial inverse M-matrix whose digraph is block-clique.
4. [JS96], [JS99], [Hog98a], [Hog00], [Hog02] A symmetric digraph with a loop at every vertex has the inverse M-completion property if and only if it is block-clique. A digraph obtained from a block-clique digraph by deleting loops from vertices not contained in any block of order greater than 2 also has the inverse M-completion property, and any symmetric digraph that has the inverse M-completion property has that form. The same is true for the symmetric inverse M-completion property (with the obvious definition).
5. [Hog98a] A digraph with a loop at every vertex has the inverse M-completion property if and only if it is path-clique and cycle-clique.
6. [Hog00], [Hog01] A digraph G has the inverse M-completion property if and only if it is path-clique and every strongly connected nonseparable induced subdigraph has the inverse M-completion property. A strongly connected nonseparable path-clique digraph is homogeneous. A simple cycle having at least one vertex without a loop has the inverse M-completion property.

Examples:

The graphs and digraphs for the examples can be found in Figures 49.1 and 49.2.

1. Let $B = \begin{bmatrix} 3 & 1 & ? & ? \\ 4 & 2 & 4 & 2 \\ ? & 1 & 5 & 1 \\ ? & 1 & 2 & 2 \end{bmatrix}$. The completion given by Fact 3 is $A = \begin{bmatrix} 3 & 1 & 2 & 1 \\ 4 & 2 & 4 & 2 \\ 2 & 1 & 5 & 1 \\ 2 & 1 & 2 & 2 \end{bmatrix}$, and $A^{-1} = \begin{bmatrix} 1 & -\frac{1}{2} & 0 & 0 \\ -2 & \frac{7}{3} & -\frac{2}{3} & -1 \\ 0 & -\frac{1}{6} & \frac{1}{3} & 0 \\ 0 & -\frac{1}{2} & 0 & 1 \end{bmatrix}$.
2. By Fact 4, the only graphs in Figure 49.1 that have the inverse M-completion property are those shown in Figures 49.1f and 49.1k.
3. The digraphs in Figures 49.2j and 49.2m have the inverse M-completion property by Fact 5.
4. The digraphs in Figures 49.2f, 49.2g, 49.2h, 49.2i, 49.2k, 49.2l, 49.2n, 49.2o, 49.2p, 49.2q, and 49.2r do not have the inverse M-completion property by Fact 5.
5. The digraphs in Figures 49.2a, 49.2b, 49.2c, 49.2d, and 49.2e do not have the inverse M-completion property by Fact 6.

49.9 P-, $P_{0,1}$-, and P_0-Matrices

In this section, all matrices are real.

Definitions:

The matrix A is a P-**matrix** (respectively, P_0-**matrix**, $P_{0,1}$-**matrix**) if every principal minor of A is positive (respectively, nonnegative, nonnegative and every diagonal element is positive).

The partial matrix B is a **partial** P-**matrix** (respectively, **partial** P_0-**matrix**, **partial** $P_{0,1}$-**matrix**) if every fully specified principal submatrix of B is a P-matrix (respectively, P_0-matrix, $P_{0,1}$-matrix).

Facts:

1. A positive definite matrix, M-matrix, or inverse M-matrix is a P-matrix. A positive semidefinite matrix or M_0-matrix is a P_0-matrix. See [HJ91] for more information on P- and P_0-matrices.
2. The classes of P-, $P_{0,1}$-, and P_0-matrices are closed under permutation similarity. The classes of P-, $P_{0,1}$-, and P_0-matrices are hereditary classes that are closed under matrix direct sums.

    (a) If a digraph G has the P- (respectively, $P_{0,1}$-, P_0-) completion property, then every induced subdigraph of G has the P- (respectively, $P_{0,1}$-, P_0-) completion property.

    (b) A digraph G has the P- (respectively, $P_{0,1}$-, P_0-) completion property if and only if every connected component of G has the P- (respectively, $P_{0,1}$-, P_0-) completion property.

3. [Hog03a] If a digraph has the P_0-completion property, then it has the $P_{0,1}$-completion property. If a digraph has the $P_{0,1}$-completion property, then it has the P-completion property.
4. [JK96], [Hog01] A digraph has the P-completion property if and only if the subdigraph induced by the vertices that have loops has the P-completion property.
5. [JK96] Every symmetric digraph has the P-completion property. The P-completion of a combinatorially symmetric partial P-matrix can be accomplished by selecting one pair of unspecified entries at a time and choosing the entries of opposite sign and large enough magnitude to make the determinants of all completed principal submatrices positive.
6. [JK96] Every order 3 digraph has the P-completion property, but there is an order 4 digraph (see the digraph in Figure 49.2k) that does not have the P-completion property. [DH00] extended a revised version of this example, the digraph in Figure 49.2r, to a family of digraphs, called *minimally chordal symmetric Hamiltonian*, that do not have the P-completion property. The digraph in Figure 49.2n is another example of a digraph in this family (so both digraphs in Figures 49.2r and 49.2n do not have the P-completion property).
7. [DH00] A digraph that can be made symmetric by adding arcs one at a time so that at each stage at most one order 3 induced subdigraph (and no larger) becomes a clique has the P-completion property.
8. [CDH02] A partial P- ($P_{0,1}$-, P_0-) matrix whose digraph is asymmetric can be completed to a P- ($P_{0,1}$-, P_0-) matrix as follows: If $i \neq j$ and b_{ji} is specified, then set $x_{ij} = -b_{ij}$; otherwise, set $x_{ij} = 0$. Every asymmetric digraph has the P- ($P_{0,1}$-, P_0-) completion property.

9. [FJT00], Let $B = \begin{bmatrix} B_{11} & \mathbf{b}_{12} & ? \\ \mathbf{b}_{21}^T & b_{22} & \mathbf{b}_{23}^T \\ ? & \mathbf{b}_{32} & B_{33} \end{bmatrix}$ be an $n \times n$ partial $P_{0,1}$-matrix, where B_{11} and B_{33} are square matrices of size k and $n-k-1$, and all entries of the submatrices shown are specified. Then $A = \begin{bmatrix} B_{11} & \mathbf{b}_{12} & \mathbf{b}_{12} b_{22}^{-1} \mathbf{b}_{23}^T \\ \mathbf{b}_{21}^T & b_{22} & \mathbf{b}_{23}^T \\ 0 & \mathbf{b}_{32} & B_{33} \end{bmatrix}$ is a $P_{0,1}$-completion of B. This method can be used to complete any partial $P_{0,1}$-matrix whose digraph is block-clique. The same method works for a partial P-matrix, but such a partial matrix can also be completed by the method in Fact 5. See [Hog01] for the details of the analogous completion for a partial P_0-matrix.
10. [FJT00] Every block-clique digraph has the P- ($P_{0,1}$-, P_0-) completion property.
11. [Hog01] A digraph G has the P- (respectively, $P_{0,1}$-, P_0-) completion property if and only if every strongly connected and nonseparable induced subdigraph of G has the P- (respectively, $P_{0,1}$-, P_0-) completion property. A method to obtain such a completion is given in Algorithm 2.

Algorithm 2:
Let B be a partial P- ($P_{0,1}$-, P_0-) matrix such that every strongly connected and nonseparable induced subdigraph K of $\mathcal{D}(B)$ has the P- ($P_{0,1}$-, P_0-) property.

1. For each such K, complete the principal submatrix of B corresponding to K to obtain a partial P- ($P_{0,1}$-, P_0-) matrix B_1 such that each strongly connected induced subdigraph S of $\mathcal{D}(B_1)$ is block-clique.
2. For each such S, complete the principal submatrix of B_1 corresponding to S to obtain a partial P- ($P_{0,1}$-, P_0-) matrix B_2.
3. Set any remaining unspecified entries to 0.

12. [Hog01] A digraph that omits all loops has the P- ($P_{0,1}$-, P_0-) completion property. Each connected component of a symmetric digraph that has the P_0-completion property must have a loop at every vertex or omit all loops.
13. [Hog01], [CDH02], [JK96] A symmetric n-cycle with a loop at every vertex has the P_0-completion property if and only if $n \neq 4$. A symmetric n-cycle with a loop at every vertex has the P- and $P_{0,1}$-completion properties for all n.
14. [CDH02] All order 2, order 3, and order 4 digraphs with a loop at every vertex have been classified as having or not having the P_0-completion property.
15. [JK96], [DH00], and [Wan05] There are some order 4 digraphs that (in 2013) have not been classified as to the P- and $P_{0,1}$-completion properties.

Examples:

The graphs and digraphs for the examples can be found in Figures 49.1 and 49.2.

1. It is easy to verify that $B = \begin{bmatrix} 1 & 2 & x_{13} & -1 \\ 1 & 3 & -2 & x_{24} \\ x_{31} & 2 & 1 & 1 \\ -1 & x_{42} & 1 & 2 \end{bmatrix}$ is a partial P-matrix. The graph in Figure 49.1a is interpreted as the digraph of B. Let $x_{24} = y$ and $x_{42} = -y$. A choice of y completes three principal minors, $\det B[\{2,4\}] = 6 + y^2$, $\det B[\{1,2,4\}] = -1 - y + y^2$, and $\det B[\{2,3,4\}] = 11 + 4y + y^2$. The choice $y = 2$ makes all three minors positive. Let $x_{13} = z$ and $x_{31} = -z$. With $y = 2$, a choice of z completes four principal minors, $\det B[\{1,3\}] =$

$1+z^2$, $\det B[\{1,2,3\}] = 5+6\,z+3\,z^2$, $\det B[\{1,3,4\}] = 2\,z^2$, and $\det B = 10+18\,z+10\,z^2$, so setting $z=1$ completes B to the P-matrix $\begin{bmatrix} 1 & 2 & 1 & -1 \\ 1 & 3 & -2 & 2 \\ -1 & 2 & 1 & 1 \\ -1 & -2 & 1 & 2 \end{bmatrix}$. Any partial P-matrix specifying Figure 49.1a, Figure 49.1d (the double triangle), or any other symmetric digraph can be completed in a similar manner.

2. The double triangle in Figure 49.1d does not have the P_0-completion property because $B = \begin{bmatrix} 1 & 2 & 1 & ? \\ -1 & 0 & 0 & -2 \\ -1 & 0 & 0 & -1 \\ ? & 1 & 1 & 1 \end{bmatrix}$ cannot be completed to a P_0-matrix [JK96]. This implies the graphs in Figures 49.1g and 49.1h do not have the P_0-completion property by Fact 2. The double triangle does have the $P_{0,1}$-completion property [Wan05].
3. All graphs in Figure 49.1 have the P-completion property by Fact 5.
4. The digraphs in Figures 49.2c and 49.2d have the P-completion property by Fact 4. Fact 4 can also be applied in conjunction with other facts to several other digraphs in Figure 49.2.
5. The digraphs in Figures 49.2a, 49.2b, 49.2c, 49.2d, 49.2f, 49.2g, 49.2h, 49.2i, 49.2j, 49.2l, 49.2m, 49.2o, 49.2p, and 49.2q have the P-completion property by Fact 7 (in conjunction with Fact 4 in some cases).
6. The digraphs in Figures 49.2b, 49.2h, 49.2i, 49.2j, and 49.2l have the P-, $P_{0,1}$-, and P_0-completion properties by Fact 8.
7. The completion of $B = \begin{bmatrix} 2 & -1 & ? & ? \\ -4 & 2 & -4 & 2 \\ ? & 1 & 5 & -1 \\ ? & 1 & 2 & 2 \end{bmatrix}$ given by Fact 9 is $A = \begin{bmatrix} 2 & -1 & 2 & -1 \\ -4 & 2 & -4 & 2 \\ 0 & 1 & 5 & -1 \\ 0 & 1 & 2 & 2 \end{bmatrix}$; B is a partial $P_{0,1}$ matrix and A is a $P_{0,1}$ matrix.
8. The graph in Figure 49.1f has the P_0- and $P_{0,1}$-completion properties by Fact 10. (It also has the P-completion property but one would not normally cite Fact 10 for that.)
9. The digraphs in Figures 49.2j, 49.2m, 49.2p, and 49.2q have the P-, $P_{0,1}$-, and P_0-completion properties by Fact 11. Fact 11 can also be applied in conjunction with other facts to several other digraphs in Figure 49.2.
10. The graph in Figure 49.1l and the digraph in Figure 49.2c have the P-, P_0-, and $P_{0,1}$-completion properties by Fact 12.
11. The graphs in Figures 49.1i, 49.1j, 49.1k, 49.1m, and 49.1n do not have the P_0-completion property by Fact 12.
12. The graphs in Figures 49.1b and 49.1c have the P_0- ($P_{0,1}$)-completion property by Fact 13.
13. The graph in Figure 49.1a does not have the P_0-completion property, but does have the P- and $P_{0,1}$-completion properties, by Fact 13.
14. The graphs in Figures 49.1e and 49.1g do not have the P_0-completion property by Facts 13 and 2.

49.10 Positive *P*- and Nonnegative *P*- ($P_{0,1}$-, P_0-) Matrices

In this section, all matrices are real.

Definitions:

The matrix A is a **positive** (respectively, **nonnegative**) ***P*-matrix** if A is a P-matrix and every entry of A is positive (respectively, nonnegative). The matrix A is a **nonnegative P_0-matrix** (respectively, **nonnegative $P_{0,1}$-matrix**) if A is a P_0-matrix (respectively, $P_{0,1}$-matrix) and every entry of A is nonnegative.

The partial matrix B is a **partial positive P-matrix** (respectively, **partial nonnegative P-matrix**, **partial nonnegative P_0-matrix**, **partial nonnegative $P_{0,1}$-matrix**) if and only if every fully specified principal submatrix of B is a positive P-matrix (respectively, nonnegative P-matrix, nonnegative P_0-matrix, partial nonnegative $P_{0,1}$-matrix) and all specified entries are positive (respectively, nonnegative, nonnegative, nonnegative).

Facts:

1. The classes of positive P-, and nonnegative P- ($P_{0,1}$-, P_0-) matrices are closed under permutation similarity. The classes of positive P-, and nonnegative P- ($P_{0,1}$-, P_0-) matrices are hereditary classes. The classes of nonnegative P- ($P_{0,1}$-, P_0-) matrices are closed under matrix direct sums.
    (a) If a digraph G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property, then every induced subdigraph of G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property.
    (b) A digraph G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property if and only if every connected component of G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property (see [Hog01] for positive P-completion).
2. [Hog03a], [Hog03b] If a digraph has the nonnegative P_0-completion property, then it has the nonnegative $P_{0,1}$-completion property. If a digraph has the nonnegative $P_{0,1}$-completion property, then it has the nonnegative P-completion property. If a digraph has the nonnegative P-completion property, then it has the positive P-completion property.
3. [Hog01] A digraph has the positive (respectively, nonnegative) P-completion property if and only if the subdigraph induced by vertices that have loops has the positive (respectively, nonnegative) P-completion property.
4. [FJT00], [Hog01], [CDH03] All order 2 and order 3 digraphs that have a loop at every vertex have the positive P- (nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property.
5. [Hog01], [BEH06] Suppose G is a digraph with the property that adding arcs, one at a time, so that at each stage at most one induced subdigraph of order 3 (and no larger) becomes a clique, and such that this process results in a digraph having the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property. Then G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property.
6. [FJT00], [Hog01] A block-clique digraph has the positive P- (nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property. See Fact 49.9.9 for information on the construction.
7. [Hog01] A digraph G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property if and only if every strongly connected and nonseparable induced subdigraph of G has the positive P- (respectively, nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property. See Algorithm 49.9.2 for information on the construction.
8. [Hog01] A digraph that omits all loops has the positive P- (nonnegative P-, nonnegative $P_{0,1}$-, nonnegative P_0-) completion property. Each connected component of

a symmetric digraph that has the nonnegative P_0-completion property must have a loop at every vertex or omit all loops.

9. [CDH03] An order 4 digraph with a loop at every vertex has the nonnegative P_0-completion property if and only if it does not contain a 4-cycle or is the clique on 4-vertices. This characterization does not extend to higher order digraphs.
10. [BEH06], [JTU03] All order 4 digraphs that have a loop at every vertex have been classified as to the positive P- (nonnegative P-) completion property.
11. [CDH03], [FJT00], [Hog01] A symmetric n-cycle that has a loop at every vertex has the nonnegative P_0-completion property if and only if $n \neq 4$. A symmetric n-cycle that has a loop at every vertex has the positive P- (nonnegative P-, nonnegative $P_{0,1}$-) completion property.
12. [BEH06] A minimally chordal symmetric Hamiltonian digraph (cf. Fact 49.9.6) has neither the positive nor the nonnegative P-completion property.

Examples:

The graphs and digraphs for the examples can be found in Figures 49.1 and 49.2.

1. The digraphs in Figures 49.2f, 49.2g, 49.2h, 49.2p, and 49.2q have the positive P- (nonnegative P-, nonnegative P_0-, nonnegative $P_{0,1}$-) completion property by Fact 4.
2. The graph in Figure 49.1f has the positive P- (nonnegative P-, nonnegative P_0-, nonnegative $P_{0,1}$-) completion property by Fact 6.
3. The graphs in Figures 49.1j, 49.1k, 49.1l, 49.1m, and 49.1n and the digraphs in Figures 49.2c and 49.2d have the positive P- (nonnegative P-) completion property by Facts 3 and 6.
4. The digraphs in Figures 49.2j, 49.2m, 49.2p, and 49.2q have the positive P- (nonnegative P-, nonnegative P_0-, nonnegative $P_{0,1}$-) completion property by Fact 7.
5. The graph in Figure 49.1l and the digraph in Figure 49.2c have the positive P-, nonnegative P-, nonnegative P_0-, and nonnegative $P_{0,1}$-completion properties by Fact 8.
6. The graphs in Figures 49.1i, 49.1j, 49.1k, 49.1m, and 49.1n do not have the nonnegative P_0-completion property by Fact 8.
7. The graphs in Figures 49.1a and 49.1d and the digraphs in Figures 49.2i, 49.2k, and 49.2r do not have the nonnegative P_0-completion property by Fact 9. The graphs in Figures 49.1e, 49.1g, and 49.1h and the digraphs in Figures 49.2l, 49.2n, and 49.2o do not have the nonnegative P_0-completion property by Facts 9 and 1.
8. By Fact 11, the graph in Figure 49.1a does not have and the graphs in Figures 49.1b and 49.1c do have the nonnegative P_0-completion property.
9. The graphs in Figures 49.1a, 49.1b, and 49.1c have the positive P- (nonnegative P-, nonnegative $P_{0,1}$-) completion property by Fact 11.

49.11 Entry Sign Symmetric P- ($P_{0,1}$-, P_0-) and Entry Weakly Sign Symmetric P- ($P_{0,1}$-, P_0-) Matrices

In this section, all matrices are real. In the literature, *entry sign symmetric* is often called *sign symmetric*; as defined in Section 26.2, the latter term is used for a different condition.

Definitions:

The matrix A is an **entry sign symmetric** P- (respectively, $P_{0,1}$-, P_0-) **matrix** if and only if A is a P-matrix (respectively, $P_{0,1}$-matrix, P_0-matrix) and for all i, j, either $a_{ij}a_{ji} > 0$ or $a_{ij} = a_{ji} = 0$.

The matrix A is an **entry weakly sign symmetric** P- (respectively, $P_{0,1}$-, P_0-) **matrix** if and only if A is a P-matrix (respectively, $P_{0,1}$-matrix, P_0-matrix) and for all i, j, $a_{ij}a_{ji} \geq 0$.

The partial matrix B is a **partial entry sign symmetric** P- (respectively, $P_{0,1}$-, P_0-) **matrix** if and only if every fully specified principal submatrix of B is an entry sign symmetric P- (respectively, $P_{0,1}$-, P_0-) matrix and if both b_{ij} and b_{ji} are specified then $b_{ij}b_{ji} > 0$ or $b_{ij} = b_{ji} = 0$.

The partial matrix B is a **partial entry weakly sign symmetric** P- (respectively, $P_{0,1}$-, P_0-) **matrix** if and only if every fully specified principal submatrix of B is an entry weakly sign symmetric P- (respectively, $P_{0,1}$-, P_0-) matrix and if both b_{ij} and b_{ji} are specified then, $b_{ij}b_{ji} \geq 0$.

Facts:

1. Let X be one of the classes entry sign symmetric P- ($P_{0,1}$-, P_0-) matrices, entry weakly sign symmetric P- ($P_{0,1}$-, P_0-) matrices. Then X is closed under permutation similarity, X is hereditary, and X is closed under matrix direct sums.
    (a) If a digraph G has X completion property, then so does every induced subdigraph of G.
    (b) A digraph G has the X completion property if and only if every connected component of G has the X completion property.
2. [Hog03a] Any digraph that has the entry sign symmetric P_0- (respectively, entry weakly sign symmetric P_0-) completion property also has the entry sign symmetric $P_{0,1}$- (respectively, entry weakly sign symmetric $P_{0,1}$-) completion property. Any digraph that has the entry sign symmetric $P_{0,1}$- (respectively, entry weakly sign symmetric $P_{0,1}$-) completion property also has the entry sign symmetric P- (respectively, entry weakly sign symmetric P-) completion property.
3. [Hog01] A digraph G has the entry sign symmetric P-completion property (respectively, entry weakly sign symmetric P-completion property) if and only if the subdigraph of G induced by vertices that have loops has the entry sign symmetric P-completion property (respectively, entry weakly sign symmetric P-completion property.
4. [FJT00], [Hog01] A digraph G has the entry sign symmetric P_0-completion property if and only if for every connected component H of G, either H omits all loops or H has a loop at every vertex and is block-clique.
5. [FJT00] A symmetric digraph with a loop at every vertex has the entry sign symmetric $P_{0,1}$-completion property if and only if every connected component is block-clique.
6. [FJT00] A block-clique digraph has the entry sign symmetric P- (entry sign symmetric $P_{0,1}$-, entry sign symmetric P_0-, entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property. See Fact 49.9.9 for information on the construction.
7. [Hog01] A digraph G has the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property if and only if every strongly connected and nonseparable induced subdigraph of G has the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property. See Algorithm 49.9.2 for information on the construction.
8. Fact 7 is not true for the entry sign symmetric P_0-matrices (cf. Fact 4) or for the entry sign symmetric $P_{0,1}$-matrices [Wan05]. In particular, the digraphs in Figures 49.2p and 49.2q have neither the entry sign symmetric P_0-completion property nor the entry sign symmetric $P_{0,1}$-completion property.
9. [DHH03] A symmetric n-cycle with a loop at every vertex has the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property if and only if $n \neq 4$ and $n \neq 5$.
10. [DHH03] An order 3 digraph G with a loop at every vertex has the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry

weakly sign symmetric P_0-) completion property if and only if its digraph does not contain a 3-cycle or is a clique.

11. [DHH03], [Wan05] All order 4 digraphs that have a loop at every vertex have been classified as to the entry sign symmetric P- (entry sign symmetric $P_{0,1}$-, entry sign symmetric P_0-, entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property.

Examples:

The graphs and digraphs for the examples can be found in Figures 49.1 and 49.2.

1. By Fact 4, the graphs in Figures 49.1f and 49.1l and the digraph in Figure 49.2c have the entry sign symmetric P_0-completion property and none of the other graphs or digraphs pictured do.
2. The graphs in Figures 49.1a, 49.1b, 49.1c, 49.1d, 49.1e, 49.1g, and 49.1h do not have the entry sign symmetric $P_{0,1}$-completion proper by Fact 5.
3. The graph in Figure 49.1f has the entry sign symmetric P- (entry sign symmetric $P_{0,1}$-, entry sign symmetric P_0-, entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion proper by Fact 6.
4. The graphs in Figures 49.1j, 49.1k, 49.1l, 49.1m, and 49.1n and the digraphs in Figures 49.2c and 49.2d have the entry sign symmetric P-completion property and entry weakly sign symmetric P-completion property by Facts 3 and 6.
5. The digraphs in Figures 49.2j, 49.2m, 49.2p, and 49.2q have the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property by Fact 7.
6. The graphs in Figures 49.1a and 49.1b do not have the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property by Fact 9.
7. The graph in Figure 49.1c has the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property by Fact 9.
8. The digraphs in Figures 49.2f, 49.2g, 49.2h, 49.2k, 49.2l, 49.2n, 49.2o, and 49.2r do not have the entry sign symmetric P- (entry weakly sign symmetric P-, entry weakly sign symmetric $P_{0,1}$-, entry weakly sign symmetric P_0-) completion property by Facts 10 and 1.

49.12 Q-Matrices

In this section, all matrices are real.

Definitions:

An $n \times n$ real matrix A is a **Q-matrix** if for every $k = 1, 2, \ldots, n$ the sum $S_k(A)$ of all $k \times k$ principal minors of A is positive.

A partial matrix B is a **partial Q-matrix** if $S_k(B) > 0$ for every $k = 1, 2, ..., n$ for which all $k \times k$ principal submatrices are fully specified.

The **complement** of a digraph $G = (V_G, E_G)$ is the digraph $\overline{G} = (V_G, E_{\overline{G}})$, where $(v, w) \in E_{\overline{G}}$ if and only if $(v, w) \notin E_G$.

Let π be a permutation of V. A **permutation digraph** is a digraph of the form $G_\pi = (V, E_\pi)$ where $E_\pi = \{(v, \pi(v)) : v \in V\}$. A permutation digraph is also called a **generalized cycle**; see Section 40.1.

Let A be an $n \times n$ matrix. Then

$$\det(A) = \sum (\text{sgn } \pi) a_{1\pi(1)} \cdots a_{n\pi(n)}$$

where the sum is taken over all permutations π of $\{1, 2, \ldots, n\}$ such that G_π is a spanning subdigraph of $\mathcal{D}(A)$, and the sum over the empty set is zero [BR91, p. 292].

A **permutation subdigraph** of a digraph G is a permutation digraph of a subdigraph of G.

A digraph G is **stratified** if G has a permutation subdigraph of order k for every $k = 2, 3, \ldots, |G|$.

A digraph is **minimally stratified** if it is stratified and the deletion of any arc results in a digraph that is not stratified.

A **signing** of a digraph is an assignment of a sign ($+$ or $-$) to each arc of the digraph; the sign of arc (v, w) is denoted $\text{sgn}(v, w)$. The result of a signing is called a **signed digraph**. The signed digraph $\mathcal{D}^{\pm}(A)$ of a real square matrix A is obtained from $\mathcal{D}(A)$ by assigning $\text{sgn}(a_{ij})$ to arc (i, j).

Let C be the cycle $(v_1, v_2), (v_2, v_3), \ldots, (v_{k-1}, v_k), (v_k, v_1)$ in a signed digraph. The **product of the cycle** C is $\text{sgn}(v_1, v_2) \cdots \text{sgn}(v_{k-1}, v_k)\text{sgn}(v_k, v_1)$, and the **sign of the cycle** C is $\text{sgn}(C) = (-)^{k+1}\text{sgn}(v_1, v_2) \cdots \text{sgn}(v_{k-1}, v_k)\text{sgn}(v_k, v_1)$.

The **fan** of order n is $F_n = (\{1, 2 \ldots, n\}, P_n \cup S_n)$ where P_n is the path $(1, 2), (2, 3), \ldots, (n-1, n)$ and S_n is the star with arcs $(k, 1), k = 2, \ldots, n$. See the digraphs in Figure 49.3.

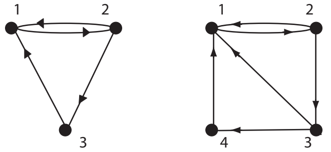

FIGURE 49.3 Fans F_3 and F_4.

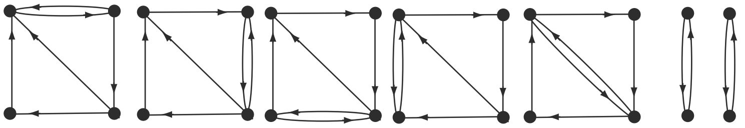
Facts:

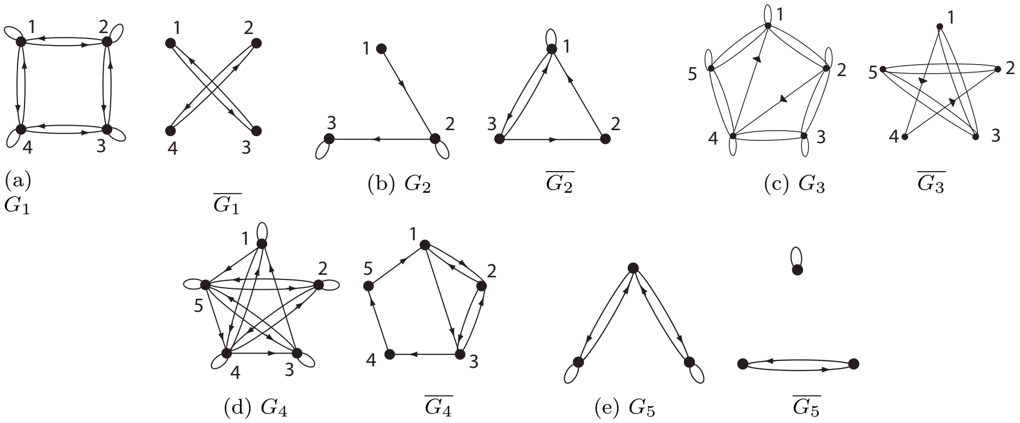
1. The class of Q-matrices is closed under similarity (including permutation similarity).
2. The class of Q-matrices is closed under matrix direct sums, so if each connected component of a digraph G has the Q-completion property, then so does G.
3. If A is a block triangular matrix and every diagonal block is a Q-matrix, then A is a Q-matrix. Thus, if each strongly connected component of a digraph G has the Q-completion property, then so does G.
4. The class of Q-matrices is not hereditary, i.e., a principal submatrix of a Q-matrix need not be a Q-matrix.
5. [DHS09] A partial matrix B is a partial Q-matrix if and only if exactly one of the following holds:
   (i) at least one diagonal entry of B is not specified,
   (ii) all diagonal entries of B are specified, $\text{tr}(B) > 0$, and at least one off-diagonal entry of B is not specified,
   (iii) all entries of B are specified and B is a Q-matrix.
6. [DHS09] If G is a digraph, $\overline{G}$ is stratified, and it is possible to sign the arcs of $\overline{G}$ so that the sign of every cycle is $+$, then G has the Q-completion property.
7. [DHS09] Let G be a digraph that omits at least one loop. If G has the Q-completion property, then $\overline{G}$ is stratified.
8. [DHS09] If $G \neq K_n$ is an order n digraph that includes all loops and has the Q-completion property, then for each $k = 2, 3, \ldots, n$,
   (i) $\overline{G}$ has a permutation digraph of order k, or
   (ii) for each $v \in V_G, \overline{G} - v$ has a permutation digraph of order $k - 1$.
   The converse is not true (see Example 3).
9. [DHS09] If G is a spanning subdigraph of an order n digraph $\hat{G} \neq K_n$ that has the Q-completion property, then G has the Q-completion property. Equivalently, if G is a digraph of order n, and a digraph $\hat{G} \neq K_n$ obtained from G by adding one or more arcs to G has the Q-completion property, then G has the Q-completion property.

10. [DHS09] If G is a digraph and $\overline{G}$ has a stratified spanning subdigraph that has a signing in which the sign of every cycle is $+$, then G has the Q-completion property. The converse is not true (see Example 4).
11. [DHS09] Let $G = (V_G, E_G)$ be an order n digraph that omits at least one loop and such that $|E_G| > n(n-1)$. Then G does not have the Q-completion property.
12. [DHS09] Let $G \neq K_n$ be an order n digraph that includes all loops and such that G has more than $(n-1)^2 - 1$ non-loop arcs. Then G does not have the Q-completion property.
13. [DHS09] Let G be an order n digraph that includes all loops and has the Q-completion property. Then $\overline{G}$ has a 2-cycle.
14. [DHS09] If G is a digraph obtained from a tournament of order n by adding all loops, or all but one loop, then G does not have the Q-completion property.
15. [DHS09] If G contains all loops and has a vertex v such that for all $w, (v, w) \in E_G$ (respectively, for all $w, (w, v) \in E_G$), then G does not have the Q-completion property.
16. [DHS09] Let G be a digraph that contains all loops.
    (a) Let $|G| = 2$. Then G has the Q-completion property if and only $\overline{G} = K_2$ or $G = K_2$.
    (b) Let $|G| = 3$. Then G has the Q-completion property if and only if its complement $\overline{G}$ has F_3 as a subdigraph or $G = K_3$.
    (c) Let $|G| = 4$. Then G has the Q-completion property if and only if its complement $\overline{G}$ has one of the six digraphs shown in Figure 49.4 as a subdigraph or $G = K_4$.



D145= F_4 D126 D138 D141 D135 D66

FIGURE 49.4 Order four Q-minimal complements (with names from [RW98]).



(a) G_1 $\overline{G_1}$ (b) G_2 $\overline{G_2}$ (c) G_3 $\overline{G_3}$

(d) G_4 $\overline{G_4}$ (e) G_5 $\overline{G_5}$

FIGURE 49.5 Digraphs for Examples 1 through 5.

Examples:

1. [DHS09] Let G_1 be the digraph shown in Figure 49.5a. Sign the arcs of $\overline{G_1}$ as $\text{sgn}(1,3) = \text{sgn}(2,4) = +$ and $\text{sgn}(3,1) = \text{sgn}(4,2) = -$. Then the signs of the two cycles in $\overline{G_1}$ are

both +. For a partial Q-matrix $B = \begin{bmatrix} b_{11} & b_{12} & x_{13} & b_{14} \\ b_{21} & b_{22} & b_{23} & x_{24} \\ x_{31} & b_{32} & b_{33} & b_{34} \\ b_{41} & x_{42} & b_{43} & b_{44} \end{bmatrix}$ that specifies G_1, define the completion $A(t)$ of B by choosing each unspecified entry to be the sign of its arc times t, i.e., $x_{13} = x_{24} = t, x_{31} = x_{42} = -t$. Then

$$\begin{aligned} S_1(A(t)) &= b_{11} + b_{22} + b_{33} + b_{44}, & & \\ S_2(A(t)) &= 2t^2 + q_2(t) & &\text{where } \deg q_2(t) \le 1, \\ S_3(A(t)) &= (b_{11} + b_{22} + b_{33} + b_{44})\, t^2 + q_3(t) & &\text{where } \deg q_3(t) \le 1, \\ S_4(A(t)) &= t^4 + q_4(t) & &\text{where } \deg q_4(t) \le 2. \end{aligned}$$

For t large enough, $S_k(A(t)) > 0$ for all $k = 2, 3, 4$ and $S_1(A(t)) = S_1(B) > 0$ because B is a partial Q-matrix.

2. [DHS09] The digraph G_2 shown in Figure 49.5b has the Q-completion property because $\overline{G_2}$ is stratified and $\operatorname{sgn}(1,1) = \operatorname{sgn}(1,3) = \operatorname{sgn}(3,2) = \operatorname{sgn}(2,1) = +$ and $\operatorname{sgn}(3,1) = -$ makes the sign of each cycle positive. But $G_2[\{1,2\}]$ does not have the Q-completion property and $\overline{G_2[\{1,2\}]}$ is not stratified.
3. [DHS09] Let G_3 be the digraph shown in Figure 49.5c. By inspection, $\overline{G_3}$ has permutation subdigraphs of orders 2, 4, and 5, and for each $v = 1, \ldots, 5$, $\overline{G_3} - v$ has a permutation digraph of order 2. Thus, G_3 satisfies the conclusion of Fact 8. However, the partial Q-matrix $B = \begin{bmatrix} 2 & 0 & x & y & 0 \\ 0 & 2 & 0 & 0 & w \\ u & 0 & 2 & 0 & v \\ 0 & t & 0 & -7 & 0 \\ 0 & r & s & 0 & 2 \end{bmatrix}$ specifies G_3 and cannot be completed to a Q-matrix: The sum of the 2×2 principal minors is $-32 - sv - rw - ux$, so for a completion to be a Q-matrix, $sv + rw + ux$ must be negative. The sum of the 3×3 principal minors is $-136 + 3sv + 3rw + 3ux$, so for a completion to be a Q-matrix, $sv + rw + ux$ to be positive. Thus, the converse of Fact 8 is false.
4. [DHS09] Let G_4 and its complement $\overline{G_4}$ be the digraphs shown in Figure 49.5d. Then $\overline{G_4}$ is stratified because it contains the cycles $(1,2)$, $(1,3,2)$, $(1,3,4,5)$, and $(1,2,3,4,5)$. It is shown in [DHS09] that $\overline{G_4}$ is minimally stratified, that there is no signing that makes all cycles positive, and that any partial Q-matrix $B = [b_{ij}]$ specifying G_4 can be completed to a Q-matrix by defining $A(t) = \begin{bmatrix} b_{11} & t^2 & -t^2 & b_{14} & b_{15} \\ t^2 & b_{22} & t^2 & b_{24} & b_{25} \\ b_{31} & -t^3 & b_{33} & t^2 & b_{35} \\ b_{41} & b_{42} & b_{43} & b_{44} & t^2 \\ t^2 & b_{52} & b_{53} & b_{54} & b_{55} \end{bmatrix}$ and choosing t sufficiently large.
5. [DHS09] Let $G_5 = (V_5, E_5)$ be the digraph shown in Figure 49.5e. Then $\overline{G_5}$ is stratified, and it is easy to sign $\overline{G_5}$ so that all cycles are positive. Hence, G_5 has the Q-completion property, but $|E_{G_5}| = 3(3-1)$. Thus, the strict inequality in Fact 11 cannot be relaxed to allow equality.

49.13 Totally Positive, Totally Nonnegative, and Totally Nonpositive Matrices

In this section, all numerical matrices are real, but may be rectangular. Unlike the classes of matrices Y listed at the beginning of the facts in Section 49.1, Facts 49.1.2 and 49.1.4

do not hold for totally positive, totally nonnegative, and totally nonpositive matrices. Thus labeled (di)graphs are used to describe the positions of the specified entries of square partial matrices, and patterns are used to describe partial rectangular matrices. See Chapter 29 or [FJ11] for information on totally positive and totally nonnegative matrices. Chapter 9 of [FJ11] is a comprehensive source for information about completions of partial totally positive and totally nonnegative matrices.

Definitions:

A **pattern** is an $m \times n$ matrix $\mathcal{Y}$ whose entries are elements of $\{*, ?\}$.

For a partial matrix $B = [b_{ij}] \in \mathbb{R}^{m\times n}$, the **pattern of** B, $\mathcal{Y}(B) = [y_{ij}]$, is the $m \times n$ pattern with

$$y_{ij} = \begin{cases} * \text{ if } b_{ij} \text{ is specified;} \\ ? \text{ if } b_{ij} \text{ is not specified.} \end{cases}$$

A partial matrix B **specifies** a pattern $\mathcal{Y}$ if $\mathcal{Y}(B) = \mathcal{Y}$.

An $m \times n$ real matrix A is a **totally positive (TP) matrix** if every minor of A is positive. Unfortunately, in the literature, the term "totally positive matrix" has sometimes been used for what is here called a "totally nonnegative matrix," including some of the references cited here, e.g., [And87] and [JT04].

An $m \times n$ real matrix A is a **totally nonnegative (TN) matrix** if every minor of A is nonnegative.

An $m \times n$ real matrix A is a **totally nonpositive matrix** if every minor of A is nonpositive.

A partial matrix B is a **partial totally positive** (respectively, **totally nonnnegative**, **totally nonpositive**) **matrix** if every completely specified submatrix is a totally positive (respectively, totally nonnnegative, totally nonpositive[1]) matrix.

A **monotonically labeled block-clique graph** is a labeled block-clique graph in which the maximal cliques are labeled in natural order; that is, the numbering within each clique is consecutive and if a pair of maximal cliques intersects in a vertex u, then u is the highest labeled vertex in one clique and the lowest labeled vertex in the other clique.

Let the graph G be a path with three vertices i, j, k in path order, as shown in Figure 49.6a. If the labeling is not monotonic, B is a partial matrix with $\mathcal{G}(B) = G$ and all diagonal entries of B nonzero, then B satisfies the **P-condition** [JT04] when the following are satisfied:

(i) if $j < i < k$ or $k < i < j$, then $b_{jk}b_{kj} \leq (b_{kk}/b_{ii})b_{ij}b_{ji}$

(ii) if $i < k < j$ or $j < k < i$, then $b_{ij}b_{ji} \leq (b_{ii}/b_{kk})b_{kj}b_{jk}$.

In general, we say that a combinatorially symmetric partial matrix B of size $n \times n$ satisfies the **P-condition** if every 3×3 principal submatrix of B, whose associated graph is a path that is not monotonically labeled, satisfies the above inequalities. In [DJK08] the P-condition is called the **adjacent edge condition**.

FIGURE 49.6 Labelled graphs and digraphs.

---

[1] There is a typographical error in [MTU06, Definition 1.1], but clearly "totally nonpositive" was intended.

Facts:

1. The classes of totally positive, totally nonnegative, and totally nonpositive matrices are hereditary classes. The class of totally nonnegative matrices is closed under matrix direct sums.
2. There is a one-to-one correspondence between $n \times n$ patterns and labeled digraphs with vertex set $\{1, \dots, n\}$.
3. In general, a totally positive, totally nonnegative, or totally nonpositive matrix does not retain that property under permutation similarity (see Example 1). Thus, the graphs and digraphs used to describe the specified entries of partial totally positive, totally nonnegative, totally nonpositive matrices in the study of completions must be labeled.
4. [And87], [MTU06] Let P denote the $n \times n$ permutation matrix induced by the permutation $i \to n - i + 1$, $1 \leq i \leq n$. If A is an $n \times n$ totally positive (respectively, totally nonnegative, totally nonpositive) matrix, then PAP^T is a totally positive (respectively, totally nonnegative, totally nonpositive) matrix. Thus reversing the order in which the vertices are labeled on a digraph does not change whether it has the totally positive, totally nonnegative, or totally nonpositive completion property.
5. If A is a totally positive (respectively, totally nonnegative, totally nonpositive) matrix and D is a positive diagonal matrix, then DA and AD are totally positive (respectively, totally nonnegative, totally nonpositive) matrices. Thus when showing that a partial totally positive (respectively, totally nonnegative, totally nonpositive) matrix can be completed to a totally positive (respectively, totally nonnegative, totally nonpositive) matrix, without loss of generality, it may be assumed that all diagonal entries are 1 (respectively, 1 or 0, -1 or 0).
6. [FJ11, Theorem 9.2.1], [JKL98] A labeled graph G has the totally nonnegative completion property if and only if G is a monotonically labeled block-clique graph.
7. [FJ11, Theorem 9.2.2], [JN09] A monotonically labeled block-clique graph has the totally positive completion property.
8. [MTU06] If B is a combinatorially symmetric partial totally nonpositive matrix, and $\mathcal{G}(B)$ is a connected monotonically labeled block-clique graph, and the diagonal entries of B corresponding to vertices common to two maximal cliques are nonzero, then B can be completed to a totally nonpositive matrix. This is not true without the hypothesis that entries corresponding to vertices in two maximal cliques are nonzero (see Example 6).
9. [FJ11, p. 37] Inserting a zero row or column into a totally nonnegative or totally nonpositive matrix[2] retains the property of being a totally nonnegative or totally nonpositive matrix. Thus if $\mathcal{Y}$ is a pattern that has the totally nonnegative (respectively, totally nonpositive) completion property and $\mathcal{Y}'$ is obtained from $\mathcal{Y}$ by adding a row or column of unspecified entries, then $\mathcal{Y}'$ has the totally nonnegative (respective totally nonpositive) completion property.
10. [FJ11, p. 185] Inserting an unspecified first or last row or column into a totally positive matrix (*exterior bordering*) always allows completion to a totally positive matrix. Thus if $\mathcal{Y}$ is a pattern that has the totally positive completion property and $\mathcal{Y}'$ is obtained from $\mathcal{Y}$ by adding a first or last row or column of unspecified entries, then $\mathcal{Y}'$ has the totally positive completion property.
11. [FJ11, Theorem 9.4.4], [FJS00] Let B be an $m \times n$ partial totally positive matrix with exactly one unspecified entry in the (s, t)-position. If $\min\{m, n\} \leq 3$, then every such

---

[2] Totally nonpositive matrices are not discussed in [FJ11] but the same argument applies.

B can be completed to a totally positive matrix. If $\min\{m,n\} \geq 4$, then every such B can be completed to a totally positive matrix if and only if $s+t \leq 4$ or $s+t \geq m+n-2$. This fact is not true for totally nonnegative matrices; see Example 7.

12. [JTG09] Let B be an $n \times n$ partial totally nonnegative matrix in which all specified entries are nonzero, and whose associated digraph is a directed path (monotonically or non-monotonically labeled). Then there exists a totally nonnegative completion of B.
13. [JT04] Let G be a graph containing a clique on vertices $\{1,2,\ldots k\}$ and with vertices $\{k+1, k+2, \ldots n\}$ all adjacent to exactly one vertex in $\{1,2,\ldots k\}$. Let B be a combinatorially symmetric partial totally nonnegative matrix with $\mathcal{G}(B) = G$ and all specified entries nonzero. Then B has a totally nonnegative completion if and only if B satisfies the P-condition.
14. [FJ11, Chap. 9], [JT04], [DJK08], [GJT08], [JTG09], [JK11], [MTU06] Numerous conditions have been established characterizing when specific labeled (di)graphs have the totally positive, totally nonnegative, or totally nonpositive completion property.

Examples:

1. The matrix $A = \begin{bmatrix} 4 & 2 & 1 \\ 2 & 2 & 1 \\ 1 & 1 & 1 \end{bmatrix}$ is totally nonnegative. However, for the permutation matrix $P = \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}$, $PAP^T = \begin{bmatrix} 2 & 2 & 1 \\ 2 & 4 & 1 \\ 1 & 1 & 1 \end{bmatrix}$ is not totally nonnegative because $\det((PAP^T)[\{1,2\},\{2,3\}]) = -2$.
2. The pattern $\mathcal{Y} = \begin{bmatrix} * & * & ? \\ * & * & * \\ ? & * & * \end{bmatrix}$ has the monotonically labeled block-clique graph shown in Figure 49.6b. By Fact 6, any partial totally nonnegative partial matrix specifying this pattern can be completed to a totally nonnegative matrix. In particular, a partial totally nonnegative matrix $B = \begin{bmatrix} b_{11} & b_{12} & x_{13} \\ b_{21} & b_{22} & b_{23} \\ x_{31} & b_{32} & b_{33} \end{bmatrix}$ with $b_{22} \neq 0$ can be completed to a totally nonnegative matrix by choosing $x_{13} = b_{12}b_{23}/b_{22}$ and $x_{31} = b_{32}b_{21}/b_{22}$; if $b_{22} = 0$, choose $x_{13} = x_{31} = 0$. This construction generalizes: If B is a partial totally nonnegative matrix, $\mathcal{D}(B)$ is monotonically labeled block-clique with two maximal cliques, and the diagonal entry associated with the vertex in both cliques is nonzero, then B can be partitioned as a block matrix $B = \begin{bmatrix} B_{11} & \mathbf{b}_{12} & X_{13} \\ \mathbf{b}_{21}^T & b_{22} & \mathbf{b}_{23}^T \\ X_{31} & \mathbf{b}_{32} & 1 \end{bmatrix}$ and completed to a totally nonnegative matrix by defining $X_{13} = \mathbf{b}_{12}\mathbf{b}_{23}^T/b_{22}$ and $X_{31} = \mathbf{b}_{32}\mathbf{b}_{21}^T/b_{22}$ [FJ11, p. 188].
3. Let $B = \begin{bmatrix} 1 & b_{12} & x_{13} \\ b_{21} & 1 & b_{23} \\ x_{31} & b_{32} & 1 \end{bmatrix}$ be a partial totally positive matrix. Since $\mathcal{G}(B)$ is the monotonically labeled block-clique graph shown in Figure 49.6b, B can be completed to a totally positive matrix. For example, let $B = \begin{bmatrix} 4 & 2 & x_{13} \\ 2 & 2 & 1 \\ x_{31} & 1 & 1 \end{bmatrix}$. The completion in Example 2, namely $x_{13} = x_{31} = 1$, is totally nonnegative but not totally positive completion. A small negative perturbation of x_{13} and x_{31}, e.g., $x_{13} = x_{31} = 0.9$, yields a totally positive completion.
4. [FJ11, Theorem 9.3.1] The pattern $\begin{bmatrix} * & ? & * \\ ? & * & * \\ * & * & * \end{bmatrix}$ has the non-monotonically labeled block-

clique graph shown in Figure 49.6c. The partial matrix $B = \begin{bmatrix} 1 & x_{12} & b_{13} \\ x_{21} & 1 & b_{23} \\ b_{31} & b_{32} & 1 \end{bmatrix}$ can be completed to a totally positive matrix if and only if B is a partial totally positive matrix and $b_{13}b_{31} < b_{23}b_{32}$.

5. [JT04], [FJ11, Theorem 9.3.1] Let $B = \begin{bmatrix} 1 & x_{12} & b_{13} \\ x_{21} & 1 & b_{23} \\ b_{31} & b_{32} & 1 \end{bmatrix}$ be a partial totally nonnegative matrix; $\mathcal{G}(B)$ is the non-monotonically labeled block-clique graph shown in Figure 49.6c. If all specified entries are nonzero, B can be completed to a totally nonnegative matrix if and only if $b_{13}b_{31} \leq b_{23}b_{32}$. If zero entries are allowed, additional conditions are necessary to ensure totally nonnegative completion: $b_{23} = 0 \Rightarrow b_{13} = 0$ and $b_{32} = 0 \Rightarrow b_{31} = 0$.[3] For example, $B = \begin{bmatrix} 1 & x_{12} & 1 \\ x_{21} & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$ is a partial totally nonnegative matrix, $b_{13}b_{31} = 0 = b_{23}b_{32}$, but B cannot be completed to a totally nonnegative matrix.
6. [MTU06] The following combinatorially symmetric partial totally nonpositive matrix $B = \begin{bmatrix} -1 & -1 & x_{13} \\ -2 & 0 & -1 \\ x_{31} & -2 & -1 \end{bmatrix}$, whose graph is the monotonically labeled block-clique graph in Figure 49.6b, does not have totally nonpositive matrix completion since $\det B[\{1,2\},\{2,3\}] > 0$ for every value of x_{13}. Therefore, the condition of having nonzero diagonal entries for vertices in two maximal cliques in Fact 8 is necessary.
7. Fact 11 is false for total nonnegativity. The partial totally nonnegative matrix $A = \begin{bmatrix} 1 & x_{12} & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$ cannot be completed to totally nonnegative matrix because $\det A[\{1,2\},\{2,3\}] = -1$.
8. [FJS00], [FJ11, p. 196] The partial totally positive matrix $B = \begin{bmatrix} 1000 & 10 & 10 & 10 \\ 20 & 9 & x & 10 \\ 2 & 1 & 9 & 10 \\ 1 & 2 & 40 & 1000 \end{bmatrix}$ is an example of a 4×4 partial totally positive matrix with the $(2,3)$ entry unspecified that has no totally positive completion. For $\det B[\{1,2\},\{3,4\}]$ to be positive, $x < 10$.[4] For $\det B[\{2,3,4\},\{1,2,3\}]$ to be positive, $x > 199/3$.
9. The partial totally nonnegative matrix $B = \begin{bmatrix} 1 & x_{12} & 1 \\ x_{21} & 1 & x_{23} \\ x_{31} & 1 & 0 \end{bmatrix}$ has the (non-monotonically) labeled directed path shown in Figure 49.6d as its digraph, but cannot be completed to a totally nonnegative matrix. This shows that Fact 12 requires the hypothesis that all specified entries are nonzero.

Calculations are subject to errors. There may be modeling errors, measurement errors, manufacturing errors, noise, equipment is subject to wear and damage, etc. In preparation for computation, data must often be perturbed by rounding it to fit a particular finite precision, floating-point format. Further errors may be introduced during a computation by using finite precision arithmetic and by truncating an infinite process down to a finite number of steps.

This chapter outlines aspects of how such errors affect the results of a mathematical computation with an emphasis on matrix computations. Topics include:

- Vector and matrix norms and seminorms that are often used to analyze errors and express error bounds.
- Floating point arithmetic.
- Condition numbers that measure how much data errors may affect computational results.
- Numerical stability, an assessment of whether excessive amounts of data may be lost to rounding errors during a finite precision computation.

For elaborative discussions of vector and matrix norms, consult [HJ85]. See [Ove01] for a textbook introduction to IEEE standard floating point arithmetic. Complete details of the standard are available in [IEEE754] and [IEEE854]. Basic concepts of numerical stability and conditioning appear in numerical linear algebra books, e.g., [GV96], [Ste98], [TB97], and [Dat10]. The two particularly authoritative books on these topics are the classical book by Wilkinson [Wil65] and the more recent one by Higham [Hig02]. For perturbation analysis, see the classic monograph [Kat66] and the more modern treatments in [SS90] and [Bha96].

The set $\mathbb{C}^n = \mathbb{C}^{n\times 1}$ is the complex vector space of n-row, 1-column matrices, and $\mathbb{R}^n = \mathbb{R}^{n\times 1}$ is the real vector space of n-row, 1-column matrices. Unless otherwise specified, $\mathbb{F}^n$ is either $\mathbb{R}^n$ or $\mathbb{C}^n$, $\mathbf{x}$ and $\mathbf{y}$ are members of $\mathbb{F}^n$, and $\alpha \in \mathbb{F}$ is a scalar $\alpha \in \mathbb{R}$ or $\alpha \in \mathbb{C}$, respectively. For $\mathbf{x} \in \mathbb{R}^n$, $\mathbf{x}^T$ is the one row n-column transpose of $\mathbf{x}$. For $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{x}^*$ is the one row n-column complex-conjugate-transpose of $\mathbf{x}$. A and B are members of $\mathbb{F}^{m\times n}$. For $A \in \mathbb{R}^{m\times n}$, $A^* \in \mathbb{R}^{n\times m}$ is the transpose of A. For $A \in \mathbb{C}^{m\times n}$, $A^* \in \mathbb{C}^{n\times m}$ is the complex-conjugate-transpose of A.

50.1 Vector Norms

Most uses of vector norms involve $\mathbb{R}^n$ or $\mathbb{C}^n$, so the focus of this section is on those vector spaces. However, the definitions given here can be extended in the obvious way to any finite dimensional real or complex vector space.

Let $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$ and $\alpha \in \mathbb{F}$, where $\mathbb{F}$ is either $\mathbb{R}$ or $\mathbb{C}$.

Definitions:

A vector **norm** is a real-valued function on $\mathbb{F}^n$ denoted $\|\mathbf{x}\|$ with the following properties for all $\mathbf{x}$, $\mathbf{y} \in \mathbb{F}^n$ and all scalars $\alpha \in \mathbb{F}$.

- **Positive definiteness:** $\|\mathbf{x}\| \geq 0$ and $\|\mathbf{x}\| = 0$ if and only if $\mathbf{x}$ is the zero vector.
- **Homogeneity:** $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$.
- **Triangle inequality:** $\|\mathbf{x}+\mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$.

For $\mathbf{x} = [x_1, x_2, x_3, \ldots, x_n]^* \in \mathbb{F}^n$, the following are commonly encountered vector norms.

- **Sum-norm or 1-norm:** $\|\mathbf{x}\|_1 = |x_1| + |x_2| + \cdots + |x_n|$.
- **Euclidean norm or 2-norm:** $\|\mathbf{x}\|_2 = \sqrt{|x_1|^2 + |x_2|^2 + \cdots + |x_n|^2}$.
- **Sup-norm or ∞-norm:** $\|\mathbf{x}\|_\infty = \max\limits_{1\leq i\leq n} |x_i|$.
- **Hölder norm or p-norm:** For $p \geq 1$, $\|\mathbf{x}\|_p = (|x_1|^p + \cdots + |x_n|^p)^{\frac{1}{p}}$.

If $\|\cdot\|$ is a vector norm on $\mathbb{F}^n$ and $M \in F^{n\times n}$ is a nonsingular matrix, then $\|\mathbf{y}\|_M \equiv \|M\mathbf{y}\|$ is an **M-norm** or **energy norm**. (Note that this notation is ambiguous, since $\|\cdot\|$ is not specified; it either does not matter or must be stated explicitly when used.)

A vector norm $\|\cdot\|$ is **absolute** if for all $\mathbf{x} \in \mathbb{F}^n$, $\|\,|\mathbf{x}|\,\| = \|\mathbf{x}\|$, where $|[x_1, \ldots, x_n]^*| = [|x_1|, \ldots, |x_n|]^*$.

A vector norm $\|\cdot\|$ is **monotone** if for all $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$, $|\mathbf{x}| \leq |\mathbf{y}|$ implies $\|\mathbf{x}\| \leq \|\mathbf{y}\|$.

A vector norm $\|\cdot\|$ is **permutation invariant** if $\|P\mathbf{x}\| = \|\mathbf{x}\|$ for all $\mathbf{x} \in \mathbb{R}^n$ and all permutation matrices $P \in \mathbb{R}^{n\times n}$.

Let $\|\cdot\|$ be a vector norm. The **dual norm** is defined by $\|\mathbf{y}\|^D = \max_{\mathbf{x}\neq 0} \frac{|\mathbf{y}^*\mathbf{x}|}{\|x\|}$.

The unit disk corresponding to a vector norm $\|\cdot\|$ is the set $\{\mathbf{x} \in \mathbb{F}^n \mid \|\mathbf{x}\| \leq 1\}$.

The unit sphere corresponding to a vector norm $\|\cdot\|$ is the set $\{\mathbf{x} \in \mathbb{F}^n \mid \|\mathbf{x}\| = 1\}$.

Facts:

For proofs and additional background, see, for example, [HJ85, Chap. 5].

Let $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$ and $\alpha \in \mathbb{F}$, where $\mathbb{F}$ is either $\mathbb{R}$ or $\mathbb{C}$.

1. The commonly encountered norms, $\|\cdot\|_1, \|\cdot\|_2, \|\cdot\|_\infty, \|\cdot\|_p$, are permutation invariant, absolute, monotone vector norms.
2. If $M \in F^{n\times n}$ is a nonsingular matrix and $\|\cdot\|$ is a vector norm, then the M-norm $\|\cdot\|_M$ is a vector norm.
3. If $\|\cdot\|$ is a vector norm, then $\big|\,\|\mathbf{x}\| - \|\mathbf{y}\|\,\big| \leq \|\mathbf{x}-\mathbf{y}\|$.
4. A sum of vector norms is a vector norm.
5. $\lim\limits_{k\to\infty} \mathbf{x}_k = \mathbf{x}_*$ if and only if in any norm $\lim\limits_{k\to\infty} \|\mathbf{x}_k - x_*\| = 0$.
6. *Cauchy–Schwartz inequality:*
    (a) $|\mathbf{x}^*\mathbf{y}| \leq \|\mathbf{x}\|_2\|\mathbf{y}\|_2$.

   (b) $|\mathbf{x}^*\mathbf{y}| = \|\mathbf{x}\|_2\|\mathbf{y}\|_2$ if and only if there exist scalars α and β, not both zero, for which $\alpha x = \beta y$.
7. *Hölder inequality:* If $p \geq 1$ and $q \geq 1$ satisfy $\frac{1}{p} + \frac{1}{q} = 1$, then $|\mathbf{x}^*\mathbf{y}| \leq \|\mathbf{x}\|_p \, \|\mathbf{y}\|_q$.
8. If $\|\cdot\|$ is a vector norm on $\mathbb{F}^n$, then its dual $\|\cdot\|^D$ is also a vector norm on $\mathbb{F}^n$, and $\|\cdot\|^{DD} = \|\cdot\|$.
9. If $p > 0$ and $q > 0$ satisfy $\frac{1}{p} + \frac{1}{q} = 1$, then $\|\cdot\|_p^D = \|\cdot\|_q$. In particular, $\|\cdot\|_2^D = \|\cdot\|_2$. Also, $\|\cdot\|_1^D = \|\cdot\|_\infty$.
10. If $\|\cdot\|$ is a vector norm on $\mathbb{F}^n$, then for any $\mathbf{x} \in \mathbb{F}^n$, $|\mathbf{x}^*\mathbf{y}| \leq \|\mathbf{x}\| \, \|\mathbf{y}\|^D$.
11. A vector norm is absolute if and only if it is monotone.
12. *Equivalence of norms:* All vector norms on $\mathbb{F}^n$ are equivalent in the sense that for any two vector norms $\|\cdot\|_\mu$ and $\|\cdot\|_\nu$ there are constants $\alpha > 0$ and $\beta > 0$ such that for all $\mathbf{x} \in \mathbb{F}^n$, $\alpha\|\mathbf{x}\|_\mu \leq \|\mathbf{x}\|_\nu \leq \beta\|\mathbf{x}\|_\mu$. The constants α and β are independent of $\mathbf{x}$ but typically depend on the dimension n.
   In particular,
   (a) $\|\mathbf{x}\|_2 \leq \|\mathbf{x}\|_1 \leq \sqrt{n}\|\mathbf{x}\|_2$.
   (b) $\|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_2 \leq \sqrt{n}\|\mathbf{x}\|_\infty$.
   (c) $\|\mathbf{x}\|_\infty \leq \|\mathbf{x}\|_1 \leq n\|\mathbf{x}\|_\infty$.
13. A set $D \subset \mathbb{F}^n$ is the unit disk of a vector norm if and only if it has the following properties:
   (a) *Point-wise bounded:* For every vector $\mathbf{x} \in \mathbb{F}^n$ there is a number $\delta > 0$ for which $\delta\mathbf{x} \notin D$.
   (b) *Absorbing:* For every vector $\mathbf{x} \in \mathbb{F}^n$ there is a number $\tau > 0$ for which $|\alpha| \leq \tau$ implies $\alpha\mathbf{x} \in D$.
   (c) *Convex:* For every pair of vectors $\mathbf{x}, \mathbf{y} \in D$ and every number t, $0 \leq t \leq 1$, $t\mathbf{x} + (1-t)\mathbf{y} \in D$.

Examples:

1. Let $\mathbf{x} = [1, 1, -2]^*$. Then $\|\mathbf{x}\|_1 = 4, \|\mathbf{x}\|_2 = \sqrt{1^2 + 1^2 + (-2)^2} = \sqrt{6}$, and $\|\mathbf{x}\|_\infty = 2$.
2. Let $M = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}$. Using the 1-norm, $\left\|\begin{bmatrix} 0 \\ 1 \end{bmatrix}\right\|_M = \left\|\begin{bmatrix} 2 \\ 4 \end{bmatrix}\right\|_1 = 6$.

50.2 Vector Seminorms

Definitions:

A **vector seminorm** is a real-valued function on $\mathbb{F}^n$, denoted $\nu(\mathbf{x})$, with the following properties for all $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$ and all scalars $\alpha \in \mathbb{F}$.

1. **Positiveness:** $\nu(\mathbf{x}) \geq 0$.
2. **Homogeneity:** $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$.
3. **Triangle inequality:** $\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$.

Vector norms are *a fortiori* also vector seminorms.

The unit disk corresponding to a vector seminorm $\|\cdot\|$ is the set $\{\mathbf{x} \in \mathbb{F}^n \mid \nu(\mathbf{x}) \leq 1\}$.

The unit sphere corresponding to a vector seminorm $\|\cdot\|$ is the set $\{\mathbf{x} \in \mathbb{F}^n \mid \nu(\mathbf{x}) = 1\}$.

Facts:

For proofs and additional background, see, for example, [HJ85, Chap. 5].

Let $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$ and $\alpha \in \mathbb{F}$, where $\mathbb{F}$ is either $\mathbb{R}$ or $\mathbb{C}$.

1. $\nu(0) = 0$.
2. $\nu(\mathbf{x} - \mathbf{y}) \geq |\nu(\mathbf{x}) - \nu(\mathbf{y})|$.
3. A sum of vector seminorms is a vector seminorm. If one of the summands is a vector norm, then the sum is a vector norm.
4. A set $D \subset \mathbb{F}^n$ is the unit disk of a seminorm if and only if it has the following properties:
    (a) *Absorbing:* For every vector $\mathbf{x} \in \mathbb{F}^n$ there is a number $\tau > 0$ for which $|\alpha| \leq \tau$ implies $\alpha x \in D$.
    (b) *Convex:* For every pair of vectors $\mathbf{x}$, $\mathbf{y} \in D$ and every number t, $0 \leq t \leq 1$, $t\mathbf{x} + (1 - t)\mathbf{y} \in D$.

Examples:

1. For $\mathbf{x} = [x_1, x_2, x_3, \ldots, x_n]^T \in \mathbb{F}^n$, the function $\nu(x) = |x_1|$ is a vector seminorm that is not a vector norm. For $n \geq 2$, this seminorm is not equivalent to any vector norm $\|\cdot\|$, since $\|\mathbf{e}_2\| > 0$ but $\nu(\mathbf{e}_2) = 0$, for $\mathbf{e}_2 = [0, 1, 0, \ldots, 0]^T$.

50.3 Matrix Norms

Definitions:

A **matrix norm** is a family of real-valued functions on $\mathbb{F}^{m\times n}$ for all positive integers m and n, denoted uniformly by $\|A\|$ with the following properties for all matrices A and B and all scalars $\alpha \in \mathbb{F}$.

- **Positive definiteness:** $\|A\| \geq 0$; $\|A\| = 0$ only if $A = 0$.
- **Homogeneity:** $\|\alpha A\| = |\alpha|\|A\|$.
- **Triangle inequality:** $\|A + B\| \leq \|A\| + \|B\|$, where A and B are compatible for matrix addition.
- **Consistency:** $\|AB\| \leq \|A\|\;\|B\|$, where A and B are compatible for matrix multiplication.

If $\|\cdot\|$ is a family of vector norms on $\mathbb{F}^n$ for $n = 1, 2, 3, \ldots$, then the matrix norm on $\mathbb{F}^{m\times n}$ **induced** by (or **subordinate** to) $\|\cdot\|$ is $\|A\| = \max_{\mathbf{x}\neq 0} \dfrac{\|A\mathbf{x}\|}{\|\mathbf{x}\|}$. Induced matrix norms are also called **operator norms** or **natural norms**. The matrix norm $\|A\|_p$ denotes the norm induced by the Hölder vector norm $\|\mathbf{x}\|_p$.

The following are commonly encountered matrix norms:

- **Maximum absolute column sum norm:** $\|A\|_1 = \max\limits_{1\leq j\leq n} \sum\limits_{i=1}^{m} |a_{ij}|$.
- **Spectral norm:** $\|A\|_2 = \sqrt{\rho(A^*A)}$, where $\rho(A^*A)$ is the largest eigenvalue of A^*A.
- **Maximum absolute row sum norm:** $\|A\|_\infty = \max\limits_{1\leq i\leq m} \sum\limits_{j=1}^{n} |a_{ij}|$.
- **Euclidean norm** or **Frobenius norm:** $\|A\|_F = \sqrt{\sum\limits_{i,j=1}^{n} |a_{ij}|^2}$.

Let $\mathcal{M} = \{M_n \in F^{n\times n} : n \geq 1\}$ be a family of nonsingular matrices and let $\|\cdot\|$ be a family of vector norms. Define a family of vector norms by $\|\mathbf{x}\|_{\mathcal{M}}$ for $\mathbf{x} \in \mathbb{F}^n$ by $\|\mathbf{x}\|_{\mathcal{M}} = \|M_n\mathbf{x}\|$. This family of vector norms is also called the **$\mathcal{M}$-norm** and denoted by $\|\cdot\|_{\mathcal{M}}$. (Note that this notation is ambiguous, since $\|\cdot\|$ is not specified; it either does not matter or must be stated explicitly when used.)

A matrix norm $\|\cdot\|$ is **minimal** if for any matrix norm $\|\cdot\|_\nu$, $\|A\|_\nu \leq \|A\|$ for all $A \in F^{n\times n}$ implies $\|\cdot\|_\nu = \|\cdot\|$.

A matrix norm is **absolute** if as a vector norm, each member of the family is absolute.

Facts:

For proofs and additional background, see, for example, [HJ85, Chap. 5]. Let $\mathbf{x}, \mathbf{y} \in \mathbb{F}^n$, $A, B \in \mathbb{F}^{m\times n}$, and $\alpha \in \mathbb{F}$, where $\mathbb{F}$ is either $\mathbb{R}$ or $\mathbb{C}$.

1. A matrix norm is a family of vector norms, but not every family of vector norms is a matrix norm (see Example 2).
2. The commonly encountered norms, $\|\cdot\|_1, \|\cdot\|_2, \|\cdot\|_\infty, \|\cdot\|_F$, and norms induced by vector norms are matrix norms. Furthermore,
   (a) $\|A\|_1$ is the matrix norm induced by the vector norm $\|\cdot\|_1$.
   (b) $\|A\|_2$ is the matrix norm induced by the vector norm $\|\cdot\|_2$.
   (c) $\|A\|_\infty$ is the matrix norm induced by the vector norm $\|\cdot\|_\infty$.
   (d) $\|A\|_F$ is not induced by any vector norm.
   (e) If $\mathcal{M} = \{M_n\}$ is a family of nonsingular matrices and $\|\cdot\|$ is an induced matrix norm, then for $A \in \mathbb{F}^{m\times n}$, $\|A\|_{\mathcal{M}} = \|M_m A M_n^{-1}\|$.
3. If $\|\cdot\|$ is the matrix norm induced by a family of vector norms $\|\cdot\|$, then $\|I_n\| = 1$ for all positive integers n (where I_n is the $n \times n$ identity matrix).
4. If $\|\cdot\|$ is the matrix norm induced by a family of vector norms $\|\cdot\|$, then for all $A \in \mathbb{F}^{m\times n}$ and all $\mathbf{x} \in \mathbb{F}^n$, $\|A\mathbf{x}\| \leq \|A\|\,\|\mathbf{x}\|$.
5. For all $A \in \mathbb{F}^{m\times n}$ and all $\mathbf{x} \in \mathbb{F}^n$, $\|A\mathbf{x}\|_F \leq \|A\|_F \|x\|_2$.
6. $\|\cdot\|_1, \|\cdot\|_\infty, \|\cdot\|_F$ are absolute norms. However, for some matrices A, $\|\,|A|\,\|_2 \neq \|A\|_2$ (see Example 3).
7. A matrix norm is minimal if and only if it is an induced norm.
8. All matrix norms are equivalent in the sense that for any two matrix norms $\|\cdot\|_\mu$ and $\|\cdot\|_\nu$, there exist constants $\alpha > 0$ and $\beta > 0$ such that for all $A \in \mathbb{F}^{m\times n}$, $\alpha\|A\|_\mu \leq \|A\|_\nu \leq \beta\|A\|_\mu$. The constants α and β are independent of A but typically depend on n and m. In particular,
   (a) $\frac{1}{\sqrt{n}}\|A\|_\infty \leq \|A\|_2 \leq \sqrt{m}\|A\|_\infty$.
   (b) $\|A\|_2 \leq \|A\|_F \leq \sqrt{n}\|A\|_2$.
   (c) $\frac{1}{\sqrt{m}}\|A\|_1 \leq \|A\|_2 \leq \sqrt{n}\|A\|_1$.
9. $\|A\|_2 \leq \sqrt{\|A\|_1\|A\|_\infty}$.
10. $\|AB\|_F \leq \|A\|_F\|B\|_2$ and $\|AB\|_F \leq \|A\|_2\|B\|_F$ whenever A and B are compatible for matrix multiplication.
11. $\|A\|_2 \leq \|A\|_F$ and $\|A\|_2 = \|A\|_F$ if and only if A has rank less than or equal to 1.
12. If $A = \mathbf{x}\mathbf{y}^*$ for some $\mathbf{x} \in \mathbb{F}^n$ and $\mathbf{y} \in \mathbb{F}^m$, then $\|A\|_2 = \|A\|_F = \|\mathbf{x}\|_2\|\mathbf{y}\|_2$.
13. $\|A\|_2 = \|A^*\|_2$ and $\|A\|_F = \|A^*\|_F$.
14. If $U \in F^{n\times n}$ is a unitary matrix, i.e., if $U^* = U^{-1}$, then the following hold:
   (a) $\|U\|_2 = 1$ and $\|U\|_F = \sqrt{n}$.
   (b) If $A \in \mathbb{F}^{m\times n}$, then $\|AU\|_2 = \|A\|_2$ and $\|AU\|_F = \|A\|_F$.
   (c) If $A \in \mathbb{F}^{n\times m}$, then $\|UA\|_2 = \|A\|_2$ and $\|UA\|_F = \|A\|_F$.

15. For any matrix norm $\|\cdot\|$ and any $A \in F^{n\times n}$, $\rho(A) \leq \|A\|$, where $\rho(A)$ is the spectral radius of A. This need not be true for a vector norm on matrices (see Example 2).
16. For any $A \in F^{n\times n}$ and $\varepsilon > 0$, there exists a matrix norm $\|\cdot\|$ such that $\|A\| < \rho(A) + \varepsilon$. A method for finding such a norm is given in Example 5.
17. For any matrix norm $\|\cdot\|$ and $A \in F^{n\times n}$, $\lim_{k\to\infty}\|A^k\|^{1/k} = \rho(A)$.
18. For $A \in F^{n\times n}$, $\lim_{k\to\infty}A^k = 0$ if and only if $\rho(A) < 1$.

Examples:

1. If $A = \begin{bmatrix} 1 & -2 \\ 3 & -4 \end{bmatrix}$, then $\|A\|_1 = 6$, $\|A\|_\infty = 7$, $\|A\|_2 = \sqrt{15+\sqrt{221}}$, and $\|A\|_F = \sqrt{30}$.
2. The family of matrix functions defined for $A \in \mathbb{F}^{m\times n}$ by

$$\nu(A) = \max_{\substack{1\leq i\leq m \\ 1\leq j\leq n}} |a_{ij}|$$

is *not* a matrix norm because consistency fails. For example, if $J = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$, then $\nu(J^2) = 2 > 1 = \nu(J)\nu(J)$. Note that ν is a family of vector norms on matrices (it is the ∞ norm on the n^2-tuple of entries), and $\nu(J) = 1 < 2 = \rho(J)$.

3. If $A = \begin{bmatrix} 3 & 4 \\ -4 & 3 \end{bmatrix}$, then $\|A\|_2 = 5$ but $\|\,|A|\,\|_2 = 7$.
4. If A is perturbed by an error matrix E and U is unitary (i.e., $U^* = U^{-1}$), then $U(A+E) = UA + UE$ and $\|UE\|_2 = \|E\|_2$. Numerical analysts often use unitary matrices in numerical algorithms because multiplication by unitary matrices does not magnify errors.
5. Given $A \in F^{n\times n}$ and $\varepsilon > 0$, we show how an $\mathcal{M}$-norm can be constructed such that $\|A\|_{\mathcal{M}} < \rho + \varepsilon$, where ρ is the spectral radius of A. The procedure below determines M_n where $A \in F^{n\times n}$. The procedure is illustrated with the matrix $A = \begin{bmatrix} -38 & 13 & 52 \\ 3 & 0 & -4 \\ -30 & 10 & 41 \end{bmatrix}$ and with $\varepsilon = 0.1$. The norm used to construct the $\mathcal{M}$-norm will be the 1-norm; note the 1-norm of $A = 97$.

   (a) Determine ρ: The characteristic polynomial of A is $p_A(x) = \det(A - xI) = x^3 - 3x^2 + 3x - 1 = (x-1)^3$, so $\rho = 1$.

   (b) Find a unitary matrix U such that $T = UAU^*$ is triangular. Using the method in Example 8.1.5, we find

$$U = \begin{bmatrix} \frac{1}{\sqrt{10}} & \frac{6}{\sqrt{65}} & -\frac{3}{\sqrt{26}} \\ \frac{3}{\sqrt{10}} & -\frac{2}{\sqrt{65}} & \frac{1}{\sqrt{26}} \\ 0 & \sqrt{\frac{5}{13}} & 2\sqrt{\frac{2}{13}} \end{bmatrix} \approx \begin{bmatrix} 0.316228 & 0.744208 & -0.588348 \\ 0.948683 & -0.248069 & 0.196116 \\ 0. & 0.620174 & 0.784465 \end{bmatrix} \text{ and}$$

$$T = U^*AU = \begin{bmatrix} 1 & 0 & 2\sqrt{65} \\ 0 & 1 & 26\sqrt{10} \\ 0 & 0 & 1 \end{bmatrix} \approx \begin{bmatrix} 1 & 0 & 16.1245 \\ 0 & 1 & 82.2192 \\ 0 & 0 & 1 \end{bmatrix}.$$

   (c) Find a diagonal matrix $\mathrm{diag}(1, \alpha, \alpha^2, \ldots, \alpha^{n-1})$ such that $\|DTD^{-1}\|_1 < \rho + \varepsilon$ (this is always possible, since $\lim_{\alpha\to\infty}\|DTD^{-1}\|_1 = \rho$).

In the example, for $\alpha = 1000$, $DTD^{-1} \approx \begin{bmatrix} 1 & 0 & 0.0000161245 \\ 0 & 1 & 0.0822192 \\ 0 & 0 & 1 \end{bmatrix}$ and $\|DTD^{-1}\|_1 \approx 1.08224 < 1.1$.

(d) Then $\|DU^*AUD^{-1}\|_1 < \rho + \varepsilon$. That is, $\|A\|_{\mathcal{M}} < 2.1$, where $M_3 = DU^*$

$$\approx \begin{bmatrix} 0.316228 & 0.948683 & 0. \\ 744.208 & -248.069 & 620.174 \\ -588348. & 196116. & 784465. \end{bmatrix}.$$

50.4 Conditioning and Condition Numbers

Data have limited precision. Measurements are inexact, equipment wears, manufactured components meet specifications only to some error tolerance, floating point arithmetic introduces errors. Consequently, the results of nontrivial calculations using data of limited precision also have limited precision. This section summarizes the topic of *conditioning*: How much errors in data can affect the results of a calculation.

(See [Ric66] for an authoritative treatment of conditioning.)

Definitions:

Consider a computational problem to be the task of evaluating a function $P : \mathbb{R}^n \to \mathbb{R}^m$ at a nominal data point $\mathbf{z} \in \mathbb{R}^n$, which, because data errors are ubiquitious, is known only to within a small relative-to-$\|\mathbf{z}\|$ error ε.

If $\hat{\mathbf{z}} \in \mathbb{F}^n$ is an approximation to $\mathbf{z} \in \mathbb{F}^n$, the **absolute error** in $\hat{\mathbf{z}}$ is $\|\mathbf{z} - \hat{\mathbf{z}}\|$ and the **relative error** in $\hat{\mathbf{z}}$ is $\|\mathbf{z} - \hat{\mathbf{z}}\|/\|\mathbf{z}\|$. If $\mathbf{z} = 0$, then the relative error is undefined.

The data $\mathbf{z}$ are **well-conditioned** if small relative perturbations of $\mathbf{z}$ cause small relative perturbations of $P(\mathbf{z})$. The data are **ill-conditioned** or **badly conditioned** if some small relative perturbation of $\mathbf{z}$ causes a large relative perturbation of $P(\mathbf{z})$. Precise meanings of "small" and "large" are dependent on the precision required in the context of the computational task.

Note that it is the data $\mathbf{z}$ — not the solution $P(\mathbf{z})$ — that is ill-conditioned or well-conditioned.

If $\mathbf{z} \neq 0$ and $P(\mathbf{z}) \neq 0$, then the **relative condition number** or simply **condition number** $\mathbf{cond}(\mathbf{z}) = \mathbf{cond}_P(\mathbf{z})$ of the data $\mathbf{z} \in \mathbb{F}^n$ with respect to the computational task of evaluating $P(\mathbf{z})$ may be defined as [TB97], [Dat10]:

$$\mathbf{cond}_P(\mathbf{z}) = \lim_{\varepsilon \to 0} \sup \left\{ \left(\frac{\|P(\mathbf{z} + \delta\mathbf{z}) - P(\mathbf{z})\|}{\|P(\mathbf{z})\|} \right) \left(\frac{\|\mathbf{z}\|}{\|\delta\mathbf{z}\|} \right) \;\middle|\; \|\delta\mathbf{z}\| \leq \varepsilon \right\}, \tag{50.1}$$

Sometimes it is useful to extend the definition to $\mathbf{z} = 0$ or to an isolated root of $P(\mathbf{z})$ by $\mathbf{cond}_P(\mathbf{z}) = \limsup_{\mathbf{x} \to \mathbf{z}} \mathbf{cond}_P(\mathbf{x})$.

Note that although the condition number depends on P and on the choice of norm, $\mathbf{cond}(\mathbf{z}) = \mathbf{cond}_P(\mathbf{z})$ is the condition number of the data $\mathbf{z}$ — not the condition number of the solution $P(\mathbf{z})$ and not the condition number of an algorithm that may be used to evaluate $P(\mathbf{z})$.

Remark: The above definition of the condition number by Rice [Ric66], though widely accepted in numerical linear algebra and fitting many situations, has some limitations. In particular, it does not take into account the fact that the effect of an error may depend on its direction. Such considerations are important for practical problems, such as the linear least-squares. The errors in the column space of the least-squares matrix A behave differently then those in the orthogonal complement (for details, see the classical but authoritative book of Stewart [Ste73]). For the results on the least-squares perturbation errors, see Section 52.6 of this book.

Facts:

For proofs and additional background, see, for example, [Dat10], [GV96], [Ste98], or [Wil65].

1. Because rounding errors are ubiquitous, a finite precision computational procedure can at best produce $P(\mathbf{z}+\delta\mathbf{z})$ where, in a suitably chosen norm, $\|\delta\mathbf{z}\| \le \varepsilon\|\mathbf{z}\|$ and ε is a modest multiple of the unit round of the floating point system. (See Section 50.6.)
2. The relative condition number determines the tight, asymptotic relative error bound
$$\frac{\|P(\mathbf{z}+\delta\mathbf{z}) - P(\mathbf{z})\|}{\|P(\mathbf{z})\|} \le \mathbf{cond}_P(\mathbf{z})\frac{\|\delta\mathbf{z}\|}{\|\mathbf{z}\|} + o\left(\frac{\|\delta\mathbf{z}\|}{\|z\|}\right)$$
as $\delta\mathbf{z}$ tends to zero. Very roughly speaking, if the larger components of the data $\mathbf{z}$ have p correct significant digits and the condition number is $\mathbf{cond}_P(\mathbf{z}) \approx 10^s$, then the larger components of the result $P(\mathbf{z})$ have $p - s$ correct significant digits.
3. [Hig02, p. 9] If $P(\mathbf{x})$ has a Frechet derivative $D(\mathbf{z})$ at $\mathbf{z} \in \mathbb{F}^n$, then the relative condition number is
$$\mathbf{cond}_P(\mathbf{z}) = \frac{\|D(\mathbf{z})\|\,\|\mathbf{z}\|}{\|P(\mathbf{z})\|}.$$
In particular, if $f(x)$ is a smooth real function of a real variable x, then $\mathbf{cond}_f(z) = |zf'(z)/f(z)|$.

Examples:

1. If $P(x) = \sin(x)$ and the nominal data point $z = 22/7$ may be in error by as much as $\pi - 22/7 \approx .00126$, then $P(z) = \sin(z)$ may be in error by as much as 100%. With such an uncertainty in $z = 22/7$, $\sin(z)$ may be off by 100%, i.e., $\sin(z)$ may have relative error equal to one. In most circumstances, $z = 22/7$ is considered to be ill-conditioned.

   The condition number of $z \in \mathbb{R}$ with respect to $\sin(z)$ is $\mathbf{cond}_{\sin}(z) = |z\cot(z)|$, and, in particular, $\mathbf{cond}(22/7) \approx 2485.47$. If $z = 22/7$ is perturbed to $z + \delta z = \pi$, then the asymptotic relative error bound in Fact 2 becomes
$$\begin{aligned}\left|\frac{\sin(z+\delta z) - \sin(z)}{\sin(z)}\right| &\le \mathbf{cond}(z)\left|\frac{\delta z}{z}\right| + o(|(\delta z)/z|)\\ &= 0.9999995\ldots + o(|(\delta z)/z|).\end{aligned}$$
   The actual relative error in $\sin(z)$ is $\left|\frac{\sin(z+\delta z)-\sin(z)}{\sin(z)}\right| = 1$.
2. *Subtractive Cancellation:* For $\mathbf{x} \in \mathbb{R}^2$, define $P(\mathbf{x})$ by $P(\mathbf{x}) = [1, -1]\mathbf{x}$. The gradient of $P(x)$ is $\bigtriangledown P(x) = [1, -1]$ independent of $\mathbf{x}$, so, using the ∞-norm, Fact 3 gives
$$\mathbf{cond}_P(\mathbf{x}) = \frac{\|\bigtriangledown f\|_\infty \|\mathbf{x}\|_\infty}{\|f(\mathbf{x})\|_\infty} = \frac{2\max\{|x_1|, |x_2|\}}{|x_1 - x_2|}.$$
   Reflecting the trouble associated with subtractive cancellation, $\mathbf{cond}_P(\mathbf{x})$ shows that $\mathbf{x}$ is ill-conditioned when $x_1 \approx x_2$.
3. *Conditioning of Matrix–Vector Multiplication:* More generally, for a fixed matrix $A \in \mathbb{F}^{m\times n}$ that is not subject to perturbation, define $P(\mathbf{x}) : \mathbb{F}^n \to \mathbb{F}^n$ by $P(\mathbf{x}) = A\mathbf{x}$. The relative condition number of $\mathbf{x} \in \mathbb{F}^n$ is
$$\mathbf{cond}(\mathbf{x}) = \|A\|\,\frac{\|\mathbf{x}\|}{\|A\mathbf{x}\|}, \tag{50.2}$$
   where the matrix norm is the operator norm induced by the chosen vector norm. If A is square and nonsingular, then $\mathbf{cond}(\mathbf{x}) \le \|A\|\,\|A^{-1}\|$.

4. *Conditioning of the Polynomial Zeros:* Let $q(x) = x^2 - 2x + 1$ and consider the computational task of determining the roots of $q(x)$ from the power basis coefficients [1, −2, 1]. Formally, the computational problem is to evaluate the function $P : \mathbb{R}^3 \to \mathbb{C}$ that maps the power basis coefficients of quadratic polynomials to their roots. If $q(x)$ is perturbed to $q(x) + \varepsilon$, then the roots change from a double root at $x = 1$ to $x = 1 \pm \sqrt{\varepsilon}$. A relative error of ε in the data [1, −2, 1] induces a relative error of $\sqrt{|\varepsilon|}$ in the roots. In particular, the roots suffer an infinite rate of change at $\varepsilon = 0$. The condition number of the coefficients [1, −2, 1] is infinite (with respect to root finding).

   The example illustrates the fact that the problem of calculating the roots of a polynomial q from its coefficients is highly ill-conditioned when q has multiple or near multiple roots. Although it is common to say that "multiple roots are ill-conditioned," strictly speaking, this is incorrect. It is the coefficients that are ill-conditioned because they are the initial data for the calculation.

5. [Dat10, p. 59], [Wil65, Wil63] *Wilkinson Polynomial:* Let $w(x)$ be the degree 20 polynomial

   $$w(x) = (x-1)(x-2)\dots(x-20) = x^{20} - 210x^{19} + 20615x^{18} \cdots + 2432902008176640000.$$

   The roots of $w(x)$ are the integers 1, 2, 3, …, 20. Although distinct, the roots are highly ill-conditioned functions of the power basis coefficients. For simplicity, consider only perturbations to the coefficient of x^{19}. Perturbing the coefficient of x^{19} from -210 to $-210 - 2^{-23}$ $\approx 210 - 1.12 \times 10^{-7}$ drastically changes some of the roots. For example, the roots 16 and 17 become a complex conjugate pair approximately equal to $16.73 \pm 2.81i$.

   Let $P_{16}(z)$ be the root of $\hat{w}(x) = w(x) + (z - 210)x^{19}$ nearest 16 and let $P_{17}(z)$ be the root nearest 17. So, for $z = 210$, $P_{16}(z) = 16$ and $P_{17}(z) = 17$. The condition numbers of $z = 210$ with respect to P_{16} and P_{17} are $\mathbf{cond}_{16}(210) = 210(16^{19}/(16w'(16))) \approx 3 \times 10^{10}$ and $\mathbf{cond}_{17}(210) = 210(17^{19}/(17w'(17))) \approx 2 \times 10^{10}$, respectively. The condition numbers are so large that even perturbations as small as 2^{-23} are outside the asymptotic region in which $o\left(\frac{\|\delta\mathbf{z}\|}{\|\mathbf{z}\|}\right)$ is negligible in Fact 2.

50.5 Conditioning of Linear Systems

This section applies conditioning concepts to the computational task of finding a solution to the system of linear equations $A\mathbf{x} = \mathbf{b}$ for a given matrix $A \in \mathbb{R}^{n\times n}$ and right-hand side vector $\mathbf{b} \in \mathbb{R}^n$.

Throughout this section, $A \in \mathbb{R}^{n\times n}$ is nonsingular. Let the matrix norm $\|\cdot\|$ be an operator matrix norm induced by the vector norm $\|\cdot\|$. Use $\|A\| + \|\mathbf{b}\|$ to measure the magnitude of the data A and b. If $E \in \mathbb{R}^{n\times n}$ is a perturbation of A and $\mathbf{r} \in \mathbb{R}^n$ is a perturbation of $\mathbf{b}$, then $\|E\| + \|r\|$ is the magnitude of the perturbation to the linear system $A\mathbf{x} = \mathbf{b}$.

Definitions:

The norm-wise **condition number** of a nonsingular matrix A (for solving a linear system) is $\kappa(A) = \|A^{-1}\|\,\|A\|$. If A is singular, then by convention, $\kappa(A) = \infty$. For a specific norm $\|\cdot\|_\mu$, the condition number of A is denoted $\kappa_\mu(A)$.

Facts:

For proofs and additional background, see, for example, [Dat10], [GV96], [Ste98], or [Wil65].

1. *Properties of the Condition Number:*
   (a) $\kappa(A) \geq 1$.

   (b) $\kappa(AB) \leq \kappa(A)\kappa(B)$.
   (c) $\kappa(\alpha A) = \kappa(A)$, for all scalars $\alpha \neq 0$.
   (d) $\kappa_2(A) = 1$ if and only if A is a nonzero scalar multiple of an orthogonal matrix, i.e., $A^T A = \alpha I$ for some scalar α.
   (e) $\kappa_2(A) = \kappa_2(A^T)$.
   (f) $\kappa_2(A^T A) = (\kappa_2(A))^2$.
   (g) $\kappa_2(A) = \|A\|_2 \|A^{-1}\|_2 = \sigma_{\max}/\sigma_{\min}$, where $\sigma_{\max}$ and $\sigma_{\min}$ are the largest and smallest singular values of A.

2. For the p-norms (including $\|\cdot\|_1$, $\|\cdot\|_2$, and $\|\cdot\|_\infty$),
$$\frac{1}{\kappa(A)} = \min\left\{ \frac{\|\delta A\|}{\|A\|} \;\middle|\; A + \delta A \text{ is singular} \right\}.$$
   So, $\kappa(A)$ is one over the relative-to-$\|A\|$ distance from A to the nearest singular matrix, and, in particular, $\kappa(A)$ is large if and only if a small-relative-to-$\|A\|$ perturbation of A is singular.
3. Regarding A as fixed and not subject to errors, it follows from Eq. (50.2) that the condition number of $\mathbf{b}$ with respect to solving $A\mathbf{x} = \mathbf{b}$ as defined in Eq. (50.1) is
$$\mathbf{cond}(\mathbf{b}) = \frac{\|A^{-1}\|\,\|\mathbf{b}\|}{\|A^{-1}\mathbf{b}\|} \leq \kappa(A).$$
   If the matrix norm used to compute $\|A^{-1}\|$ is induced by the vector norm used to compute $\|b\|$, then equality is possible.
4. Regarding $\mathbf{b}$ as fixed and not subject to errors, the condition number of A with respect to solving $A\mathbf{x} = \mathbf{b}$ as defined in Eq. (50.1) is $\mathbf{cond}(A) = \|A^{-1}\|\,\|A\| = \kappa(A)$.
5. $\kappa(A) \leq \mathbf{cond}([A, b]) \leq \left(\frac{(\|A\|+\|\mathbf{b}\|)^2}{\|A\|\,\|\mathbf{b}\|}\right) \kappa(A)$, where $\mathbf{cond}([A, \mathbf{b}])$ is the condition number of the data $[A,\, \mathbf{b}]$ with respect to solving $A\mathbf{x} = \mathbf{b}$ as defined in Eq. (50.1). Hence, the data $[A,\, \mathbf{b}]$ are norm-wise ill-conditioned for the problem of solving $A\mathbf{x} = \mathbf{b}$ if and only if $\kappa(A)$ is large.
6. If $\mathbf{r} = b - A(\mathbf{x} + \delta\mathbf{x})$, then the 2-norm and Frobenius norm smallest perturbation $\delta A \in \mathbb{R}^{n\times n}$ satisfying $(A + \delta A)(x + \delta x) = \mathbf{b}$ is $\delta A = \frac{\mathbf{r}\mathbf{x}^T}{\mathbf{x}^T\mathbf{x}}$ and $\|\delta A\|_2 = \|\delta A\|_F = \frac{\|\mathbf{r}\|_2}{\|\mathbf{x}\|_2}$.
7. Let δA and $\delta\mathbf{b}$ be perturbations of the data A and $\mathbf{b}$, respectively. If $\|A^{-1}\delta A\| < 1$, then $A + \delta A$ is nonsingular, there is a unique solution $\mathbf{x} + \delta\mathbf{x}$ to $(A + \delta A)(\mathbf{x} + \delta\mathbf{x}) = (\mathbf{b} - \delta\mathbf{b})$, and
$$\frac{\|\delta\mathbf{x}\|}{\|\mathbf{x}\|} \leq \frac{\|A\|\,\|A^{-1}\|}{(1 - \|A^{-1}\delta A\|)} \left(\frac{\|\delta A\|}{\|A\|} + \frac{\|\delta\mathbf{b}\|}{\|\mathbf{b}\|} \right).$$

Examples:

1. *An Ill-Conditioned Linear System:* For $\varepsilon \in \mathbb{R}$, let $A = \begin{bmatrix} 1 & 1 \\ 1 & 1+\varepsilon \end{bmatrix}$ and $\mathbf{b} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$. For $\varepsilon \neq 0$, A is nonsingular and $\mathbf{x} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$ satisfies $A\mathbf{x} = \mathbf{b}$. The system of equations is ill-conditioned when ε is small because some small changes in the data cause a large change in the solution. For example, perturbing $\mathbf{b}$ to $\mathbf{b} + \delta\mathbf{b}$, where $\delta\mathbf{b} = \begin{bmatrix} 0 \\ \varepsilon \end{bmatrix} \in \mathbb{R}^2$, changes the solution $\mathbf{x}$ to $\mathbf{x} + \delta\mathbf{x} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$ independent of the choice of ε no matter how small.

Using the 1-norm, $\kappa_1(A) = \|A^{-1}\|_1 \|A\|_1 = (2+\varepsilon)^2\varepsilon^{-1}$. As ε tends to zero, the perturbation $\delta\mathbf{b}$ tends to zero, but the condition number $\kappa_1(A)$ explodes to infinity.

Geometrically, $\mathbf{x}$ gives the coordinates of the intersection of the two lines $x + y = 1$ and $x + (1+\varepsilon)y = 1$. If ε is small, then these lines are nearly parallel, so a small change in them may move the intersection a long distance.

Also notice that the singular matrix $\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ is a ε perturbation of A.

2. *A Well-Conditioned Linear System Problem:* Let $A = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$. For $\mathbf{b} \in \mathbb{R}^2$, the solution to $A\mathbf{x} = \mathbf{b}$ is $\mathbf{x} = \frac{1}{2}\begin{bmatrix} b_1 + b_2 \\ b_1 - b_2 \end{bmatrix}$. In particular, perturbing $\mathbf{b}$ to $\mathbf{b} + \delta\mathbf{b}$ changes $\mathbf{x}$ to $\mathbf{x} + \delta\mathbf{x}$ with $\|\delta\mathbf{x}\|_1 \le \|\mathbf{b}\|_1$ and $\|\delta\mathbf{x}\|_2 = \|\delta\mathbf{b}\|_2$, i.e., $\mathbf{x}$ is perturbed by no more than $\mathbf{b}$ is perturbed. This is a well-conditioned system of equations.

   The 1-norm condition number of A is $\kappa_1(A) = 2$, and the 2-norm condition number is $\kappa_2(A) = 1$, which is as small as possible.

   Geometrically, $\mathbf{x}$ gives the coordinates of the intersection of the perpendicular lines $x+y = 1$ and $x-y = 1$. Slightly perturbing the lines only slightly perturbs their intersection.

   Also notice that for both the 1-norm and 2-norm $\min_{\|x\|=1} \|A\mathbf{x}\| = 1$, so no small-relative-to-$\|A\|$ perturbation of A is singular. If $A + \delta A$ is singular, then $\|\delta A\| \ge 1$.

3. *Some Well-known Ill-conditioned Matrices:*

   (a) The upper triangular matrices $B_n \in \mathbb{R}^n$ of the form

$$B_3 = \begin{bmatrix} 1 & -1 & -1 \\ 0 & 1 & -1 \\ 0 & 0 & 1 \end{bmatrix}$$

   have ∞-norm condition number $\kappa_\infty = n2^{n-1}$. Replacing the $(n,1)$ entry by -2^{2-n} makes B_n singular. Note that the determinant $\det(B_n) = 1$ gives no indication of how nearly singular the matrices B_n are.

   (b) *The Hilbert matrix:* The order n Hilbert matrix $H_n \in \mathbb{R}^{n\times n}$ is defined by $h_{ij} = 1/(i+j-1)$. The Hilbert matrix arises naturally in calculating best L_2 polynomial approximations. The following table lists the 2-norm condition numbers to the nearest power of 10 of selected Hilbert matrices.

n:	1	2	3	4	5	6	7	8	9	10
$\kappa_2(H_n)$:	1	10	10^3	10^4	10^5	10^7	10^8	10^{10}	10^{11}	10^{13}

   (c) *Vandermonde matrix:* The Vandermonde matrix corresponding to $\mathbf{x} \in \mathbb{R}^n$ is $V(\mathbf{x}) \in \mathbb{R}^{n\times n}$ given by $v_{ij} = x_i^{j-1}$. Vandermonde matrices arise naturally in polynomial interpolation computations. The following table lists the 2-norm condition numbers to the nearest power of 10 of selected Vandermonde matrices.

n:	1	2	3	4	5	6	7	8	9	10
$\kappa_2\left(V_{[1,2,3,\ldots,n]}\right)$:	1	10	10	10^3	10^4	10^5	10^7	10^9	10^{10}	10^{12}

50.6 Floating Point Numbers

Most scientific and engineering computations rely on *floating point arithmetic.* At this writing, the IEEE 754 standard of binary floating point arithmetic [IEEE754] and the IEEE 854 standard of radix-independent floating point arithmetic [IEEE854] are the most widely accepted standards for floating point arithmetic. The still incomplete revised floating point arithmetic standard [IEEE754r] is planned to incorporate both [IEEE754] and [IEEE854] along with extensions, revisions, and clarifications. See [Ove01] for a textbook introduction to IEEE standard floating point arithmetic.

Even 20 years after publication of [IEEE754], implementations of floating point arithmetic vary in so many different ways that few axiomatic statements hold for all of them. Reflecting this unfortunate state of affairs, the summary of floating point arithmetic here is based upon IEEE 754r draft standard [IEEE754r] (necessarily omitting most of it), with frequent digressions to nonstandard floating point arithmetic.

In this section, the phrase *standard-conforming* refers to the October 20, 2005 IEEE 754r draft standard.

Definitions:

A p-digit, radix b **floating point number** with exponent bounds $e_{\max}$ and $e_{\min}$ is a real number of the form $x = \pm\left(\frac{m}{b^{p-1}}\right) b^e$, where e is an integer **exponent**, $e_{\min} \leq e \leq e_{\max}$, and m is a $p-$digit, base b integer **significand**. The related quantity m/b^p is called the **mantissa**. Virtually all floating point systems allow $m = 0$ and $b^{p-1} \leq m < b^p$. Standard-conforming, floating point systems allow all significands $0 \leq m < b^p$. If two or more different choices of significand m and exponent e yield the same floating point number, then the largest possible significand m with the smallest possible exponent e is preferred.

In addition to finite floating point numbers, standard-conforming, floating point systems include elements that are not numbers, including ∞, $-\infty$, and not-a-number elements collectively called `NaN`s. Invalid or indeterminate arithmetic operations like $0/0$ or $\infty - \infty$ as well as arithmetic operations involving `NaN`s result in `NaN`s.

The representation $\pm(m/b^{p-1})b^e$ of a floating point number is said to be **normalized** or **normal**, if $b^{p-1} \leq m < b^p$.

Floating point numbers of magnitude less than $b^{e_{\min}}$ are said to be **subnormal** because they are too small to be normalized. The term **gradual underflow** refers to the use of subnormal floating point numbers. Standard-conforming, floating point arithmetic allows gradual underflow.

For $x \in \mathbb{R}$, a **rounding mode** maps x to a floating point number $\mathbf{fl}(x)$. Except in cases of overflow discussed below, $\mathrm{fl}(x)$ is either the smallest floating point number greater than or equal to x or the largest floating point number less than or equal to x. Standard-conforming, floating point arithmetic allows program control over which choice is used. The default rounding mode in standard conforming arithmetic is **round-to-nearest, ties-to-even** in which, except for overflow (described below), $\mathrm{fl}(x)$ is the nearest floating point number to x. In case there are two floating point numbers equally distant from x, $\mathrm{fl}(x)$ is the one with even significand.

Underflow occurs in $\mathrm{fl}(x) = 0$ when $0 < |x| \leq b^{e_{\min}}$. Often, underflows are set quietly to zero. **Gradual underflow** occurs when $\mathrm{fl}(x)$ is a subnormal floating point number. **Overflow** occurs when $|x|$ equals or exceeds a threshold at or near the largest floating point number $(b - b^{1-p})b^{e_{\max}}$. Standard-conforming arithmetic allows some, very limited program control over the overflow and underflow threshold, whether to set overflows to $\pm\infty$ and whether to trap program execution on overflow or underflow in order to take corrective action or to issue error messages. In the default round-to-nearest, ties-to-even rounding mode, overflow occurs if $|x| \geq (b - \frac{1}{2}b^{1-p})b^{e_{\max}}$, and in that case, $\mathrm{fl}(x) = \pm\infty$ with the sign chosen to agree with the sign of x. By default, program execution continues without traps or interruption.

A variety of terms describe the precision with which a floating point system models real numbers.

- The **precision** is the number p of base-b digits in the significand.
- **Big M** is the largest integer M with the property that all integers 1, 2, 3, ..., M are floating point numbers, but $M+1$ is not a floating point number. If the exponent upper bound $e_{\max}$ is greater than the precision p, then $M = b^p$.
- The **machine epsilon**, $\epsilon = b^{1-p}$, is the distance between the number one and the next larger floating point number.
- The **unit round** $u = \inf\{\delta > 0 \mid \mathrm{fl}(1+\delta) > 1\}$. Depending on the rounding mode, u may be as large as the machine epsilon ϵ. In round-to-nearest, ties-to-even rounding mode, $u = \frac{1}{2}\epsilon$.

In standard-conforming, floating point arithmetic, if α and β are floating point numbers, then **floating point addition** $\oplus$, **floating point subtraction** $\ominus$, **floating point multiplication** $\otimes$, and **floating point division** $\oslash$ are defined by

$$\alpha \oplus \beta = \mathrm{fl}(\alpha + \beta), \tag{50.3}$$

$$\alpha \ominus \beta = \mathrm{fl}(\alpha - \beta), \tag{50.4}$$

$$\alpha \otimes \beta = \mathrm{fl}(\alpha \times \beta), \tag{50.5}$$

$$\alpha \oslash \beta = \mathrm{fl}(\alpha \div \beta), \tag{50.6}$$

The IEEE 754r [IEEE754r] standard also includes a fused addition-multiply operation that evaluates $\alpha\beta + \gamma$ with only one rounding error.

In particular, if the exact, infinitely precise value of $\alpha+\beta$, $\alpha-\beta$, $\alpha\times\beta$, or $\alpha\div\beta$ is also a floating point number, then the corresponding floating point arithmetic operation occurs without rounding error. Floating point sums, products, and differences of small integers have zero rounding error.

Nonstandard-conforming, floating point arithmetics do not always conform to this definition, but often they do. Even when they deviate, it is nearly always the case that if $\bullet$ is one of the arithmetic operations $+$, $-$, $\times$, or $\div$ and $\odot$ is the corresponding nonstandard floating point operation, then $\alpha \odot \beta$ is a floating point number satisfying $\alpha \odot \beta = \alpha(1+\delta\alpha) \bullet \beta(1+\delta\beta)$ with $|\delta\alpha| \le b^{2-p}$ and $|\delta\beta| \le b^{2-p}$.

If $\bullet$ is one of the arithmetic operations $+$, $-$, $\times$, or $\div$ and $\odot$ is the corresponding floating point operation, then the **rounding error** in $\alpha \odot \beta$ is $(\alpha \bullet \beta) - (\alpha \cdot \beta)$, i.e., rounding error is the difference between the exact, infinitely precise arithmetic operation and the floating point arithmetic operation. In more extensive calculations, **rounding error** refers to the cumulative effect of the rounding errors in the individual floating point operations.

In machine computation, **truncation error** refers to the error made by replacing an infinite process by a finite process, e.g., truncating an infinite series of numbers to a finite partial sum.

Many computers implement floating point numbers of two or more different precisions. Typical **single precision** floating point numbers have machine epsilon roughly 10^{-7} and precision roughly 7 decimal digits or 24 binary digits. Typical **double precision** floating point numbers have machine epsilon roughly 10^{-16} and precision roughly 16 decimal digits or 53 binary digits. Specification of IEEE standard arithmetic [IEEE754r] includes these three precisions. See the table in Example 1. In addition, it is not unusual to also implement **extended precision** floating point numbers with even greater precision.

If $\hat{x} \in \mathbb{F}$ is an approximation to $x \in \mathbb{F}$, the **absolute error** in $\hat{x}$ is $|x - \hat{x}|$ and the **relative error** in $\hat{x}$ is $|(x - \hat{x})/x|$. If $x = 0$, then the relative error is undefined.

Subtractive cancellation of significant digits occurs in floating point sums when the relative error in the rounding-error-corrupted approximate sum is substantially greater than the relative error in the summands. In cases of subtractive cancellation, the sum has magnitude substantially smaller than the magnitude of the individual summands.

Facts:

For proofs and additional background, see, for example, [Ove01].

In this section, we make the following assumptions.

1. The numbers α, β, and γ are p-digit radix b floating point numbers with exponent bounds $e_{\max}$ and $e_{\min}$.
2. The floating point arithmetic operations satisfy Eqs. (50.3) to (50.6).
3. In the absence of overflows, the rounding mode $\mathrm{fl}(x)$ maps $x \in \mathbb{R}$ to the closest floating point number or to one of the two closest in case of a tie. In particular, the unit round is $\frac{1}{2}b^{1-p}$.

Standard-conforming arithmetic in round-to-nearest, ties-to-even rounding mode satisfies these assumptions.

For vectors $\mathbf{x} \in \mathbb{R}^n$ and matrices $M \in \mathbb{R}^{m\times n}$, the notation $|\mathbf{x}|$ and $|M|$ indicates the vector and matrix whose entries are the absolute values of the corresponding entries of $\mathbf{x}$ and M, respectively. For $\mathbf{x}$, $\mathbf{y} \in \mathbb{R}^n$ the inequality $\mathbf{x} \le \mathbf{y}$ represents the n scalar inequalities $x_i \le y_i$, $i = 1, 2, 3, \ldots, n$. Similarly, for A, $B \in \mathbb{R}^{m\times n}$, the inequality $A \le B$ represents the mn inequalities $a_{ij} \le b_{ij}$, $i = 1, 2, 3, \ldots, m$ and $j = 1, 2, 3, \ldots, n$.

If e is an arithmetic expression involving only floating point numbers, the notation $\mathrm{fl}(e)$ represents the expression obtained by replacing each arithmetic operation by the corresponding floating point arithmetic operation (50.3), (50.4), (50.5), or (50.6). Note that $\mathrm{fl}(\cdot)$ is not a function because its value may depend on the order of operations in e—not value of e.

1. At this writing, the only radixes in common use on computers and calculators are $b = 2$ and $b = 10$.
2. The commutative properties of addition and multiplication hold for floating point addition (50.3) and floating point multiplication (50.5), i.e., $\alpha \oplus \beta = \beta \oplus \alpha$ and $\alpha \otimes \beta = \beta \otimes \alpha$. (Examples below show that the associative and distributive properties of addition and multiplication *do not* in general hold for floating point arithmetic.)
3. In the absence of overflow or any kind of underflow, $\mathrm{fl}(x) = x(1+\delta)$ with $|\delta| < \frac{1}{2}b^{1-p}$.
4. *Rounding in Arithmetic Operations:* If $\bullet$ is an arithmetic operation and $\odot$ is the corresponding floating point operation, then

   $$\alpha \odot \beta = (\alpha \bullet \beta)(1+\delta)$$

   with $|\delta| \le \frac{1}{2}b^{1-p}$. The error δ may depend on α and β as well as the arithmetic operation.
5. *Differences of Nearby Floating Point Numbers:* If $\alpha > 0$ and $\beta > 0$ are normalized floating point numbers and $\frac{1}{2} < \alpha/\beta < 2$, then $\mathrm{fl}(\alpha - \beta) = \alpha \ominus \beta = \alpha - \beta$, i.e., there is zero rounding error in floating point subtraction of nearby numbers.
6. *Product of Floating Point Numbers:* If α_i, $i = 1, 2, 3, \ldots n$ are n floating point numbers, then

   $$\mathrm{fl}\left(\prod_{i=1}^{n} \alpha_i\right) = \left(\prod_{i=1}^{n} \alpha_i\right)(1+\delta)^n$$

   with $|\delta| < \frac{1}{2}b^{1-p}$. Consequently, rounding errors in floating point products create only minute relative errors.
7. [Ste98], [Wil65] *Dot (or Inner) Product of Floating Point Numbers:* Let $\mathbf{x} \in \mathbb{R}^n$ and $\mathbf{y} \in \mathbb{R}^n$ be vectors of floating point numbers and let s be the finite precision dot product $s = \mathrm{fl}(\mathbf{x}^T\mathbf{y}) = x_1 \otimes y_1 \oplus x_2 \otimes y_2 \oplus x_3 \otimes y_3 \oplus \cdots \oplus x_n \otimes y_n$ evaluated in the order shown, multiplications first followed by additions from left to right. If $n < 0.1/(\frac{1}{2}b^{1-p})$ and neither overflow nor any kind of underflow occurs, then the following hold.

(a) $s = \text{fl}(\mathbf{x}^T\mathbf{y}) = x_1y_1(1+\delta_1) + x_2y_2(1+\delta_2) + x_3y_3(1+\delta_3) + \cdots + x_ny_n(1+\delta_3)$ with $|\delta_1| < 1.06n(\frac{1}{2}b^{1-p})$ and $|\delta_j| < 1.06(n-j+2)(\frac{1}{2}b^{1-p}) \leq 1.06n(\frac{1}{2}b^{1-p})$, for $j = 2$, 3, 4, …, n.

(b) $s = \text{fl}(\mathbf{x}^T\mathbf{y}) = \hat{\mathbf{x}}^T\hat{\mathbf{y}}$ for some vectors $\hat{\mathbf{x}}, \hat{\mathbf{y}} \in \mathbb{R}^n$ satisfying $|\mathbf{x} - \hat{\mathbf{x}}| \leq |\mathbf{x}|(1 + 1.06n(\frac{1}{2}b^{1-p}))$ and $|\mathbf{y} - \hat{\mathbf{y}}| \leq |\mathbf{y}|(1 + 1.06n(\frac{1}{2}b^{1-p}))$. So, s is the mathematically correct product of the vectors $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ each of whose entries differ from the corresponding entries of $\mathbf{x}$ or $\mathbf{y}$ by minute relative errors.

There are infinitely many choices of $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$. In the notation of Fact 7(a), two are $\hat{x}_j = x_j(1+\delta_j)$, $\hat{y}_j = y_j$ and $\hat{x}_j = x_j(1+\delta_j)^{1/2}$, $\hat{y}_j = y_j(1+\delta_j)^{1/2}$, $j = 1$, 2, 3, …, n.

(c) If $x^Ty \neq 0$, then the relative error in s is bounded as

$$\left|\frac{s - x^Ty}{x^Ty}\right| \leq 1.06n(\tfrac{1}{2}b^{1-p})\frac{|x|^T|y|}{|x^Ty|}.$$

The bound shows that if there is little cancellation in the sum, then s has small relative error. The bound allows the possibility that s has large relative error when there is substantial cancellation in the sum. Indeed this is often the case.

8. *Rounding Error Bounds for Floating Point Matrix Operations:* In the following, A and B are matrices each of whose entries is a floating point number, $\mathbf{x}$ is a vector of floating point numbers, and c is a floating point number. The matrices A and B are compatible for matrix addition or matrix multiplication as necessary and E is an error matrix (usually different in each case) whose entries may or may not be floating point numbers. The integer dimension n is assumed to satisfy $n < 0.1/(\frac{1}{2}b^{1-p})$.

If neither overflows nor any kind of underflow occurs, then

(a) $\text{fl}(cA) = cA + E$ with $|E| \leq \frac{1}{2}b^{1-p}|cA|$.

(b) $\text{fl}(A+B) = (A+B) + E$ with $|E| \leq \frac{1}{2}b^{1-p}|A+B|$.

(c) If $\mathbf{x} \in \mathbb{R}^n$ and $A \in \mathbb{R}^{m\times n}$, then $\text{fl}(A\mathbf{x}) = (A+E)\mathbf{x}$ with $|E| \leq 1.06n(\frac{1}{2}b^{1-p})$.

(d) *Matrix multiplication:* If $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times q}$, $\text{fl}(AB) = AB + E$ with $|E| \leq 1.06n(\frac{1}{2}b^{1-p})\ |A|\,|B|$.

Note that if $|AB| \approx |A|\,|B|$, then each entry in $\text{fl}(AB)$ is correct to within a minute relative error. Otherwise, subtractive cancellation is possible and some entries of $\text{fl}(AB)$ may have large relative errors.

(e) Let $\|\cdot\|$ be a matrix norm satisfying $\|E\| \leq \|\,|E|\,\|$. (All of $\|\cdot\|_1$, $\|\cdot\|_2$, $\|\cdot\|_p$, $\|\cdot\|_\infty$ and $\|\cdot\|_F$ satisfy this requirement.) If $A \in \mathbb{R}^{m\times n}$ and $B \in \mathbb{R}^{n\times q}$, then $\text{fl}(AB) = AB + E$ with $\|E\| \leq 1.06n(\frac{1}{2}b^{1-p})\|\,|A|\,\|\,\|\,|B|\,\|$.

(f) *Matrix multiplication by an orthogonal matrix:* If $Q \in \mathbb{R}^{n\times n}$ is an orthogonal matrix, i.e., if $Q^T = Q^{-1}$, and if $A \in \mathbb{R}^{m\times n}$, then

(i) $\text{fl}(QA) = QA + E$ with $\|E\|_2 \leq 1.06n^2\left(\frac{1}{2}b^{1-p}\right)\|A\|_2$ and $\|E\|_F \leq 1.06n^{3/2}\left(\frac{1}{2}b^{1-p}\right)\|A\|_F$.

(ii) $\text{fl}(QA) = Q(A + \hat{E})$ with $\|\hat{E}\|_2 \leq 1.06n^2\left(\frac{1}{2}b^{1-p}\right)\|A\|_2$ and $\|\hat{E}\|_F \leq 1.06n^{3/2}\left(\frac{1}{2}b^{1-p}\right)\|A\|_F$.

Note that this bound shows that if one of the factors is an orthogonal matrix, then subtractive cancellation in floating point matrix multiplication is limited to those entries (if any) that have magnitude substantially smaller than the other, possibly nonorthogonal factor. Many particularly successful numerical methods derive their robustness in the presence of rounding errors from this observation. (See, for example, [Dat10], [GV96], [Ste98], or [Wil65].)

Examples:

1. The following table lists typical floating point systems in common use at the time of this writing.

	radix b	precision p	$e_{\min}$	$e_{\max}$
Some calculators	10	14	–99	99
Some calculators	10	14	–999	999
IEEE 754r decimal 64 [IEEE754r]	10	16	–383	384
IEEE 754r decimal 128 [IEEE754r]	10	34	–6143	6144
IEEE 754r binary 32 (Single) [IEEE754r]	2	24	–126	127
IEEE 754r binary 64 (Double) [IEEE754r]	2	53	–1022	1023
IEEE 754r binary 128 (Double Extended) [IEEE754r]	2	113	–16382	16383

2. Consider $p = 5$ digit, radix $b = 10$ floating-point arithmetic with round-to-nearest, ties-to-even rounding mode.
   (a) *Floating point addition is not associative:* If $\alpha = 1$, $\beta = 10^5$, and $\gamma = -10^5$, then $(\alpha \oplus \beta) \oplus \gamma = 0$ but $\alpha \oplus (\beta \oplus \gamma) = 1$. (This is also an example of subtractive cancellation.)
   (b) *Floating point multiplication/division is not associative:* If $\alpha = 3$, $\beta = 1$, and $\gamma = 3$, then $\alpha \otimes (\beta \oslash \gamma) = .99999$ but $(\alpha \otimes \beta) \oslash \gamma = 1$. If $\alpha = 44444$, $\beta = 55555$ and $\gamma = 66666$, then $\alpha \otimes (\beta \otimes \gamma) = 1.6460 \times 10^{14}$ but $(\alpha \otimes \beta) \otimes \gamma = 1.6461 \times 10^{14}$. Although different, both expressions have minute relative error. It is generally the case that floating point products have small relative errors. (See Fact 6.)
   (c) *Floating point multiplication does not distribute across floating point addition:* If $\alpha = 9$, $\beta = 1$, and $\gamma = -.99999$, then $\alpha \otimes (\beta \oplus \gamma) = 9.0000 \times 10^{-5}$ but $(\alpha \otimes \beta) \oplus (\alpha \otimes \gamma) = 1.0000 \times 10^{-4}$.
3. *Subtractive Cancellation:* In $p = 5$, radix $b = 10$ arithmetic with round-to-nearest, ties-to-even rounding, the expression $(\sqrt{1 + 10^{-4}} - 1)/10^{-4}$ evaluates as follows. (Here we assume that the floating point evaluation of the square root gives the same result as rounding the exact square root to $p = 5$, radix $b = 10$ digits.)

$$\begin{aligned}(\mathrm{fl}(\sqrt{1.0000 \oplus 10^{-4}}) \ominus 1) \oslash 10^{-4} &= (\mathrm{fl}(\sqrt{1.0001}) \ominus 1.0000) \oslash 10^{-4} \\ &= (\mathrm{fl}(1.000049999\ldots) \ominus 1.0000) \oslash 10^{-4} \\ &= (1.0000 \ominus 1.0000) \oslash 10^{-4} \\ &= 0.0000.\end{aligned}$$

In exact, infinite precision arithmetic, $(\sqrt{1 + 10^{-4}} - 1)/10^{-4} = .4999875\ldots$, so the relative error is 1. Note that zero rounding error occurs in the subtraction. The only nonzero rounding error is the square root, which has minute relative error roughly 5×10^{-5}, but this is enough to ruin the final result. Subtractive cancellation did not cause the large relative error. It only exposed the unfortunate fact that the result was ruined by earlier rounding errors.

4. *Relative vs. Absolute Errors:* Consider $\hat{x}_1 = 31416$ as an approximation to $x_1 = 10000\pi$ and $\hat{x}_2 = 3.07$ as an approximation to $x_2 = \pi$, The absolute errors are nearly the same: $|\hat{x}_1 - x_1| \approx -0.0735$ and $|\hat{x}_2 - x_2| \approx -0.0716$. On the other hand, the relative error in the first case, $\frac{|\hat{x}_1 - x_1|}{|x_1|} \approx 2 \times 10^{-6}$, is much smaller than the relative error in the second case, $\frac{|\hat{x}_2 - x_2|}{|x_2|} \approx 2 \times 10^{-2}$. The smaller relative error shows that $\hat{x}_1 = 31416$ is a better approximation to 10000π than $\hat{x}_2 = 3.07$ is to π. The absolute errors gave no indication of this.

50.7 Algorithms and Efficiency

In this section, we introduce efficiency of algorithms.

Definitions:

An **algorithm** is a precise set of instructions to perform a task. The algorithms discussed here perform mathematical tasks that transform an initial data set called the **input** into a desired result final data set called the **output** using an ordered list of arithmetic operations, comparisons, and decisions. For example, the Gaussian elimination algorithm (see Section 52.3) solves the linear system of equations $A\mathbf{x} = \mathbf{b}$ by transforming the given, nonsingular matrix $A \in \mathbb{R}^{n\times n}$ and right-hand side $\mathbf{b} \in \mathbb{R}^n$ into a vector $\mathbf{x}$ satisfying $A\mathbf{x} = \mathbf{b}$.

One algorithm is more **efficient** than another if it accomplishes the same task with a lower cost of computation. Cost of computation is usually dominated by the direct and indirection cost of execution time. So, in general, in a given computational environment, the more efficient algorithm finishes its task sooner. (The very real economic cost of algorithm development and implementation is not a part of the efficiency of an algorithm.) However, the amount of primary and secondary memory required by an algorithm or the expense of and availability of the necessary equipment to execute the algorithm may also be a significant part of the cost. In this sense, an algorithm that can accomplish its task on an inexpensive, programmable calculator is more efficient than one that needs a supercomputer.

For this discussion, a floating point operation or **flop** consists of a floating point addition, subtraction, multiplication, division, or square root along with any necessary subscripting and loop index overhead. In Fortran `A(I,J) = A(I,J) + C*A(K,J)` performs two flops. (Note that this is a slightly different definition of flop than is used in computer engineering.)

Formal algorithms are often specified in terms of an informal computer program called **pseudocode**.

On early digital computers, computation time was heavily dominated by evaluating floating point operations. So, traditionally, numerical analysts compare the efficiency of two algorithms by counting the number of floating point operations each of them executes. If n measures the input data set size, e.g., an input matrix $A \in \mathbb{R}^{n\times n}$, then an $O(n^p)$ algorithm is one that, for some positive constant c, performs cn^p plus a sum of lower powers of n floating point operations.

Facts:

For proofs and additional background, see, for example, [Dat10], [GV96], [Ste98], or [Wil65].

In choosing a numerical method, efficiency must be balanced against considerations like robustness against rounding error and likelihood of failure.

There are factors other than floating point operations that directly affect the execution time of an algorithm. On modern computers with fast floating point arithmetic, factors such as management of memory access, use of a fixed number of parallel processors, etc. must be taken into consideration when determining the execution time. In addition, the relative execution time of of algorithms depend strongly on the environment in which they are executed.

Nevertheless, for algorithms highly dominated by floating point arithmetic, flop counts are still useful. Despite the complexities of modern computers, flop counts typically expose the rate at which execution time increases as the size of the problem increases.

1. Triangular back substitution is an $O(n^2)$ algorithm to solve a triangular system of linear equations $T\mathbf{x} = b$, $\mathbf{b} \in \mathbb{R}^n$ and $T \in \mathbb{R}^{n\times n}$, with $t_{ij} = 0$ whenever $i > j$ [GV96]. (See the pseudo-code algorithm below.)
2. [GV96] Gaussian elimination with partial pivoting (cf. Algorithm 51.3.1) is an $O(n^3)$ algorithm to solve a system of equations $A\mathbf{x} = \mathbf{b}$ with $A \in \mathbb{R}^{n\times n}$ and $\mathbf{b} \in \mathbb{R}^n$. However, searching for the pivoting in each column requires $O(n^2)$ comparisons.
3. Gaussian elimination with complete pivoting is also an $O(n^3)$ algorithm; nonetheless, because of the need to repeatedly search an entire submatrix to locate a pivot in each step, it requires $O(n^3)$ comparisons which makes it slightly less efficient them Gaussian elimination with partial pivoting.
4. [GV96] The QR-factorization by Householder's method is an $O(n^3)$ algorithm to solve a system of equations $A\mathbf{x} = \mathbf{b}$ with $A \in \mathbb{R}^{n\times n}$ and $\mathbf{b} \in \mathbb{R}^n$.
5. [GV96] The QR factorization by Householder's method to solve the least squares problem $\min \|A\mathbf{x} - \mathbf{b}\|_2$ for given $A \in \mathbb{R}^{m\times n}$ and $\mathbf{b} \in \mathbb{R}^m$ is an $O(n^2(m - n/3))$ algorithm.
6. [GV96] The singular value decomposition using the Golub–Kahan–Reinsch algorithm to solve the least squares problem $\min \|A\mathbf{x} - \mathbf{b}\|_2$ for given $A \in \mathbb{R}^{m\times n}$ and $\mathbf{b} \in \mathbb{R}^m$ is an $O(m^2n + mn^2 + n^3)$ algorithm.
7. [GV96] The implicit, double-shift QR iteration algorithm to find all eigenvalues of a given matrix $A \in \mathbb{R}^{n\times n}$ is an $O(n^3)$ algorithm.
8. Cramer's rule for solving the system of equations $A\mathbf{x} = \mathbf{b}$ for given $A \in \mathbb{R}^{n\times n}$ and $\mathbf{b} \in \mathbb{R}^n$ in which determinants are evaluated using minors and cofactors is an $O((n+1)n!)$ algorithm and is impractical for all but small values of n.

Examples:

1. It takes roughly 4.6 seconds on a 2GHz Pentium workstation, using Gaussian elimination with partial pivoting, to solve the $n = 2000$ linear equations in 2000 unknowns $A\mathbf{x} = \mathbf{b}$ in which the entries of A and $\mathbf{b}$ are normally distributed pseudo-random numbers with mean zero and variance one. It takes roughly 34 seconds to solve a similar $n = 4000$ system of equations. This is consistent with the estimate that Gaussian elimination with partial pivoting is an $O(n^3)$ algorithm.
2. This is an example of a formal algorithm specified in pseudo-code. Consider the problem of solving for $\mathbf{y}$ in the upper triangular system of equations $T\mathbf{y} = \mathbf{b}$, where $\mathbf{b} \in \mathbb{R}^n$ is a given right-hand-side vector and $T \in \mathbb{R}^{n\times n}$ is a given nonsingular upper triangular matrix; i.e., $t_{ij} = 0$ for $i > j$ and $t_{ii} \neq 0$ for $i = 1, 2, 3, \ldots, n$.

```
Input: A nonsingular, upper triangular matrix $T \in \mathbb{R}^{n\times n}$ and a vector $\mathbf{b} \in \mathbb{R}^n$.
Output: The vector $\mathbf{y} \in \mathbb{R}^n$ satisfying $T\mathbf{y} = \mathbf{b}$.
Step 1. $y_n \leftarrow b_n/t_{nn}$
Step 2. For $i = n-1, n-2, ..., 2, 1$ do
    2.1 $s_i \leftarrow b_i - \sum_{j=i+1}^{n} t_{ij} y_j$
    2.2 $y_i = s_i/t_{ii}$
```

50.8 Numerical Stability and Instability

Numerically stable algorithms, despite rounding and truncation errors, produce results that are roughly as accurate as the errors in the input data allow. *Numerically unstable* algorithms allow rounding and truncation errors to produce results that are substantially less accurate than the errors in the input data allow. This section concerns numerical stability and instability and is loosely based on [Bun87].

Definitions:

A computational problem is the task of evaluating a function $f : \mathbb{R}^n \to \mathbb{R}^m$ at a particular data point $\mathbf{x} \in \mathbb{R}^n$. A numerical algorithm that is subject to rounding and truncation errors evaluates a perturbed function $\hat{f}(\mathbf{x})$. Throughout this section ε represents a modest multiple of the unit round.

The **forward error** is $f(\mathbf{x}) - \hat{f}(\mathbf{x})$, the difference between the mathematically exact function evaluation and the perturbed function evaluation.

The **backward error** is a vector $\mathbf{e} \in \mathbb{R}^n$ of smallest norm for which $f(\mathbf{x}+\mathbf{e}) = \hat{f}(\mathbf{x})$. If no such $\mathbf{e}$ exists, then the backward error is undefined. This definition is illustrated in Figure 50.1 [Ste98, p. 123].

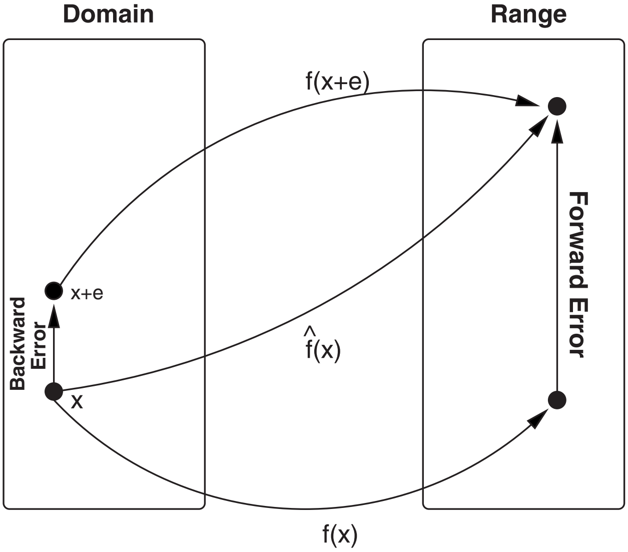

FIGURE 50.1 A computational problem is the task of evaluating a function f at a particular data point $\mathbf{x}$. A numerical algorithm that is subject to rounding and truncation errors evaluates a perturbed function $\hat{f}(\mathbf{x})$. The **forward error** is $f(\mathbf{x}) - \hat{f}(\mathbf{x})$, the difference between the mathematically exact function evaluation and the perturbed function evaluation. The **backward error** is a vector $\mathbf{e} \in \mathbb{R}^n$ of smallest norm for which $f(\mathbf{x}+\mathbf{e}) = \hat{f}(\mathbf{x})$ [Ste98, p. 123]. If no such vector e exists, then there is no backward error.

An algorithm is **forward stable** if, despite rounding and truncation errors,

$$\frac{\|f(\mathbf{x}) - \hat{f}(\mathbf{x})\|}{\|f(\mathbf{x})\|} \leq \varepsilon$$

for all valid input data $\mathbf{x}$. In a forward stable algorithm, the forward relative error is small for all valid input data $\mathbf{x}$ despite rounding and truncation errors in the algorithm.

An algorithm is **backward stable** or **strongly stable** if the backward relative error $\mathbf{e}$ exists and satisfies the relative error bound $\|\mathbf{e}\| \leq \varepsilon\|\mathbf{x}\|$ for all valid input data $\mathbf{x}$ despite rounding and truncation errors.

In this context, “small” means a modest multiple of the size of the errors in the data $\mathbf{x}$. If rounding errors are the only relevant errors, then “small” means a modest multiple of the unit round.

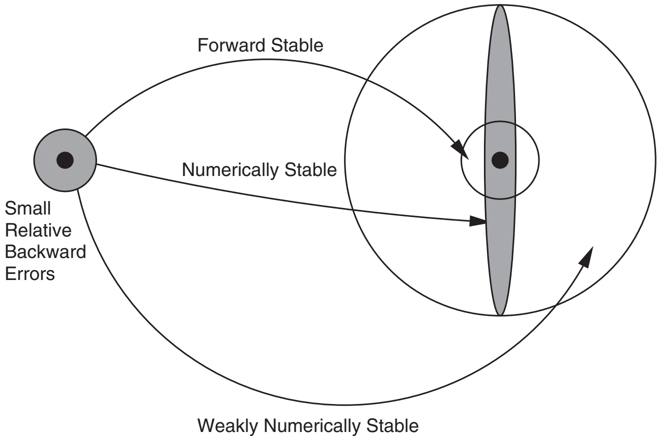

FIGURE 50.2 The black dot on the left represents a nominal data point $\mathbf{x}$. The black dot on the right is the exact, unperturbed value of $f(\mathbf{x})$. The shaded region on the left represents the small relative-to-$\|\mathbf{x}\|$ perturbations of $\mathbf{x}$. The shaded region on the right is its exact image under $f(\mathbf{x})$. The diagram illustrates the error behavior of a weakly numerically stable algorithm, a numerically stable algorithm, and a forward stable algorithm.

A finite precision numerical algorithm is **weakly numerically stable** if rounding and truncation errors cause it to evaluate a perturbed function $\hat{f}(\mathbf{x})$ satisfying the relative error bound

$$\frac{\|f(\mathbf{x}) - \hat{f}(\mathbf{x})\|}{\|f(\mathbf{x})\|} \leq \varepsilon \mathbf{cond}_f(\mathbf{x})$$

for all valid input data $\mathbf{x}$. In a weakly stable algorithm, the *magnitude* of the forward error is no greater than magnitude of an error that could be induced by perturbing the data by small multiples of the unit round. Note that this does *not* imply that there is a small backward error or even that a backward error exists. (An even weaker kind of “weak stability” requires the relative error bound only when $\mathbf{x}$ is well-conditioned [Bun87].)

An algorithm is **numerically stable** if rounding errors and truncation errors cause it to evaluate a perturbed function $\hat{f}(\mathbf{x})$ satisfying

$$\frac{\|f(\mathbf{x}+\mathbf{e}) - \hat{f}(\mathbf{x})\|}{\|f(\mathbf{x})\|} \leq \varepsilon$$

for some small relative-to-$\|\mathbf{x}\|$ backward error $\mathbf{e}$, $\|\mathbf{e}\| \leq \varepsilon\|\mathbf{x}\|$. In a numerically stable algorithm, $\hat{f}(\mathbf{x})$ lies near a function with small backward error.

Figure 50.2 illustrates the definitions of stability. The black dot on the left represents a nominal data point $\mathbf{x}$. The black dot on the right is the exact, unperturbed value of $f(\mathbf{x})$. The shaded region on the left represents the small relative-to-$\|\mathbf{x}\|$ perturbations of $\mathbf{x}$. The shaded region on the right is its exact image under $f(\mathbf{x})$.

In a weakly stable numerical method, the computed function value $\hat{f}(\mathbf{x})$ lies inside the large circle with radius equal to the longest distance from the black dot $f(\mathbf{x})$ to the furthest point in the shaded region containing it. The error in a weakly stable algorithm is no larger than would have been obtained from a backward stable algorithm. However, the actual result may or may not correspond to a small perturbation of the data.

In a numerically stable algorithm, $\hat{f}(\mathbf{x})$ lies either near or inside the shaded region on the right.

In a backward stable algorithm, $\hat{f}(\mathbf{x})$ lies in the shaded region, but, if the data are ill-conditioned as in the illustration, $\hat{f}(\mathbf{x})$ may have a large relative error. (To avoid clutter, there is no arrow illustrating a backward stable algorithm.)

In a forward stable algorithm, $\hat{f}(\mathbf{x})$ has a small relative error, but $\hat{f}(\mathbf{x})$ may or may not correspond to a small perturbation of the data.

Facts:

1. A numerically stable algorithm applied to an ill-conditioned problem may produce inaccurate results. For ill-conditioned problems, even small errors in the input data may lead to large errors in the computed solution. Just as no numerical algorithm can reliably correct errors in the data or create information not originally implicit in the data, nor can a numerical algorithm reliably calculate accurate solutions to ill-conditioned problems.
2. Rounding and truncation errors in a backward stable algorithm are equivalent to a further perturbation of the data. The computed results of a backward stable algorithm are realistic in the sense that they are what would have been obtained in exact arithmetic from an extra rounding-error-small relative perturbation of the data. Typically this extra error is negligible compared to other errors already present in the data.
3. The forward error that occurs in a backward stable algorithm obeys the asymptotic condition number bound in Fact 50.4.2. *Backward error analysis* is based on this observation.
4. [Dat10], [GV96] *Some Well-Known Backward Stable Algorithms:*

   (a) Fact 50.6.4 implies that a single floating point operation is both forward and backward stable.

   (b) Fact 50.6.7b shows that the given naive dot product algorithm is backward stable. The algorithm is not, in general, forward stable because there may be cancellation of significant digits in the summation.

   (c) *Gaussian elimination:* Gaussian elimination with complete pivoting is backward stable. Gaussian elimination with partial pivoting is not, strictly speaking, backward stable. However, linear equations for which the algorithm exhibits instability are so extraordinarily rare that the algorithm is said to be "backward stable in practice" [Dat10, GV96].

   (d) *Triangular back substitution:* The back-substitution algorithm in Example 50.7.2 in is backward stable. It can be shown that the rounding error corrupted computed solution $\hat{x}$ satisfies $(T+E)\hat{\mathbf{x}} = \mathbf{b}$, where $\mid e_{ij} \mid \leq \epsilon \mid t_{ij} \mid, i, j = 1, 2, 3, \ldots, n$. Thus, the computed solution $\hat{x}$ solves a nearby system. The back-substitution process is, therefore, backward stable.

(e) *QR factorization:* The Householder and Givens methods for factorization of $A = QR$, where Q is orthogonal and R is upper triangular, are backward stable.

(f) *SVD computation:* The Golub–Kahan–Reinsch algorithm is a backward stable algorithm for finding the singular value decomposition $A = U\Sigma V^T$, where Σ is diagonal and U and V are orthogonal.

(g) *Least-square problem:* The Householder QR factorization, the Givens QR factorization, and Singular Value Decomposition (SVD) methods for solving linear least squares problems are backward stable.

(h) *Eigenvalue computations:* The implicit double-shift QR iteration is backward stable.

(i) *Residual and Backward Stability:* [Hig02] If a computed solution to a linear system has a small, *suitably scaled residual*, the computation is backward stable.

Examples:

1. An example of an algorithm that is forward stable but not backward stable is the natural computation of the outer product $A = \mathbf{x}\mathbf{y}^T$ from vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$: for i, $j = 1, 2, 3, \ldots n$, set $a_{ij} \leftarrow x_i \otimes y_i$. This algorithm produces the correctly rounded value of the exact outer product, so it is forward stable. However, in general, rounding errors perturb the rank 1 matrix $\mathbf{x}\mathbf{y}^T$ into a matrix of higher rank. So, the rounding error perturbed outer product is not equal to the outer product of any pair of vectors; i.e., there is no backward error, so the algorithm is not backward stable.
2. *Backward vs. Forward Errors:* Consider the problem of evaluating $f(x) = e^x$ at $x = 1$. One numerical method is to sum several terms of the Taylor series for e^x. If $f(x)$ is approximated by the truncated Taylor series $\hat{f}(x) = 1 + x + \frac{x^2}{2} + \frac{x^3}{3!}$, then $f(1) = e \approx 2.7183$ and $\hat{f}(1) \approx 2.6667$. The forward error is $f(1) - \hat{f}(1) \approx 2.7183 - 2.6667 = 0.0516$. The backward error is $1 - y$, where $f(y) = \hat{f}(1)$, i.e., the backward error is $1 - \ln(\hat{f}(1)) \approx .0192$.
3. *A Numerically Unstable Algorithm:* Consider the computational problem of evaluating the function $f(x) = \ln(1 + x)$ for x near zero. The naive approach is to use $\mathrm{fl}(\ln(1 \oplus x))$, i.e., add one to x in finite precision arithmetic and evaluate the natural logarithm of the result also in finite precision arithmetic. (For this discussion, assume that if z is a floating point number, then $\ln(z)$ returns the correctly rounded exact value of $\ln(z)$.) Applying this very simple algorithm to $x = 10^{-16}$ in $p = 16$, radix $b = 10$ arithmetic, gives $\mathrm{fl}(\ln(1 \oplus 10^{-16})) = \mathrm{fl}(\ln(1)) = 0$. The exact value of $\ln(1 + 10^{-16}) \approx 10^{-16}$, so the rounding error corrupted result has relative error 1. It is 100% incorrect.

   However, the function $f(x) = \ln(1 + x)$ is well-conditioned when x is near zero. Moreover, $\lim_{x\to 0} \mathbf{cond}_f(x) = 1$. The large relative error is not due to ill-conditioning. It demonstrates that this simple algorithm is numerically unstable for x near zero.
4. An alternative algorithm to evaluate $f(x) = \ln(1 + x)$ that does not suffer the above gross numerical instability for x near zero is to sum several terms of the Taylor series

$$\ln(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \cdots .$$

   Although it is adequate for many purposes, this method can be improved. Note also that the series does not converge for $|x| > 1$ and converges slowly if $|x| \approx 1$, so some other method (perhaps $\mathrm{fl}(\ln(1 \oplus x))$) is needed when x is not near zero.
5. *Gaussian Elimination without Pivoting:* Gaussian elimination without pivoting is not numerically stable. For example, consider solving a system of two equations in two unknowns

$$\begin{aligned} 10^{-10}x_1 + \ x_2 &= 1 \\ x_1 + 2x_2 &= 3 \end{aligned}$$

using $p = 9$ digit, radix $b = 10$ arithmetic. Eliminating x_2 from the second equation, we obtain

$$\begin{aligned} 10^{-10}x_1 + {} & x_2 = 1 \\ (2 \ominus 10^{10}) & x_2 = 3 \ominus 10^{10}, \end{aligned}$$

which becomes

$$\begin{aligned} 10^{-10}x_1 + {} & x_2 = 1 \\ -10^{10} & x_2 = -10^{10}, \end{aligned}$$

giving $x_2 = 1$, $x_1 = 0$. The exact solution is $x_1 = (1 - 2 \times 10^{-10}) \approx 1$, $x_2 = (1 - 3 \times 10^{-10})/1 - 2 \times 10^{-10}) \approx 1$.

The ∞-norm condition number of the coefficient matrix $A = \begin{bmatrix} 10^{-10} & 1 \\ 1 & 2 \end{bmatrix}$ is $\kappa(A) \approx 9$, so the large error in the rounding error corrupted solution is not due to ill-conditioning. Hence, Gaussian elimination without pivoting is numerically unstable.

6. *An Unstable Algorithm for Eigenvalue Computations:* Finding the eigenvalues of a matrix by finding the roots of its characteristic polynomial is a numerically unstable process because the roots of the characteristic polynomial may be ill-conditioned when the eigenvalues of the corresponding matrix are well-conditioned. Transforming a matrix to companion form often requires an ill-conditioned similarity transformation, so even calculating the coefficients of the characteristic polynomial may be an unstable process. A well-known example is the diagonal matrix $A = \operatorname{diag}(1, 2, 3, \ldots, 20)$. The Wielandt-Hoffman theorem [GV96] shows that perturbing A to a nearby matrix $A + E$ perturbs the eigenvalues by no more than $\|E\|_F$. However, the characteristic polynomial is the infamous Wilkinson polynomial discussed in Example 50.4.5, which has highly ill-conditioned roots.

Acknowledgment. Some useful comments by G.W. Stewart on the first edition of this chapter are highly appreciated. Those comments led to several improvements in the current chapter.

The need to solve systems of linear equations arises often within diverse disciplines of science, engineering, and finance. The expression "direct solution of linear systems" refers generally to computational strategies that are able to produce solutions to linear systems after a predetermined number of arithmetic operations that depends only on the structure and dimension of the coefficient matrix. The evolution of computers has and continues to influence the development of these strategies and has also fostered particular styles of perturbation analysis suited to illuminating their behavior. Some general themes have become dominant, as a result; others have been pushed aside. For example, Cramer's Rule may be properly thought of as a direct solution strategy for solving linear systems; however as normally manifested, it requires a much larger number of arithmetic operations than Gauss elimination and is generally much more susceptible to the deleterious effects of rounding. Most current approaches for the direct solution of a linear system, $A\mathbf{x} = \mathbf{b}$, are patterned after Gauss elimination and favor an initial phase that partially decouples the system of equations: zeros are introduced systematically into the coefficient matrix, transforming it into triangular form; the resulting triangular system is easily solved. The entire process can be viewed in this way:

1. Find invertible matrices $\{S_i\}_{i=1}^{\rho}$ such that $S_\rho \dots S_2 S_1 A = U$ is triangular; then
2. Calculate a modified right-hand side $\mathbf{y} = S_\rho \dots S_2 S_1 \mathbf{b}$; and then
3. Determine the solution set to the triangular system $U\mathbf{x} = \mathbf{y}$.

The matrices S_1, S_2, … S_ρ are typically either row permutations of lower triangular matrices (Gauss transformations) or unitary matrices. In either case, inverses are readily available. Evidently, A can be written as $A = NU$, where $N = (S_\rho \dots S_2 S_1)^{-1}$. A solution framework may be built around the availability of decompositions such as this:

1. Find a decomposition $A = NU$ such that U is triangular and $N\mathbf{y} = \mathbf{b}$ is easily solved;
2. Solve $N\mathbf{y} = \mathbf{b}$; then
3. Determine the solution set to the triangular system $U\mathbf{x} = \mathbf{y}$.

51.1 Perturbations of Linear Systems

In the computational environment afforded by current computers, the finite representation of real numbers creates a small but persistent source of errors that may on occasion severely degrade the overall accuracy of a calculation. This effect is of fundamental concern in assessing strategies for solving linear systems.

Rounding errors can be introduced into the solution process for linear systems often before any calculations are performed — as soon as data are stored within the computer and represented within the internal floating point number system of the computer. Further errors that may be introduced in the course of computation often may be viewed in aggregate effectively as an additional contribution to this initial representation error. Inevitably, the linear system for which a solution is computed will deviate slightly from the "true" linear system and it becomes of critical interest to determine whether such deviations will have a significant effect on the accuracy of the final computed result.

Definitions:

Let $A \in \mathbb{C}^{n\times n}$ be a nonsingular matrix, $\mathbf{b} \in \mathbb{C}^n$, and then denote by $\hat{\mathbf{x}} = A^{-1}\mathbf{b}$ the unique solution of the linear system $A\mathbf{x} = \mathbf{b}$.

Given **data perturbations** $\delta A \in \mathbb{C}^{n\times n}$ and $\delta\mathbf{b} \in \mathbb{C}^n$ to A and $\mathbf{b}$, respectively, the **solution perturbation**, $\delta\mathbf{x} \in \mathbb{C}^n$ satisfies the associated **perturbed linear system** $(A + \delta A)(\hat{\mathbf{x}} + \delta\mathbf{x}) = \mathbf{b} + \delta\mathbf{b}$ (presuming then that the perturbed system is consistent).

For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$, the **residual vector** associated with $\tilde{\mathbf{x}}$ as an approximate solution to the linear system $A\mathbf{x} = \mathbf{b}$ is defined as $\mathbf{r}(\tilde{\mathbf{x}}) = \mathbf{b} - A\tilde{\mathbf{x}}$.

For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$, the associated (norm-wise) **relative backward error of the linear system** $A\mathbf{x} = \mathbf{b}$ (with respect to the the p-norm, for $1 \le p \le \infty$) is

$$\eta_p(A, \mathbf{b}; \tilde{\mathbf{x}}) = \min\left\{ \varepsilon \;\middle|\; \begin{array}{l} \text{there exist } \delta A, \delta\mathbf{b} \text{ such that} \\ \qquad (A + \delta A)\tilde{\mathbf{x}} = \mathbf{b} + \delta\mathbf{b} \text{ with} \end{array} \begin{array}{c} \|\delta A\|_p \le \varepsilon\|A\|_p \\ \|\delta b\|_p \le \varepsilon\|\mathbf{b}\|_p \end{array} \right\}.$$

For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$, the associated **component-wise relative backward error of the linear system** $A\mathbf{x} = \mathbf{b}$ is

$$\omega(A, \mathbf{b}; \tilde{\mathbf{x}}) = \min\left\{ \varepsilon \;\middle|\; \begin{array}{l} \text{there exist } \delta A, \delta\mathbf{b} \text{ such that} \\ \qquad (A + \delta A)\tilde{\mathbf{x}} = \mathbf{b} + \delta\mathbf{b} \text{ with} \end{array} \begin{array}{c} |\delta A| \le \varepsilon|A| \\ |\delta\mathbf{b}| \le \varepsilon|\mathbf{b}| \end{array} \right\},$$

where the absolute values and inequalities applied to vectors and matrices are interpreted component-wise: for example, $|B| \le |A|$ means $|b_{ij}| \le |a_{ij}|$ for all index pairs i, j.

The (norm-wise) **condition number of the linear system** $A\mathbf{x} = \mathbf{b}$ (with respect to the the p-norm, for $1 \le p \le \infty$) is

$$\kappa_p(A, \hat{\mathbf{x}}) = \|A^{-1}\|_p \frac{\|\mathbf{b}\|_p}{\|\hat{\mathbf{x}}\|_p}.$$

The **matrix condition number** of A (with respect to the the p-norm, for $1 \le p \le \infty$) is

$$\kappa_p(A) = \|A\|_p \|A^{-1}\|_p.$$

The **Skeel condition number of the linear system** $A\mathbf{x} = \mathbf{b}$ is

$$\text{cond}(A, \hat{\mathbf{x}}) = \frac{\|\, |A^{-1}|\; |A|\; |\hat{\mathbf{x}}| \|_\infty}{\|\hat{\mathbf{x}}\|_\infty}.$$

The **Skeel matrix condition number** is $\text{cond}(A) = \|\; |A^{-1}|\; |A|\; \|_\infty$.

Facts: [Hig02], [SS90]

1. For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$, $\tilde{\mathbf{x}}$ is the exact solution to any one of the following families of perturbed linear systems
$$(A + \delta A_\theta)\tilde{\mathbf{x}} = \mathbf{b} + \delta \mathbf{b}_\theta,$$
where $\theta \in \mathbb{C}$, $\delta \mathbf{b}_\theta = (\theta - 1)\,\mathbf{r}(\tilde{\mathbf{x}})$, $\delta A_\theta = \theta\,\mathbf{r}(\tilde{\mathbf{x}})\tilde{\mathbf{y}}^*$, and $\tilde{\mathbf{y}} \in \mathbb{C}^n$ is any vector such that $\tilde{\mathbf{y}}^*\tilde{\mathbf{x}} = 1$. In particular, for $\theta = 0$, $\delta A = 0$ and $\delta \mathbf{b} = -\mathbf{r}(\tilde{\mathbf{x}})$; for $\theta = 1$, $\delta A = \mathbf{r}(\tilde{\mathbf{x}})\tilde{\mathbf{y}}^*$ and $\delta \mathbf{b} = 0$.
2. (Rigal–Gaches Theorem) For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$,
$$\eta_p(A, \mathbf{b}; \tilde{\mathbf{x}}) = \frac{\|\mathbf{r}(\tilde{\mathbf{x}})\|_p}{\|A\|_p\|\tilde{\mathbf{x}}\|_p + \|\mathbf{b}\|_p}.$$
If $\tilde{\mathbf{y}}$ is the dual vector to $\tilde{\mathbf{x}}$ with respect to the p-norm ($\tilde{\mathbf{y}}^*\tilde{\mathbf{x}} = \|\tilde{\mathbf{y}}\|_q\,\|\tilde{\mathbf{x}}\|_p = 1$ with $\frac{1}{p} + \frac{1}{q} = 1$), then $\tilde{\mathbf{x}}$ is an exact solution to the perturbed linear system $(A + \delta A_{\tilde{\theta}})\tilde{\mathbf{x}} = \mathbf{b} + \delta \mathbf{b}_{\tilde{\theta}}$ with data perturbations as in (1) and $\tilde{\theta} = \frac{\|A\|_p\|\tilde{\mathbf{x}}\|_p}{\|A\|_p\|\tilde{\mathbf{x}}\|_p + \|\mathbf{b}\|_p}$, and as a result
$$\frac{\|\delta A_{\tilde{\theta}}\|_p}{\|A\|_p} = \frac{\|\delta \mathbf{b}_{\tilde{\theta}}\|_p}{\|\mathbf{b}\|_p} = \eta_p(A, \mathbf{b}; \tilde{\mathbf{x}}).$$
3. (Oettli–Prager Theorem) For any $\tilde{\mathbf{x}} \in \mathbb{C}^n$,
$$\omega(A, \mathbf{b}; \tilde{\mathbf{x}}) = \max_i \frac{|r_i|}{(|A|\ |\tilde{\mathbf{x}}|\ +\ |\mathbf{b}|)_i}.$$
If $D_1 = \operatorname{diag}\left(\frac{r_i}{(|A|\ |\tilde{\mathbf{x}}|\ +\ |\mathbf{b}|)_i}\right)$ and $D_2 = \operatorname{diag}(\mathit{sign}(\tilde{\mathbf{x}})_i)$, then $\tilde{\mathbf{x}}$ is an exact solution to the perturbed linear system $(A + \delta A)\tilde{\mathbf{x}} = \mathbf{b} + \delta \mathbf{b}$ with $\delta A = D_1\,|A|\,D_2$ and $\delta \mathbf{b} = -D_1\,|\mathbf{b}|$
$$|\delta A| \leq \omega(A, \mathbf{b}; \tilde{\mathbf{x}})\,|A| \quad \text{and} \quad |\delta \mathbf{b}| \leq \omega(A, \mathbf{b}; \tilde{\mathbf{x}})\,|A|$$
and no smaller constant can be used in place of $\omega(A, \mathbf{b}; \tilde{\mathbf{x}})$.
4. The reciprocal of $\kappa_p(A)$ is the smallest norm-wise relative distance of A to a singular matrix, i.e.,
$$\frac{1}{\kappa_p(A)} = \min\left\{ \frac{\|\delta A\|_p}{\|A\|_p} \;\middle|\; A + \delta A \text{ is singular} \right\}.$$
In particular, the perturbed coefficient matrix $A + \delta A$ is nonsingular if
$$\frac{\|\delta A\|_p}{\|A\|_p} < \frac{1}{\kappa_p(A)}.$$
5. $1 \leq \kappa_p(A, \hat{\mathbf{x}}) \leq \kappa_p(A)$ and $1 \leq \operatorname{cond}(A, \hat{\mathbf{x}}) \leq \operatorname{cond}(A) \leq \kappa_\infty(A)$.
6. $\operatorname{cond}(A) = \min\{\kappa_\infty(DA) \mid D \text{ diagonal}\}$.
7. If $\delta A = 0$, then
$$\frac{\|\delta \mathbf{x}\|_p}{\|\hat{\mathbf{x}}\|_p} \leq \kappa_p(A, \hat{\mathbf{x}})\frac{\|\delta \mathbf{b}\|_p}{\|\mathbf{b}\|_p}.$$
8. If $\delta \mathbf{b} = 0$ and $A + \delta A$ is nonsingular, then
$$\frac{\|\delta \mathbf{x}\|_p}{\|\hat{\mathbf{x}} + \delta \mathbf{x}\|_p} \leq \kappa_p(A)\frac{\|\delta A\|_p}{\|A\|_p}.$$
9. If $\|\delta A\|_p \leq \epsilon\|A\|_p$, $\|\delta \mathbf{b}\|_p \leq \epsilon\|\mathbf{b}\|_p$, and $\epsilon < \dfrac{1}{\kappa_p(A)}$, then
$$\frac{\|\delta \mathbf{x}\|_p}{\|\hat{\mathbf{x}}\|_p} \leq \frac{2\,\epsilon\,\kappa_p(A)}{1 - \epsilon\,\kappa_p(A)}.$$

10. If $|\delta A| \leq \epsilon |A|$, $|\delta \mathbf{b}| \leq \epsilon\, |\mathbf{b}|$, and $\epsilon < \dfrac{1}{\text{cond}(A)}$, then
$$\frac{\|\delta \mathbf{x}\|_\infty}{\|\hat{\mathbf{x}}\|_\infty} \leq \frac{2\,\epsilon\, \text{cond}(A,\hat{\mathbf{x}})}{1-\epsilon\, \text{cond}(A)}.$$

Examples:

1. Let $A = \begin{bmatrix} 1000 & 999 \\ 999 & 998 \end{bmatrix}$ so $A^{-1} = \begin{bmatrix} -998 & 999 \\ 999 & -1000 \end{bmatrix}$. Then $\|A\|_1 = \|A^{-1}\|_1 = 1999$ so that $\kappa_1(A) \approx 3.996 \times 10^6$. Consider
$$\mathbf{b} = \begin{bmatrix} 1999 \\ 1997 \end{bmatrix} \text{ associated with a solution } \hat{\mathbf{x}} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.$$
A perturbation of the right-hand side $\delta\mathbf{b} = \begin{bmatrix} -0.01 \\ 0.01 \end{bmatrix}$ constitutes a relative change in the right-hand side of $\frac{\|\delta \mathbf{b}\|_1}{\|\hat{\mathbf{b}}\|_1} \approx 5.005 \times 10^{-6}$ yet it produces a perturbed solution $\hat{\mathbf{x}} + \delta\mathbf{x} = \begin{bmatrix} 20.97 \\ -18.99 \end{bmatrix}$ constituting a relative change $\frac{\|\delta \mathbf{x}\|_1}{\|\hat{\mathbf{x}}\|_1} = 19.98 \leq 20 = \kappa_1(A) \frac{\|\delta \mathbf{b}\|_1}{\|\mathbf{b}\|_1}$. The bound determined by the condition number is very nearly achieved. Note that the same perturbed solution $\hat{\mathbf{x}} + \delta\mathbf{x}$ could be produced by a change in the coefficient matrix
$$\delta A = \tilde{\mathbf{r}}\tilde{\mathbf{y}}^* = -\begin{bmatrix} -0.01 \\ 0.01 \end{bmatrix} \begin{bmatrix} \frac{1}{39.96} & -\frac{1}{39.96} \end{bmatrix} = (1/3996) \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$$
constituting a relative change $\frac{\|\delta A\|_1}{\|A\|_1} \approx 2.5 \times 10^{-7}$. Then $(A+\delta A)(\hat{\mathbf{x}} + \delta\mathbf{x}) = \mathbf{b}$.
2. Let $n = 100$ and A be tridiagonal with diagonal entries equal to -2 and all superdiagonal and subdiagonal entries equal to 1 (associated with a centered difference approximation to the second derivative). Let $\mathbf{b}$ be a vector with a quadratic variation in entries
$$b_k = (k-1)(100-k)/10{,}000.$$
Then
$$\kappa_2(A,\hat{\mathbf{x}}) \approx 1, \qquad \text{but} \qquad \kappa_2(A) \approx 4.1336 \times 10^3.$$
Since the elements of $\mathbf{b}$ do not have an exact binary representation, the linear system that is presented to any computational algorithm will be $A\mathbf{x} = \mathbf{b} + \delta\mathbf{b}$ with $\|\delta\mathbf{b}\|_2 \leq \epsilon \|\mathbf{b}\|_2$, where ϵ is the unit roundoff error. For example, if the linear system data is stored in IEEE single precision format, $\epsilon \approx 6 \times 10^{-8}$. The matrix condition number, $\kappa_2(A)$, would yield a bound of $(6 \times 10^{-8})(4.1336 \times 10^3) \approx 2.5 \times 10^{-4}$ anticipating the loss of more than 4 significant digits in solution components even if all computations were done on the stored data with no further error. However, the condition number of the linear system, $\kappa_2(A,\hat{\mathbf{x}})$, is substantially smaller and the predicted error for the system is roughly the same as the initial representation error $\approx 6 \times 10^{-8}$, indicating that the solution will be fairly insensitive to the consequences of rounding of the right-hand side data—assuming no further errors occur. But, in fact, this conclusion remains true even if further errors occur, if whatever computational algorithm that is used produces small backward error, as might be asserted if, say, a final residual satisfies $\|\mathbf{r}\|_2 \leq \mathcal{O}(\epsilon)\, \|\mathbf{b}\|_2$. This situation changes substantially if the right-hand side is changed to
$$b_k = (-1)^k (k-1)(100-k)/10{,}000,$$
which only introduces a sign variation in $\mathbf{b}$. In this case, $\kappa_2(A,\hat{\mathbf{x}}) \approx \kappa_2(A)$, and the components of the computed solution can be expected to lose about 4 significant digits purely on

the basis of errors that are made in the initial representation. Additional errors made in the course of the computation can hardly be expected to improve this situation.

51.2 Triangular Linear Systems

Systems of linear equations for which the unknowns may be solved for one at a time in sequence may be reordered to produce linear systems with triangular coefficient matrices. Such systems can be solved both with remarkable accuracy and remarkable efficiency. Triangular systems are the archetype for easily solvable systems of linear equations. As such, they often constitute an intermediate goal in strategies for solving linear systems.

Definitions:

A linear system of equations $T\mathbf{x} = \mathbf{b}$ with $T \in \mathbb{C}^{n\times n}$ (representing n equations in n unknowns) is a **triangular system** if $T = [t_{ij}]$ is either an **upper triangular matrix** ($t_{ij} = 0$ for $i > j$) or a **lower triangular matrix** ($t_{ij} = 0$ for $i < j$).

Facts: [Hig02], [GV96]

1. [GV96, pp. 88–90]

```
Algorithm 1: Row-wise forward substitution for solving lower triangular system
  Input: $L = [\ell_{ij}] \in \mathbb{R}^{n\times n}$ with $\ell_{kj} = 0$ for $k < j$; $\mathbf{b} \in \mathbb{R}^n$
  Output: solution vector $\mathbf{x} \in \mathbb{R}^n$ that satisfies $L\mathbf{x} = \mathbf{b}$
  $x_1 \leftarrow b_1/\ell_{1,1}$
  for $k = 2$ to $n$
      $x_k \leftarrow (b_k - L_{k,1:k-1} \cdot x_{1:k-1})/\ell_{k,k}$
```

```
Algorithm 2: Column-wise back substitution for solving upper triangular system
  Input: $U = [u_{ij}] \in \mathbb{R}^{n\times n}$ with $u_{kj} = 0$ for $k > j$; $\mathbf{b} \in \mathbb{R}^n$
  Output: solution vector $\mathbf{x} \in \mathbb{R}^n$ that satisfies $U\mathbf{x} = \mathbf{b}$
  for $k = n$ down to 2 in steps of $-1$,
      $x_k \leftarrow b_k/u_{k,k}$
      $b_{1:k-1} \leftarrow b_{1:k-1} - x_k U_{1:k-1,k}$
  $x_1 \leftarrow b_1/u_{1,1}$
```

2. Algorithm 1 involves as a core calculation dot products of portions of coefficient matrix rows with portions of the emerging solution vector. This can incur a performance penalty for large n from accumulation of dot products using a scalar recurrence. A "column-wise" reformulation may have better performance for large n. Algorithm 2 is such a "column-wise" formulation for upper triangular systems.
3. An efficient and reliable implementation for the solution of triangular systems is offered as part of the standard BLAS software library in `xTRSz` (see Chapter 92), where `x`=`S`, `D`, `C`, or `Z` according to whether data are single or double precision real, or single or double precision complex floating point numbers, respectively, and `z`=`V` or `M` according to whether a single system of equations is to be solved or multiple systems (sharing the same coefficient matrix) are to be solved, respectively.

4. The solution of triangular systems using either Algorithm 1 or 2 is *component-wise backward stable.* In particular the computed result, $\tilde{\mathbf{x}}$, produced either by Algorithm 1 or 2 in solving a triangular system, $T\mathbf{x} = \mathbf{b}$, will be the exact result of a perturbed system $(T + \delta T)\tilde{\mathbf{x}} = \mathbf{b}$, where $|\delta T| \leq \frac{n\,\epsilon}{1 - n\,\epsilon}|T|$ and ϵ is the unit roundoff error.
5. The error in the solution of a triangular system, $T\mathbf{x} = \mathbf{b}$, using either Algorithm 1 or 2 satisfies
$$\frac{\|\tilde{\mathbf{x}} - \hat{\mathbf{x}}\|_\infty}{\|\hat{\mathbf{x}}\|_\infty} \leq \frac{n\,\epsilon\,\mathrm{cond}(T, \hat{\mathbf{x}})}{1 - n\,\epsilon\,(\mathrm{cond}(T) + 1)}.$$
6. If $T = [t_{ij}]$ is a lower triangular matrix satisfying $|t_{ii}| \geq |t_{ij}|$ for $j \leq i$, the computed solution to the linear system $T\mathbf{x} = \mathbf{b}$ produced by either Algorithm 1 or the variant of Algorithm 2 for lower triangular systems satisfies
$$|\hat{x}_i - \tilde{x}_i| \leq \frac{2^i\,n\,\epsilon}{1 - n\,\epsilon} \max_{j \leq i} |\tilde{x}_j|,$$
where $\tilde{x}_i$ are the components of the computed solution, $\tilde{\mathbf{x}}$, and $\hat{x}_i$ are the components of the exact solution, $\hat{\mathbf{x}}$. Although this bound degrades exponentially with i, it shows that early solution components will be computed to high accuracy relative to those components already computed.

Examples:

1. Use Algorithm 2 to solve the triangular system
$$\begin{bmatrix} 1 & 2 & -3 \\ 0 & 2 & -6 \\ 0 & 0 & 3 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}.$$
$k = 3$ step: Solve for $x_3 = 1/3$. Update right-hand side:
$$\begin{bmatrix} 1 & 2 \\ 0 & 2 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} - (1/3) \begin{bmatrix} -3 \\ -6 \\ 3 \end{bmatrix} = \begin{bmatrix} 2 \\ 3 \\ 0 \end{bmatrix}.$$
$k = 2$ step: Solve for $x_2 = 3/2$. Update right-hand side:
$$\begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \begin{bmatrix} x_1 \end{bmatrix} = \begin{bmatrix} 2 \\ 3 \\ 0 \end{bmatrix} - (3/2) \begin{bmatrix} 2 \\ 2 \\ 0 \end{bmatrix} = \begin{bmatrix} -1 \\ 0 \\ 0 \end{bmatrix}.$$
$k = 1$ step: Solve for $x_1 = -1$.
2. [Hig02, p. 156] For $\epsilon > 0$, consider $T = \begin{bmatrix} 1 & 0 & 0 \\ \varepsilon & \varepsilon & 0 \\ 0 & 1 & 1 \end{bmatrix}$. Then $T^{-1} = \begin{bmatrix} 1 & 0 & 0 \\ -1 & \frac{1}{\varepsilon} & 0 \\ 1 & -\frac{1}{\varepsilon} & 1 \end{bmatrix}$, and so $\mathrm{cond}(T) = 5$, even though
$$\kappa_\infty(T) = 2(2 + \frac{1}{\varepsilon}) \approx \frac{2}{\varepsilon} + \mathcal{O}(1).$$
Thus, linear systems having T as a coefficient matrix will be solved to high relative accuracy, independent of both right-hand side and size of ϵ, despite the poor conditioning of T (as measured by κ_∞) as ϵ becomes small. However, note that
$$\mathrm{cond}(T^T) = 1 + \frac{2}{\varepsilon} \quad \text{and} \quad \kappa_\infty(T^T) = (1 + \varepsilon)\frac{2}{\varepsilon} \approx \frac{2}{\varepsilon} + \mathcal{O}(1).$$

So, linear systems having T^T as a coefficient matrix may have solutions that are sensitive to perturbations and indeed, $\text{cond}(T^T, \hat{\mathbf{x}}) \approx \text{cond}(T^T)$ for any right-hand side $\mathbf{b}$ with $b_3 \neq 0$ yielding solutions that are sensitive to perturbations for small ϵ.

51.3 Gauss Elimination and LU Decomposition

Gauss elimination is an elementary approach to solving systems of linear equations, yet it still constitutes the core of the most sophisticated of solution strategies. In the k^{th} step, a transformation matrix, M_k, (a "Gauss transformation") is designed so as to introduce zeros into A — typically into a portion of the k^{th} column — without harming zeros that have been introduced in earlier steps. Typically, successive applications of Gauss transformations are interleaved with row interchanges. Remarkably, this reduction process can be viewed as producing a decomposition of the coefficient matrix $A = NU$, where U is a triangular matrix and N is a row permutation of a lower triangular matrix.

Definitions:

For each index k, a **Gauss vector** is a vector in $\mathbb{C}^n$ with the leading k entries equal to zero: $\boldsymbol{\ell}_k = [\underbrace{0, \ldots, 0}_{k}, \ell_{k+1}, \ldots, \ell_n]^T$. The entries $\ell_{k+1}, \ldots, \ell_n$ are **Gauss multipliers**. The related matrix

$$M_k = I - \boldsymbol{\ell}_k \mathbf{e}_k^T$$

is called a **Gauss transformation**.

For the pair of indices (i, j), with $i \leq j$ the associated **permutation matrix**, $\Pi_{i,j}$ is an $n \times n$ identity matrix with the i^{th} row and j^{th} row interchanged. Note that $\Pi_{i,i}$ is the identity matrix.

A matrix $U \in \mathbb{C}^{m \times n}$ is in **row-echelon form** if (1) the first nonzero entry of each row has a strictly smaller column index than all nonzero entries with strictly larger row index and (2) zero rows occur at the bottom. The first nonzero entry in each row is called a **pivot**. The determining feature of row echelon form is that pivots occur to the left of all nonzero entries in lower rows.

A matrix $A \in \mathbb{C}^{m \times n}$ has an ***LU* decomposition** if there exists a unit lower triangular matrix $L \in \mathbb{C}^{m \times m}$ ($L_{i,j} = 0$ for $i < j$ and $L_{i,i} = 1$ for all i) and an upper triangular matrix $U \in \mathbb{C}^{m \times n}$ ($U_{i,j} = 0$ for $i > j$) such that $A = LU$.

Facts: [GV96]

1. Let $\mathbf{a} \in \mathbb{C}^n$ be a vector with a nonzero component in the r^{th} entry, $a_r \neq 0$. Define the Gauss vector, $\boldsymbol{\ell}_r = [\underbrace{0, \ldots, 0}_{r}, \frac{a_{r+1}}{a_r}, \ldots, \frac{a_n}{a_r}]^T$. The associated Gauss transformation $M_r = I - \boldsymbol{\ell}_r \mathbf{e}_r^T$ introduces zeros into the last $n - r$ entries of $\mathbf{a}$:
$$M_r \mathbf{a} = [a_1, \ldots, a_r, 0, \ldots, 0]^T.$$
2. If $A \in \mathbb{C}^{m \times n}$ with $\text{rank}\, A = \rho \geq 1$ has ρ leading principal submatrices nonsingular, $A_{1:r,1:r}$, $r = 1, \ldots, \rho$, then there exist Gauss transformations $M_1, M_2, \ldots, M_\rho$ so that
$$M_\rho M_{\rho-1} \cdots M_1 A = U$$
with U upper triangular. Each Gauss transformation M_r introduces zeros into the r^{th} column.
3. Gauss transformations are unit lower triangular matrices. They are invertible, and for the Gauss transformation, $M_r = I - \boldsymbol{\ell}_r \mathbf{e}_r^T$,
$$M_r^{-1} = I + \boldsymbol{\ell}_r \mathbf{e}_r^T.$$

4. If Gauss vectors $\boldsymbol{\ell}_1, \boldsymbol{\ell}_2, \ldots, \boldsymbol{\ell}_{n-1}$ are given with
$$\boldsymbol{\ell}_1 = \begin{Bmatrix} 0 \\ \ell_{21} \\ \ell_{31} \\ \vdots \\ \ell_{n1} \end{Bmatrix}, \quad \boldsymbol{\ell}_2 = \begin{Bmatrix} 0 \\ 0 \\ \ell_{32} \\ \vdots \\ \ell_{n2} \end{Bmatrix}, \ldots, \quad \boldsymbol{\ell}_{n-1} = \begin{Bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ \ell_{n,n-1} \end{Bmatrix},$$
then the product of Gauss transformations $M_{n-1}M_{n-2}\cdots M_2M_1$ is invertible and has an explicit inverse
$$(M_{n-1}M_{n-2}\ldots M_2M_1)^{-1} = I + \sum_{k=1}^{n-1} \boldsymbol{\ell}_k \mathbf{e}_k^T = \begin{bmatrix} 1 & 0 & \ldots & 0 & 0 \\ \ell_{21} & 1 & & & 0 \\ \ell_{31} & \ell_{32} & \ddots & & 0 \\ \vdots & & & 1 & 0 \\ \ell_{n1} & \ell_{n2} & \ldots & \ell_{n,n-1} & 1 \end{bmatrix}.$$
5. If $A \in \mathbb{C}^{m\times n}$ with $\operatorname{rank} A = \rho$ has ρ leading principal submatrices nonsingular, $A_{1:r,1:r}$, $r = 1, \ldots, \rho$, then A has an *LU* decomposition: $A = LU$, with L unit lower triangular and U upper triangular. The (i, j) entry of L: $L_{i,j}$, with $i > j$, is the Gauss multiplier that was used to introduce a zero into the corresponding (i, j) entry of A.
6. If $A \in \mathbb{C}^{m\times n}$ with $\operatorname{rank} A = m$ (full), then the *LU* decomposition is unique.
7. Let $\mathbf{a}$ be an arbitrary vector in $\mathbb{C}^n$. For any index r, there is an index $\mu \geq r$, a permutation matrix $\Pi_{r,\mu}$, and a Gauss transformation M_r so that
$$M_r\Pi_{r,\mu}\mathbf{a} = [a_1, \ldots, a_{r-1}, a_\mu, \underbrace{0, \ldots, 0}_{n-r}]^T.$$
The index μ is chosen so that $a_\mu \neq 0$ out of the set $\{a_r, a_{r+1}, \ldots, a_n\}$. If $a_r \neq 0$, then $\mu = r$ and $\Pi_{r,\mu} = I$ is a possible choice; if each element is zero, $a_r = a_{r+1} = \cdots = a_n = 0$, then $\mu = r$, $\Pi_{r,\mu} = I$, and $M_r = I$ is a possible choice.
8. For every matrix $A \in \mathbb{C}^{m\times n}$ with $\operatorname{rank} A = \rho$, there exists a sequence of ρ indices $\mu_1, \mu_2, \ldots, \mu_\rho$ with $i \leq \mu_i \leq m$ for $i = 1, \ldots, \rho$ and Gauss transformations $M_1, \ldots, M_\rho$ so that $M_\rho\Pi_{\rho,\mu_\rho}M_{\rho-1}\Pi_{\rho-1,\mu_{\rho-1}}\cdots M_1\Pi_{1,\mu_1}A = U$ with U upper triangular and in row echelon form. Each pair of transformations $M_r\Pi_{r,\mu_r}$ introduces zeros below the r^{th} pivot.
9. For $r < i < j$, $\Pi_{i,j}M_r = \widetilde{M}_r\Pi_{i,j}$, where $\widetilde{M}_r = I - \tilde{\boldsymbol{\ell}}_r\mathbf{e}_r^T$ and $\tilde{\boldsymbol{\ell}}_r = \Pi_{i,j}\boldsymbol{\ell}_r$ (i.e., the i and j entries of $\boldsymbol{\ell}_r$ are interchanged to form $\tilde{\boldsymbol{\ell}}_r$).
10. For every matrix $A \in \mathbb{C}^{m\times n}$ with $\operatorname{rank} A = \rho$, there is a row permutation of A that has an *LU* decomposition: $PA = LU$, with a permutation matrix P, unit lower triangular matrix L, and an upper triangular matrix U that is in row echelon form. P can be chosen as $P = \Pi_{\rho,\mu_\rho}\Pi_{\rho-1,\mu_{\rho-1}}\ldots\Pi_{1,\mu_1}$ from Fact 8, though in general there can be many other possibilities as well.
11. Reduction of A with Gauss transformations (or, equivalently, calculation of an *LU* factorization) must generally incorporate row interchanges. As a practical matter, these row interchanges commonly are chosen so as to bring the largest magnitude entry within the column being reduced up into the pivot location. This strategy is called "partial pivoting." In particular, if zeros are to be introduced into the k^{th} column below the r^{th} row (with $r \leq k$), then one seeks an index μ_r such that $r \leq \mu_r \leq m$ and $|A_{\mu_r,k}| = \max_{r\leq i\leq m} |A_{i,k}|$. When $\mu_1, \mu_2, \ldots, \mu_\rho$ in Fact 8 are chosen in this way, the reduction process is called "Gaussian Elimination with Partial Pivoting" (GEPP) or, within the context of factorization, the permuted *LU* factorization (PLU).

12. [GV96, p. 115]

Algorithm 3: GEPP/PLU decomposition of a rectangular matrix (outer product)

```
    Input: $A \in \mathbb{R}^{m\times n}$
    Output: $L \in \mathbb{R}^{m\times m}$ (unit lower triangular matrix)
            $U \in \mathbb{R}^{m\times n}$ (upper triangular matrix - row echelon form)
            $P \in \mathbb{R}^{m\times m}$ (permutation matrix) so that $PA = LU$
    ($P$ is represented with an index vector $\mathbf{p}$ such that $\mathbf{y} = P\mathbf{z} \Leftrightarrow y_j = z_{p_j}$)
$L \leftarrow I_m$; $U \leftarrow 0 \in \mathbb{R}^{m\times n}$; $\mathbf{p} = [1, 2, 3, \ldots, m]$; and $r \leftarrow 1$;
for $k = 1$ to $n$
    Find $\mu$ such that $r \le \mu \le m$ and $|A_{\mu,k}| = \max_{r\le i\le m} |A_{i,k}|$
    if $A_{\mu,k} \ne 0$, then
        Exchange $A_{\mu,k:n} \leftrightarrow A_{r,k:n}$, $L_{\mu,1:r-1} \leftrightarrow L_{r,1:r-1}$, and $p_\mu \leftrightarrow p_r$
        $L_{r+1:m,r} \leftarrow A_{r+1:m,k}/A_{r,k}$
        $U_{r,k:n} \leftarrow A_{r,k:n}$
        for $i = r+1$ to $m$
            for $j = k+1$ to $n$
                $A_{i,j} \leftarrow A_{i,j} - L_{i,r}U_{r,j}$
        $r \leftarrow r+1$
```

Algorithm 4: GEPP/PLU decomposition of a rectangular matrix (gaxpy)

```
    Input: $A \in \mathbb{R}^{m\times n}$
    Output: $L \in \mathbb{R}^{m\times m}$ (unit lower triangular matrix),
            $U \in \mathbb{R}^{m\times n}$ (upper triangular matrix - row echelon form), and
            $P \in \mathbb{R}^{m\times m}$ (permutation matrix) so that $PA = LU$
    ($P$ is represented with an index vector $\boldsymbol{\pi}$ that records row interchanges
        $\pi_r = \mu$ means row $r$ and row $\mu \ge r$ were interchanged in step $r$)
    $L \leftarrow I_m \in \mathbb{R}^{m\times m}$; $U \leftarrow 0 \in \mathbb{R}^{m\times n}$; and $r \leftarrow 1$;
    for $j = 1$ to $n$
        $\mathbf{v} \leftarrow A_{1:m,j}$
        if $r > 1$, then
            for $i = 1$ to $r-1$,
                Exchange $v_i \leftrightarrow v_{\pi_i}$
            Solve the triangular system, $L_{1:r-1,1:r-1} \cdot \mathbf{z} = \mathbf{v}_{1:r-1}$
            $U_{1:r-1,j} \leftarrow \mathbf{z}$
            Update $\mathbf{v}_{r:m} \leftarrow \mathbf{v}_{r:m} - L_{r:m,1:r-1} \cdot \mathbf{z}$
        Find $\mu$ such that $|v_\mu| = \max_{r\le i\le m} |v_i|$
        if $v_\mu \ne 0$, then
            $\pi_r \leftarrow \mu$
            Exchange $v_\mu \leftrightarrow v_r$
            for $i = 1$ to $r-1$,
                Exchange $L_{\mu,i} \leftrightarrow L_{r,i}$
            $L_{r+1:m,r} \leftarrow \mathbf{v}_{r+1:m}/v_r$
            $U_{r,j} \leftarrow v_r$
            $r \leftarrow r+1$
```

13. The condition for skipping reduction steps (that is, when $A_{\mu,k} = 0$ in Algorithm 3 or when $v_\mu = 0$ in Algorithm 4) indicates deficiency of column rank and the potential for an infinite number of solutions. These conditions are sensitive to rounding errors that may occur in the calculation of those columns and as such, GEPP/PLU is applied for the most part in full column rank settings ($\operatorname{rank} A = n$), guaranteeing that no zero pivots are encountered and that no reduction steps are skipped.
14. Both Algorithms 3 and 4 require approximately $\frac{2}{3}\rho^3 + \rho m(n-\rho) + \rho n(m-\rho)$ arithmetic operations (with $\operatorname{rank} A = \rho$). Algorithm 3 involves as a core calculation the updating of a submatrix having ever diminishing size. For large matrix dimension, the contents of this submatrix, $A_{r+1:m,k+1:n}$, may be widely scattered through computer memory and a performance penalty can occur in gathering the data for computation (which can be costly relative to the number of arithmetic operations that are performed with that data). Algorithm 4 is a reorganization that avoids excess data motion by delaying updates to columns until the step within which they have zeros introduced. This forces modifications to the matrix entries to be made just one column at a time and the necessary data motion can be more efficient.
15. The overhead associated with partial pivoting comes from lines beginning "Find μ such that ..." in Algorithms 3 and 4, involving a net $mn - \frac{n^2}{2}$ floating point comparison each of which are comparable in computational effort to a floating point subtraction. Typically this adds negligible overhead relative to the core complexity of $\mathcal{O}(\rho^3)$ arithmetic operations. Other strategies for avoiding the adverse effects of small pivots exist. Some are more aggressive than partial pivoting in producing the largest possible pivot (consequently have higher overhead), others are more restrained (and so, are cheaper).

    (a) *"Complete pivoting"* uses both row and column permutations to bring in the largest possible pivot: If zeros are to be introduced into the k^{th} column in row entries $r+1$ to m, then one seeks indices μ and ν such that $r \leq \mu \leq m$ and $k < \nu \leq n$ such that $|A_{\mu,\nu}| = \max_{\substack{r \leq i \leq m \\ k < j \leq n}} |A_{i,j}|$. Gauss elimination with complete pivoting produces a unit lower triangular matrix $L \in \mathbb{R}^{m \times m}$, an upper triangular matrix $U \in \mathbb{R}^{m \times n}$, and two permutation matrices, P and Q, so that $PAQ = LU$. This strategy can require $\mathcal{O}(\frac{mn^2}{2} - \frac{n^3}{6})$ floating point comparisons, potentially adding now nonnegligible overhead to the core arithmetic requirements. Overhead associated with data motion can become significant as well. The added stability that complete pivoting provides is rarely perceived to be worth the additional overhead.

    (b) *"Threshold pivoting"* identifies pivot candidates in each step that achieve a significant (predetermined) fraction of the magnitude of the pivot that would have been used in that step for partial pivoting: Consider all $\hat{\mu}$ such that $r \leq \hat{\mu} \leq m$ and $|A_{\hat{\mu},k}| \geq \tau \cdot \max_{r \leq i \leq m} |A_{i,k}|$, where $\tau \in (0,1)$ is a given threshold. This allows pivots to be chosen on the basis of other criteria such as influence on sparsity while still providing some protection from instability. τ can often be chosen quite small ($\tau = 0.1$ or $\tau = 0.025$ are typical values). See Section 53.5.

    (c) *"Rook pivoting"* searches the unreduced portion of the matrix for a pivot by tracing a path alternately along columns and rows ("rook"-like) following largest magnitude entries until an entry having largest magnitude in both its row and column is discovered. This approach is more aggressive than partial pivoting, yet typically has overhead that is a small multiple of that for partial pivoting. For some matrices overhead can be comparable to complete pivoting.
16. An efficient and reliable implementation of the GEPP/PLU factorization is offered in the LAPACK software library as `xGETRF`; solving associated linear systems may be done with `xGESV` (see Section 93.2).

17. If $\hat{P} \in \mathbb{R}^{m\times m}$, $\hat{L} \in \mathbb{R}^{m\times m}$, and $\hat{U} \in \mathbb{R}^{m\times n}$ are the computed permutation matrix and LU factors from either Algorithm 3 or 4 on $A \in \mathbb{R}^{m\times n}$, then
$$\hat{L}\hat{U} = \hat{P}(A + \delta A) \quad \text{with} \quad |\delta A| \leq \frac{2\,n\,\epsilon}{1 - n\,\epsilon}\,|\hat{L}|\,|\hat{U}|$$
and for the particular case that $m = n$ and A is nonsingular, if an approximate solution, $\hat{\mathbf{x}}$, to $A\mathbf{x} = \mathbf{b}$ is computed by solving the two triangular linear systems, $\hat{L}\mathbf{y} = \hat{P}\mathbf{b}$ and $\hat{U}\hat{\mathbf{x}} = \mathbf{y}$, then $\hat{\mathbf{x}}$ is the exact solution to a perturbed linear system:
$$(A + \delta A)\hat{\mathbf{x}} = \mathbf{b} \quad \text{with} \quad |\delta A| \leq \frac{2\,n\,\epsilon}{1 - n\,\epsilon}\,\hat{P}^T\,|\hat{L}|\,|\hat{U}|.$$
Furthermore, $|L_{i,j}| \leq 1$ and $|U_{i,j}| \leq 2^{i-1}\max_{k\leq i}|A_{k,j}|$, so
$$\|\delta A\|_\infty \leq \frac{2^n\,n^2\,\epsilon}{1 - n\,\epsilon}\,\|A\|_\infty.$$

Examples:

1. Using Algorithm 3, find a permuted LU factorization of
$$A = \begin{bmatrix} 1 & 1 & 2 & 2 \\ 2 & 2 & 4 & 6 \\ -1 & -1 & -1 & 1 \\ 1 & 1 & 3 & 1 \end{bmatrix}.$$

Setup:	$\mathbf{p} = [1\ 2\ 3\ 4]$, $\quad r \leftarrow 1$
$k = 1$ *step*:	$\mu \leftarrow 2$, $\quad \mathbf{p} = [2\ 1\ 3\ 4]$ Permuted A: $\begin{bmatrix} 2 & 2 & 4 & 6 \\ 1 & 1 & 2 & 3 \\ -1 & -1 & -2 & 1 \\ 1 & 1 & 3 & 1 \end{bmatrix}$
LU snapshot:	$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ \frac{1}{2} & 1 & 0 & 0 \\ -\frac{1}{2} & 0 & 1 & 0 \\ \frac{1}{2} & 0 & 0 & 1 \end{bmatrix}$ and $U = \begin{bmatrix} 2 & 2 & 4 & 6 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$. Updated $A_{2:4,2:4}$: $\begin{bmatrix} 0 & 0 & -1 \\ 0 & 1 & 4 \\ 0 & 1 & -2 \end{bmatrix}$ $r \leftarrow 2$
$k = 2$ *step*:	$\mu \leftarrow 2$, $|A_{2,2}| = \max_{2\leq i\leq 4}|A_{i,2}| = 0$ (skip reduction step)
$k = 3$ *step*:	$\mu \leftarrow 3$, $\mathbf{p} = [2\ 3\ 1\ 4]$, $|A_{3,3}| = \max_{2\leq i\leq 4}|A_{i,3}| = 1$ Permuted $A_{2:4,3:4}$: $\begin{bmatrix} 1 & 4 \\ 0 & -1 \\ 1 & -2 \end{bmatrix}$
LU snapshot:	$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -\frac{1}{2} & 1 & 0 & 0 \\ \frac{1}{2} & 0 & 1 & 0 \\ \frac{1}{2} & 1 & 0 & 1 \end{bmatrix}$ and $U = \begin{bmatrix} 2 & 2 & 4 & 6 \\ 0 & 0 & 1 & 4 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$. Updated $A_{3:4,4}$: $\begin{bmatrix} -1 \\ -6 \end{bmatrix}$ $r \leftarrow 3$

---

k = 4 *step*: $\mu \leftarrow 4$, $\mathbf{p} = [2\ 3\ 4\ 1]$, $|A_{4,4}| = \max_{3 \le i \le 4} |A_{i,4}| = 6$

Permuted $A_{2:4,3:4}$: $\begin{bmatrix} -6 \\ -1 \end{bmatrix}$

LU snapshot:

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -\frac{1}{2} & 1 & 0 & 0 \\ \frac{1}{2} & 1 & 1 & 0 \\ \frac{1}{2} & 0 & \frac{1}{6} & 1 \end{bmatrix} \quad \text{and} \quad U = \begin{bmatrix} 2 & 2 & 4 & 6 \\ 0 & 0 & 1 & 4 \\ 0 & 0 & 0 & -6 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

$r \leftarrow 4$

The permutation matrix associated with $\mathbf{p} = [2\ 3\ 4\ 1]$ is

$$P = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix} \text{ and } PA = \begin{bmatrix} 2 & 2 & 4 & 6 \\ -1 & -1 & -1 & 1 \\ 1 & 1 & 3 & 1 \\ 1 & 1 & 2 & 2 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ -\frac{1}{2} & 1 & 0 & 0 \\ \frac{1}{2} & 1 & 1 & 0 \\ \frac{1}{2} & 0 & \frac{1}{6} & 1 \end{bmatrix} \begin{bmatrix} 2 & 2 & 4 & 6 \\ 0 & 0 & 1 & 4 \\ 0 & 0 & 0 & -6 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

$$= L \cdot U.$$

2. Using Algorithm 4, solve the system of linear equations

$$\begin{bmatrix} 1 & 3 & 1 \\ 2 & 2 & -1 \\ 2 & -1 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} 1 \\ -3 \\ 3 \end{bmatrix}.$$

Phase 1: Find permuted LU decomposition.

$r \leftarrow 1$

---

j = 1 *step*: $\mathbf{v} \leftarrow \begin{bmatrix} 1 \\ 2 \\ 2 \end{bmatrix}$. $\pi_1 \leftarrow \mu = 2$. Permuted $\mathbf{v}$: $\begin{bmatrix} 2 \\ 1 \\ 2 \end{bmatrix}$

LU snapshot: $\boldsymbol{\pi} = [2]$ $L = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{2} & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix}$ and $U = \begin{bmatrix} 2 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$.

$r \leftarrow 2$

---

j = 2 *step*: $\mathbf{v} \leftarrow \begin{bmatrix} 3 \\ 2 \\ -1 \end{bmatrix}$. Permuted $\mathbf{v}$: $\begin{bmatrix} 2 \\ 3 \\ -1 \end{bmatrix}$.

Solve $1 \cdot \mathbf{z} = 2$. $U_{1,2} \leftarrow \mathbf{z} = [2]$.

$$\begin{bmatrix} \mathbf{v}_2 \\ \mathbf{v}_3 \end{bmatrix} \leftarrow \begin{bmatrix} 2 \\ -3 \end{bmatrix} = \begin{bmatrix} 3 \\ -1 \end{bmatrix} - \begin{bmatrix} \frac{1}{2} \\ 1 \end{bmatrix} [2]$$

$\pi_2 \leftarrow \mu = 3$. $L_{3,2} \leftarrow -\frac{2}{3}$ and $U_{2,2} \leftarrow -3$

LU snapshot: $\boldsymbol{\pi} = [2,\ 3]$ $L = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ \frac{1}{2} & -\frac{2}{3} & 1 \end{bmatrix}$ and $U = \begin{bmatrix} 2 & 2 & 0 \\ 0 & -3 & 0 \\ 0 & 0 & 0 \end{bmatrix}$.

$r \leftarrow 3$

$j = 3$ step: $\mathbf{v} \leftarrow \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix}$ Permuted $\mathbf{v}$: $\begin{bmatrix} -1 \\ 0 \\ 1 \end{bmatrix}$. Solve $\begin{bmatrix} 1 & 0 \\ 1 & 1 \end{bmatrix} \cdot \mathbf{z} = \begin{bmatrix} -1 \\ 0 \end{bmatrix}$,

$\begin{bmatrix} U_{1,3} \\ U_{2,3} \end{bmatrix} \leftarrow \mathbf{z} = \begin{bmatrix} -1 \\ 1 \end{bmatrix}$. $v_3 \leftarrow 2\frac{1}{6} = 1 - [\frac{1}{2},\ -\frac{2}{3}] \cdot \begin{bmatrix} -1 \\ 1 \end{bmatrix}$

$\pi_3 \to 3$ and $U_{3,3} \leftarrow 2\frac{1}{6}$

LU snapshot: $\boldsymbol{\pi} = [2,\ 3,\ 3]$ $L = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ \frac{1}{2} & -\frac{2}{3} & 1 \end{bmatrix}$ and $U = \begin{bmatrix} 2 & 2 & -1 \\ 0 & -3 & 1 \\ 0 & 0 & 2\frac{1}{6} \end{bmatrix}$.

The permutation matrix associated with $\boldsymbol{\pi}$ is

$$P = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix} \text{ and } PA = \begin{bmatrix} 2 & 2 & -1 \\ 2 & -1 & 0 \\ 1 & 3 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ \frac{1}{2} & -\frac{2}{3} & 1 \end{bmatrix} \begin{bmatrix} 2 & 2 & -1 \\ 0 & -3 & 1 \\ 0 & 0 & 2\frac{1}{6} \end{bmatrix} = L \cdot U.$$

Phase 2: Solve the lower triangular system $L\mathbf{y} = P\mathbf{b}$.

$$\begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ \frac{1}{2} & -\frac{2}{3} & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \begin{bmatrix} -3 \\ 3 \\ 1 \end{bmatrix} \quad \Rightarrow \quad y_1 = -3,\ y_2 = 6,\ y_3 = 6\frac{1}{2}.$$

Phase 3: Solve the upper triangular system $U\mathbf{x} = \mathbf{y}$.

$$\begin{bmatrix} 2 & 2 & -1 \\ 0 & -3 & 1 \\ 0 & 0 & 2\frac{1}{6} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} = \begin{bmatrix} -3 \\ 6 \\ 6\frac{1}{2} \end{bmatrix} \quad \Rightarrow \quad x_1 = 1,\ x_2 = -1,\ x_3 = 3.$$

51.4 Symmetric Factorizations

Real symmetric matrices ($A = A^T$) and their complex analogs, Hermitian matrices (Chapter 9), are specified by roughly half the number of parameters than general $n \times n$ matrices, so one could anticipate benefits that take advantage of this structure.

Definitions:

An $n \times n$ matrix, A, is **Hermitian** if $A = A^* = \bar{A}^T$.

$A \in \mathbb{C}^{n \times n}$ is **positive-definite** if $\mathbf{x}^* A\mathbf{x} > 0$ for all $\mathbf{x} \in \mathbb{C}^n$ with $\mathbf{x} \neq 0$.

The **Cholesky decomposition** (or **Cholesky factorization**) of a positive-definite matrix A is $A = GG^*$ with $G \in \mathbb{C}^{n \times n}$ lower triangular and having positive diagonal entries.

Facts: [Hig02], [GV96]

1. A positive-definite matrix is Hermitian. Note that the similar but weaker assertion for a matrix $A \in \mathbb{R}^{n \times n}$ that "$\mathbf{x}^T A\mathbf{x} > 0$ for all $\mathbf{x} \in \mathbb{R}^n$ with $\mathbf{x} \neq 0$" does not imply that $A = A^T$.

2. If $A \in \mathbb{C}^{n\times n}$ is positive-definite, then A has an LU decomposition, $A = LU$, and the diagonal of U, $\{u_{11}, u_{22}, \ldots, u_{nn}\}$, has strictly positive entries.
3. If $A \in \mathbb{C}^{n\times n}$ is positive-definite, then the LU decomposition of A satisfies $A = LU$ with $U = D\,L^*$ and $D = \mathrm{diag}(U)$. Thus, A can be written as $A = LDL^*$ with L unit lower triangular and D diagonal with positive diagonal entries. Furthermore, A has a Cholesky decomposition $A = G\,G^*$ with $G \in \mathbb{C}^{n\times n}$ lower triangular. Indeed, if
$$\widehat{D} = diag(\{\sqrt{u_{11}}, \sqrt{u_{22}}, \ldots, \sqrt{u_{nn}}\})$$
then $\widehat{D}\widehat{D} = D$ and $G = L\,\widehat{D}$.
4. [GV96, p. 144] The Cholesky decomposition of a positive-definite matrix A can be computed directly:

```
Algorithm 5: Cholesky decomposition of a positive-definite matrix
  Input: $A \in \mathbb{C}^{n\times n}$ positive definite
  Output: $G \in \mathbb{C}^{n\times n}$ (lower triangular matrix so that $A = G\,G^*$)
    $G \leftarrow 0 \in \mathbb{C}^{n\times n}$;
    for $j = 1$ to $n$
        $\mathbf{v} \leftarrow A_{j:n,j}$
        for $k = 1$ to $j-1$,
            $\mathbf{v} \leftarrow \mathbf{v} - \overline{G_{j,k}} G_{j:n,k}$
        $G_{j:n,j} \leftarrow \frac{1}{\sqrt{v_1}}\mathbf{v}$    ($v_1$ is $\mathbf{v}(1)$)
```

5. Algorithm 5 requires approximately $n^3/3$ floating point arithmetic operations and n floating point square roots to complete (roughly half of what is required for an LU decomposition).
6. If $A \in \mathbb{R}^{n\times n}$ is symmetric and positive-definite and Algorithm 5 runs to completion producing a computed Cholesky factor $\hat{G} \in \mathbb{R}^{n\times n}$, then
$$\hat{G}\hat{G}^T = A + \delta A \quad \text{with} \quad |\delta A| \le \frac{(n+1)\,\epsilon}{1-(n+1)\,\epsilon}\,|\hat{G}|\,|\hat{G}^T|.$$
Furthermore, if an approximate solution, $\hat{\mathbf{x}}$, to $A\mathbf{x} = \mathbf{b}$ is computed by solving the two triangular linear systems $\hat{G}\mathbf{y} = \mathbf{b}$ and $\hat{G}^T\hat{\mathbf{x}} = \mathbf{y}$, and a scaling matrix is defined as $\Delta = \mathrm{diag}(\sqrt{a_{ii}})$, then the scaled error $\Delta(\mathbf{x} - \hat{\mathbf{x}})$ satisfies
$$\frac{\|\Delta(\mathbf{x} - \hat{\mathbf{x}})\|_2}{\|\Delta\mathbf{x}\|_2} \le \frac{\kappa_2(H)\,\epsilon}{1-\kappa_2(H)\,\epsilon},$$
where $A = \Delta\,H\,\Delta$. If $\kappa_2(H) \ll \kappa_2(A)$, then it is quite likely that the entries of $\Delta\hat{\mathbf{x}}$ will have mostly the same magnitude and so the error bound suggests that all entries of the solution will be computed to high relative accuracy.
7. If $A \in \mathbb{C}^{n\times n}$ is Hermitian and has all leading principal submatrices nonsingular, then A has an LU decomposition that can be written as $A = LU = L\,D\,L^*$ with L unit lower triangular and D diagonal with real diagonal entries. Furthermore, the number of positive and negative entries of D is equal to the number of positive and negative eigenvalues of A, respectively (the *Sylvester law of inertia*).
8. It may not be prudent to compute the LU (or LDL^T) decomposition of a Hermitian indefinite matrix A without pivoting, yet the usual pivoting strategies will likely eliminate advantages that symmetry might offer. Alternatives use *symmetric pivoting*

to produce a factorization of the permuted matrix: $PAP^T = LDL^T$ where L is unit lower triangular as before, but D is block diagonal with 1×1 or 2×2 diagonal blocks. The block structure is due to the possibility of using 2×2 principal submatrices as "pivots" during the reduction process. (see [GV96, Hig02, Ste98] for details).

(a) *"Bunch-Parlett pivoting"* uses either the largest magnitude diagonal entry in the unreduced submatrix provided it is not much smaller in magnitude than the entry that would have been chosen with complete pivoting, or failing that, permutes into pivot position a 2×2 principal submatrix that captures the complete pivoting choice. The number of comparisons necessary for this strategy is the same as what is necessary for complete pivoting, so the added overhead is nonnegligible and, as is the case with complete pivoting, this approach is generally viewed as unnecessarily conservative.

(b) *"Bunch-Kaufman pivoting"* uses a similar strategy but akin to partial pivoting, using either a 2×2 principal submatrix that captures the partial pivoting choice or one of the two diagonal entries of this submatrix, the choice being governed by their relative magnitudes. The number of comparisons necessary for this strategy is similar to what is necessary for partial pivoting, so the added overhead is generally insignificant. Although the magnitude of the Gauss multipliers (entries of L) cannot be bounded uniformly with respect to A, the solution of linear systems with this approach is nonetheless backward stable (see [Hig02] for a discussion).

(c) *"Symmetric Rook pivoting"* is a refinement of the Bunch-Kaufman approach using a symmetrized form of rook pivoting. It is more aggressive than Bunch-Kaufman pivoting; generally has similar overhead; may on occasion require overhead comparable to complete pivoting; but, significantly for certain applications, will produce an L factor that may be bounded uniformly with respect to A.

9. An efficient and reliable implementation of Cholesky factorization (Algorithm 5) is in the LAPACK software library as `xPOTRF`; for symmetric indefinite matrices, the LDL^T factorization with Bunch-Kaufman pivoting is available as `xSYTRF`. Solving associated linear systems may be done with `xPOSV` and `xSYSV`, respectively (see Section 93.2).

Examples:

1. Calculate the Cholesky decomposition of the 3×3 Hilbert matrix,

$$A = \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{3} \\ \frac{1}{2} & \frac{1}{3} & \frac{1}{4} \\ \frac{1}{3} & \frac{1}{4} & \frac{1}{5} \end{bmatrix}.$$

Setup:	$G \leftarrow \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$
$j = 1$ *step*:	$\mathbf{v} \leftarrow [1,\ \frac{1}{2},\ \frac{1}{3}]^T$
G snapshot:	$G = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{2} & 0 & 0 \\ \frac{1}{3} & 0 & 0 \end{bmatrix}$

---

j = 2 *step*:
$$\mathbf{v} \leftarrow \begin{bmatrix} \frac{1}{3} \\ \frac{1}{4} \end{bmatrix} - \frac{1}{2} \begin{bmatrix} \frac{1}{2} \\ \frac{1}{3} \end{bmatrix} = \begin{bmatrix} \frac{1}{12} \\ \frac{1}{12} \end{bmatrix}$$

G snapshot:
$$G = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{2} & \frac{1}{2\sqrt{3}} & 0 \\ \frac{1}{3} & \frac{1}{2\sqrt{3}} & 0 \end{bmatrix}$$

---

j = 3 *step*:
$$\mathbf{v} \leftarrow \frac{1}{5} - \left(\frac{1}{3}\right)^2 - \left(\frac{1}{2\sqrt{3}}\right)^2 = \frac{1}{180} = \left(\frac{1}{6\sqrt{5}}\right)^2$$

G snapshot:
$$G = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{2} & \frac{1}{2\sqrt{3}} & 0 \\ \frac{1}{3} & \frac{1}{2\sqrt{3}} & \frac{1}{6\sqrt{5}} \end{bmatrix}$$

51.5 Orthogonalization and the QR Factorization

The process of transforming an arbitrary linear system into a triangular system may also be approached by systematically introducing zeros into the coefficient matrix with unitary transformations: Given a system $A\mathbf{x} = \mathbf{b}$, (1) find unitary matrices V_1, V_2, $\cdots$ V_ℓ such that $V_\ell \ldots V_2 V_1 A = T$ is triangular; (2) calculate $\mathbf{y} = V_\ell \cdots V_2 V_1 \mathbf{b}$; and (3) solve the triangular system $T\mathbf{x} = \mathbf{y}$. Or equivalently,

1. Factor $A = QR$, where Q is unitary ($Q^{-1} = Q^*$) and R is upper triangular.
2. Calculate $\mathbf{y} = Q^*\mathbf{b}$.
3. Solve the triangular system, $R\mathbf{x} = \mathbf{y}$.

The classical approach of Gram-Schmidt orthogonalization leads spontaneously to the QR factorization of a matrix. This topic is discussed in Section 5.5. Two other types of rudimentary unitary transformations to affect the QR factorization will be described here: Householder transformations and Givens transformations.

Definitions:

A ***QR* factorization** of a matrix $A \in \mathbb{C}^{m\times n}$ is a factorization of $A = QR$ where $Q \in \mathbb{C}^{m\times m}$ is unitary ($Q^{-1} = Q^*$) and $R \in \mathbb{C}^{m\times n}$ is upper triangular ($R = [r_{ij}]$ with $r_{ij} = 0$ when $i > j$). See also Section 5.5.

Let $\mathbf{v} \in \mathbb{C}^n$ be a unit vector: $\|\mathbf{v}\|_2 = 1$. The matrix $H = I - 2\mathbf{v}\mathbf{v}^*$ is called a **Householder transformation** (or **Householder reflector**). In this context, $\mathbf{v}$ is a **Householder vector**.

For θ, $\vartheta \in [0, 2\pi)$, let G_{ij} be an $n \times n$ identity matrix modified so that the (i,i) and (j,j) entries are each replaced by $c = \cos(\theta)$, the (i,j) entry is replaced by $s = e^{\imath\vartheta}\sin(\theta)$, and the (j,i) entry is replaced by $-\bar{s} = -e^{-\imath\vartheta}\sin(\theta)$:

$$G_{ij} = \begin{bmatrix} 1 & \cdots & 0 & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & & \vdots & & \vdots \\ 0 & \cdots & c & \cdots & s & \cdots & 0 \\ \vdots & & \vdots & \ddots & \vdots & & \vdots \\ 0 & \cdots & -\bar{s} & \cdots & c & \cdots & 0 \\ \vdots & & \vdots & & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & 0 & \cdots & 1 \end{bmatrix}.$$

G_{ij} is called a **Givens transformation** (or **Givens rotation**).

Facts: [GV96, Hig02, Ste98]

1. The QR factorization plays in important role in the solution of least squares problems: Given $A \in \mathbb{C}^{m\times n}$ and $\mathbf{b} \in \mathbb{C}^m$, find $\hat{\mathbf{x}}$ that solves $\min_{\mathbf{x}\in\mathbb{C}^n} \|A\mathbf{x}-\mathbf{b}\|_2$. (See Chapter 52.)
2. A closely related problem is the solution of *underdetermined linear systems*: Given $A \in \mathbb{R}^{m\times n}$ with $m < n$ and $\mathbf{b} \in \mathbb{R}^m$, find $\hat{\mathbf{x}}$ that solves $A\mathbf{x} = \mathbf{b}$. The solution to this problem (if it exists) will not be unique but may be characterized as follows: Calculate a QR decomposition of A^T as $A^T = QR = Q\begin{bmatrix}\widehat{R}\\ \mathbf{0}\end{bmatrix}$. Then the solution set to $A\mathbf{x} = \mathbf{b}$ may be parameterized as $\hat{\mathbf{x}}(\mathbf{z}) = Q\begin{bmatrix}\widehat{R}^{-T}\mathbf{b}\\ \mathbf{z}\end{bmatrix}$ for arbitrary $\mathbf{z} \in \mathbb{R}^{n-m}$. The solution to $A\mathbf{x} = \mathbf{b}$ that has minimum norm is given by $\hat{\mathbf{x}}(\mathbf{0})$ (i.e., with $\mathbf{z} = \mathbf{0}$).
3. If $A \in \mathbb{R}^{m\times n}$ with $m \geq n$ and $A = QR = Q\begin{bmatrix}\widehat{R}\\ \mathbf{0}\end{bmatrix}$ is the QR factorization of A, then $\widehat{R}^T$ is the Cholesky factor of the positive-semidefinite matrix, A^TA: $A^TA = \widehat{R}^T\widehat{R}$ (see Section 51.4).
4. The rank of A is the same as the rank of R. If A is full rank, the diagonal entries of R provide a bound on how near A is to rank deficiency:
$$\min\{\|E\| \mid \operatorname{rank}(A+E) < \operatorname{rank} A\} \leq \min_i |r_{ii}|.$$
This bound may be very pessimistic. There are refinements of QR factorization that incorporate pivoting among other strategies to obtain a *rank-revealing factorization.* See Sections 52.9 and 59.3.
5. Householder transformations are unitary matrices. The action of H on a vector $\mathbf{a}$ has a geometric interpretation as a reflection of $\mathbf{a}$ across the hyperplane with a normal $\mathbf{v}$.
6. Let $\mathbf{a} \in \mathbb{C}^n$ be a nonzero vector. Define $\mathbf{w} = \operatorname{sign}(a_1)\|\mathbf{a}\|\mathbf{e}_1 + \mathbf{a}$ with $\mathbf{e}_1 = [1, 0, \ldots, 0]^T \in \mathbb{C}^n$ and $\mathbf{v} = \mathbf{w}/\|\mathbf{w}\|_2$ Then the Householder transformation $H = I - 2\mathbf{v}\mathbf{v}^*$ satisfies
$$H\mathbf{a} = \alpha\mathbf{e}_1 \quad \text{with} \quad \alpha = -\operatorname{sign}(a_1)\|\mathbf{a}\|,$$
i.e., H is a unitary matrix that introduces $n-1$ zeros into the vector $\mathbf{a}$.
7. [GV96, pp. 210–213]

Algorithm 6: Householder QR factorization of a rectangular matrix

```
Input: $A \in \mathbb{C}^{m\times n}$ with $m \geq n$
Output: the QR factorization $A = QR$; $R$ overwrites $A$.
for $k = 1$ to $n$
    $\mathbf{x} \leftarrow A_{k:m,k}$
    $\mathbf{v}_k \leftarrow \operatorname{sign}(x_1)\|\mathbf{x}\|\mathbf{e}_1 + \mathbf{x}$, where $\mathbf{e}_1 \in \mathbb{C}^{m-k+1}$
    $\mathbf{v}_k \leftarrow \mathbf{v}_k/\|\mathbf{v}_k\|$
    $A_{k:m,k:n} \leftarrow (I_{m-k+1} - 2\mathbf{v}_k\mathbf{v}_k^*)A_{k:m,k:n}$
$Q \leftarrow I_m$
for $k = n$ to $1$ by $-1$
    $Q_{k:m,k:m} \leftarrow Q_{k:m,k:m}(I_{m-k+1} - 2\mathbf{v}_k\mathbf{v}_k^*)$
```

8. In Algorithm 6, the Householder reflectors are accumulated to form Q in order of size, reversing the order in which they were generated. This is more efficient than accumulating the reflectors in the order that they are generated. In many applications,

it suffices to have Q represented *implicitly* as the product of Householder reflectors and it may not be necessary to compute Q explicitly. Data necessary to recreate the action of Q may be stored in subdiagonal entries of A as zeros are created there.

9. If $A \in \mathbb{R}^{m\times n}$ with $m \geq n$, then the cost of Algorithm 6 without explicitly computing Q is $2n^2(m - n/3)$ flops.
10. If $\widehat{R} \in \mathbb{C}^{m\times n}$ is the *computed* upper triangular matrix provided by Algorithm 6, then there is a unitary matrix, $\widetilde{Q} \in \mathbb{C}^{m\times m}$ such that $\widetilde{Q}\widehat{R}$ is the exact QR factorization of a perturbation of A: $A + \delta A = \widetilde{Q}\widehat{R}$ where δA has columns $\delta A = [\delta\mathbf{a}_1\, \delta\mathbf{a}_2\, \ldots,\, \delta\mathbf{a}_n] \in \mathbb{C}^{m\times n}$ and $\|\delta\mathbf{a}_k\|_2 \leq \dfrac{c\,m\,n\,\epsilon}{1 - c\,m\,n\,\epsilon}\|\mathbf{a}_k\|_2$ for a $c > 0$ having modest magnitude. If $\widehat{Q}$ is the *computed* Q provided by Algorithm 6, then $\|\widehat{Q} - \widetilde{Q}\|_F \leq \dfrac{c\,m\,n\sqrt{n}\,\epsilon}{1 - c\,m\,n\,\epsilon}$.
11. An efficient and reliable implementation of the QR factorization using Householder reflectors (as in Algorithm 6) appears in the LAPACK software library as `xGEQRF` (see Section 93.2).
12. A Givens rotation is a unitary matrix. The action of G_{ij} on a vector $\mathbf{a}$ has a geometric interpretation as a (complex) rotation of $\mathbf{a}$ within the (i, j) coordinate plane.
13. For any scalars $x, y \in \mathbb{C}$, there exists a Givens rotation $G \in \mathbb{C}^{2\times 2}$ such that

$$G\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} c & s \\ -\bar{s} & c \end{bmatrix}\begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} r \\ 0 \end{bmatrix},$$

where c, s, and r can be computed via

(a) If $y = 0$ (includes the case $x = y = 0$), then $c = 1,\ s = 0,\ r = x$.

(b) If $x = 0$ (y must be nonzero), then $c = 0,\ s = \operatorname{sign}(\bar{y}),\ r = |y|$.

(c) If both x and y are nonzero, then $c = |x|/\sqrt{|x|^2 + |y|^2}$, $s = \operatorname{sign}(x)\bar{y}/\sqrt{|x|^2 + |y|^2}$, $r = \operatorname{sign}(x)\sqrt{|x|^2 + |y|^2}$.

14. [GV96, pp. 226–227]

Algorithm 7: Givens QR factorization of a rectangular matrix

```
  Input: $A \in \mathbb{C}^{m\times n}$ with $m \geq n$
  Output: the QR factorization $A = QR$; the upper triangular part of $R$
    is stored in the upper triangular part of $A$
$Q \leftarrow I_m$
for $k = 1$ to $n$
    for $i = k + 1$ to $m$
        Compute $G = \begin{bmatrix} c & s \\ -\bar{s} & c \end{bmatrix}$ such that $G\begin{bmatrix} A_{kk} \\ A_{ik} \end{bmatrix} = \begin{bmatrix} r \\ 0 \end{bmatrix}$ (via Fact 13).
        $\begin{bmatrix} A_{k,k:n} \\ A_{i,k:n} \end{bmatrix} \leftarrow G\begin{bmatrix} A_{k,k:n} \\ A_{i,k:n} \end{bmatrix}$
        $[Q_{1:m,k}, Q_{1:m,i}] \leftarrow [Q_{1:m,k}, Q_{1:m,i}]G^*$
```

15. As noted above, in many applications it suffices to have Q represented *implicitly* removing the need to accumulate Givens rotations to form Q explicitly. Data needed to recreate Q may be stored in subdiagonal locations in A, as zeros are introduced.
16. If $A \in \mathbb{R}^{m\times n}$ with $m \geq n$, then the cost of Algorithm 7 without explicitly computing Q is $3n^2(m - n/3)$ flops.

17. If $\widehat{R} \in \mathbb{C}^{m\times n}$ is the *computed* upper triangular matrix provided by Algorithm 7, then there is a unitary matrix, $\widetilde{Q} \in \mathbb{C}^{m\times m}$ such that $\widetilde{Q}\widehat{R}$ is the exact QR factorization of a perturbation of A: $A + \delta A = \widetilde{Q}\widehat{R}$ where δA has columns $\delta A = [\delta\mathbf{a}_1\, \delta\mathbf{a}_2\, \ldots,\, \delta\mathbf{a}_n] \in \mathbb{C}^{m\times n}$ and $\|\delta\mathbf{a}_k\|_2 \le \dfrac{c\,(m+n-2)\,\epsilon}{1 - c\,(m+n-2)\,\epsilon}\|\mathbf{a}_k\|_2$ for a $c > 0$ having modest magnitude.

Examples:

1. We shall use Givens rotations to transform $A = \begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{bmatrix}$ to upper triangular form, as in Algorithm 7. First, to annihilate the element in position (2,1), we use Fact 5 with $(x, y) = (1, 1)$ and obtain $c = s = 1/\sqrt{2}$; hence:

$$A^{(1)} = G_1 A = \begin{bmatrix} 0.7071 & 0.7071 & 0 \\ -0.7071 & 0.7071 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{bmatrix} = \begin{bmatrix} 1.4142 & 2.1213 \\ 0 & 0.7071 \\ 1 & 3 \end{bmatrix}.$$

Next, to annihilate the element in position (3,1), we use $(x, y) = (1.4142, 1)$ in Fact 5 and get

$$A^{(2)} = G_2 A^{(1)} = \begin{bmatrix} 0.8165 & 0 & 0.5774 \\ 0 & 1 & 0 \\ -0.5774 & 0 & 0.8165 \end{bmatrix} A^{(1)} = \begin{bmatrix} 1.7321 & 3.4641 \\ 0 & 0.7071 \\ 0 & 1.2247 \end{bmatrix}.$$

Finally, we annihilate the element in position (3,2) using $(x, y) = (.7071, 1.2247)$:

$$A^{(3)} = G_3 A^{(2)} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0.5000 & 0.8660 \\ 0 & -0.8660 & 0.5000 \end{bmatrix} A^{(2)} = \begin{bmatrix} 1.7321 & 3.4641 \\ 0 & 1.4142 \\ 0 & 0 \end{bmatrix}.$$

As a result, $R = A^{(3)}$ and $\widehat{R}$ consists of the first two rows of $A^{(3)}$. The matrix Q can be computed as the product $G_1^T G_2^T G_3^T$.

2. We shall use Householder reflections to transform A from Example 1 to upper triangular form as in Algorithm 6. First, let $\mathbf{a} = A_{:,1} = \begin{bmatrix} 1 & 1 & 1 \end{bmatrix}^T$, $\gamma_1 = -\sqrt{3}$, $\widetilde{\mathbf{a}} = \begin{bmatrix} -\sqrt{3} & 0 & 0 \end{bmatrix}^T$, and $\mathbf{u}_1 = \begin{bmatrix} 0.8881 & 0.3251 & 0.3251 \end{bmatrix}^T$; then

$$A^{(1)} = \left(I - 2\mathbf{u}_1\mathbf{u}_1^T\right) A = A - \mathbf{u}_1 \overbrace{\begin{bmatrix} 3.0764 & 5.0267 \end{bmatrix}}^{2\mathbf{u}_1^T A} = \begin{bmatrix} -1.7321 & -3.4641 \\ 0 & 0.3660 \\ 0 & 1.3660 \end{bmatrix}.$$

Next, $\gamma_2 = -\|A^{(1)}_{2:3,2}\|_2$, $\mathbf{u}_2 = \begin{bmatrix} 0 & 0.7934 & 0.6088 \end{bmatrix}^T$, and

$$A^{(2)} = \left(I - 2\mathbf{u}_2\mathbf{u}_2^T\right) A^{(1)} = A^{(1)} - \mathbf{u}_2 \overbrace{\begin{bmatrix} 0 & 2.2439 \end{bmatrix}}^{2\mathbf{u}_2^T A^{(1)}} = \begin{bmatrix} -1.7321 & -3.4641 \\ 0 & -1.4142 \\ 0 & 0 \end{bmatrix}.$$

Note that $R = A^{(2)}$ has changed signs as compared with Example 1. The matrix Q can be computed as $\left(I - 2\mathbf{u}_1\mathbf{u}_1^T\right)\left(I - 2\mathbf{u}_2\mathbf{u}_2^T\right)$. Therefore, we have full information about the transformation if we store the vectors $\mathbf{u}_1$ and $\mathbf{u}_2$.

52.1 Basic Concepts

(See Chapter 5 for additional information.)

Definitions:

Given a vector $\mathbf{b} \in \mathbb{R}^m$ and a matrix $A \in \mathbb{R}^{m\times n}$ with $m > n$, the **least squares problem** is to find a vector $\mathbf{x}_0 \in \mathbb{R}^n$ that minimizes the Euclidean length of the difference between $A\mathbf{x}$ and $\mathbf{b}$:

$$\textbf{Problem LS:}\ \text{Find } \mathbf{x}_0 \text{ satisfying } \|\mathbf{b} - A\mathbf{x}_0\|_2 = \min \|\mathbf{b} - A\mathbf{x}\|_2.$$

Such an $\mathbf{x}_0$ is called a **least squares solution**.

For any vector $\mathbf{x}$ the vector $\mathbf{r} = \mathbf{r}(\mathbf{x}) = \mathbf{b} - A\mathbf{x}$ is the **residual vector**. The residual of a least squares solution is denoted by $\mathbf{r}_0$. The least squares problem is **consistent** if $\mathbf{b} \in \text{range}(A)$.

A **basic solution**, $\mathbf{x}_{0\text{B}}$, is a least squares solution with at least $n - \text{rank}(A)$ zero components. The **minimum-norm least squares solution**, $\mathbf{x}_{0\text{M}}$, is the least squares solution of minimum Euclidean norm.

In a **weighted least squares problem**, we are also given weights $w_i \geq 0$ for $i = 1, \ldots, m$, and the objective is to minimize $\|W(\mathbf{b} - A\mathbf{x})\|_2$, where $W = \text{diag}(w_1, \ldots, w_m)$. This is an important special case of the **generalized least squares problem**:

$$\begin{array}{ll}\textbf{Problem GLS:} & \text{Let} A\mathbf{x} + B\mathbf{v} = \mathbf{b}, \text{where} B \in \mathbb{R}^{m\times p} \text{ with } p \leq m. \\ & \text{Find } \mathbf{x}_\text{G},\ \mathbf{v}_\text{G} \text{ such that } \|\mathbf{v}\|_2 \text{ is minimized.}\end{array}$$

Note that $B\mathbf{v}$ plays the role of the residual vector.

In the **total least squares problem**, we allow for errors both in the vector $\mathbf{b}$ and in the matrix A:

$$\textbf{Problem TLS:}\ \text{Let } (A+E)\mathbf{x}+\mathbf{r}=\mathbf{b}, \text{where } E\in\mathbb{R}^{m\times n} \text{ with } n\le m.$$
$$\text{Find } \mathbf{x}_{\mathrm{T}} \text{ such that } \|(E,\mathbf{r})\|_F \text{is minimized.}$$

$\|\cdot\|_F$ denotes the Frobenius norm.

In this chapter, $A_{i,:}$ and $A_{:,j}$ denote the vectors given by the elements in the ith row and jth column of matrix A, respectively. Similarly, $A_{k:l,:}$ (or $A_{:,k:l}$) is the submatrix consisting of rows (or columns) k through l of A.

In the examples in this chapter, the computation is done with about 16 digits accuracy, but the displayed results are rounded to fewer digits.

Facts:

(See, e.g., Chapters 1 and 2 in [Bjo96].)

1. If $m > n = \text{rank}(A)$, then the least squares solution $\mathbf{x}_0$ is analytically equivalent to the solution to the *normal equations* $A^TA\,\mathbf{x} = A^T\mathbf{b}$.
2. If the least squares problem is consistent, then $\mathbf{r}_0 = \mathbf{0}$.
3. The least squares solution is unique if $m \ge n$ and A has full rank.
4. If the system is underdetermined ($m < n$) or if A is rank deficient, then the solution to Problem LS is not unique. Also, a basic solution is not unique.
5. The minimum-norm least squares solution $\mathbf{x}_{0\mathrm{M}}$ is always unique.
6. If $m > n = \text{rank}(A)$, then the least squares solution can be written as $\mathbf{x}_0 = A^\dagger b$, where the matrix $A^\dagger$ is the Moore–Penrose generalized inverse or pseudoinverse of A. (See Section 5.7.) In general, $A^\dagger$ produces the minimum-norm solution: $\mathbf{x}_{0\mathrm{M}} = A^\dagger\mathbf{b}$.
7. If B is nonsingular, then $\mathbf{x}_{\mathrm{G}}$ minimizes $\|B^{-1}(\mathbf{b} - A\mathbf{x})\|_2$.
8. If the covariance matrix for $\mathbf{b}$ has the Cholesky factorization $\text{Cov}(\mathbf{b}) = C^TC$, then $\mathbf{x}_{\mathrm{G}}$ is the *best linear unbiased estimate* (BLUE) in the general linear model with $B = C^T$.
9. If $\text{Cov}(\mathbf{b})$ has full rank, then $\mathbf{x}_{\mathrm{G}}$ is the solution to the least squares problem $\min\|C^{-T}(\mathbf{b} - A\mathbf{x})\|_2$.
10. In particular, if $\text{Cov}(\mathbf{b}) = \sigma^2 I$, then $\mathbf{x}_{\mathrm{G}} = \mathbf{x}_0$ and $\text{Cov}(\mathbf{x}_0) = \sigma^2(A^TA)^{-1}$.
11. An English translation of the original work on least squares problems by C. F. Gauss is available in [Gau95].

Examples:

1. Consider problem LS with $m = 3$ and $n = 2$:

$$\min\left\|\begin{bmatrix}1 & 1\\ 1 & 2\\ 1 & 3\end{bmatrix}\begin{bmatrix}x_1\\ x_2\end{bmatrix} - \begin{bmatrix}0.75\\ 1.13\\ 1.39\end{bmatrix}\right\|_2.$$

The associated normal equations and the least squares solution are

$$\begin{bmatrix}3 & 6\\ 6 & 14\end{bmatrix}\begin{bmatrix}x_1\\ x_2\end{bmatrix} = \begin{bmatrix}3.27\\ 7.18\end{bmatrix}, \qquad \mathbf{x}_0 = \begin{bmatrix}0.45\\ 0.32\end{bmatrix}.$$

The residual vector corresponding to $\mathbf{x}_0$ is

$$\mathbf{r}_0 = \mathbf{r}(\mathbf{x}_0) = \mathbf{b} - A\mathbf{x}_0 = \begin{bmatrix}-0.02\\ 0.04\\ -0.02\end{bmatrix},$$

and $A^T\mathbf{r}_0 = \mathbf{0}$.

2. If we use the weights $w_1 = 10$ and $w_2 = w_3 = 1$, the problem is changed to

$$\min \left\| \begin{bmatrix} 10 & 10 \\ 1 & 2 \\ 1 & 3 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - \begin{bmatrix} 7.5 \\ 1.13 \\ 1.39 \end{bmatrix} \right\|_2$$

   whose least squares solution and corresponding residual are

$$\mathbf{x}_0 = \begin{bmatrix} 0.41838 \\ 0.33186 \end{bmatrix}, \qquad \mathbf{r}_0 = \begin{bmatrix} -0.00024 \\ 0.04790 \\ -0.02395 \end{bmatrix}.$$

   Note that the first component of $\mathbf{r}_0$ is reduced when w_1 is increased from 1 to 10.

52.2 Least Squares Data Fitting

Definitions:

Given m data points (t_i, y_i), $i = 1, \ldots, m$, and n linearly independent functions f_j, $j = 1, \ldots, n$ (with $m > n$), find the linear combination

$$F(\mathbf{x}, t) = \sum_{j=1}^{n} x_j f_j(t)$$

that minimizes the sum of squared residuals $y_i - F(\mathbf{x}, t_i)$ at the data points:

$$\min_{\mathbf{x}} \sum_{i=1}^{m} \big(y_i - F(\mathbf{x}, t_i)\big)^2.$$

The coefficients x_i are the components of the least squares solution to $\min \|\mathbf{b} - A\mathbf{x}\|_2$, where the columns $A_{:,j}$ of A are samples of f_j at t_i and the elements of $\mathbf{b}$ are the values y_i:

$$A_{ij} = f_j(t_i), \qquad b_i = y_i, \qquad i = 1, \ldots, m \qquad j = 1, \ldots, n.$$

The solution $F(\mathbf{x}_0, t)$ is said to fit the data in the least squares sense.

Facts:

(See, e.g., Chapter 4 in [Bjo96].)

1. The fit can be made more robust to outliers by solving a weighted least squares problem $\min \|W(\mathbf{b} - A\mathbf{x})\|_2$ with $W = \operatorname{diag}(w_1, \ldots, w_m)$, $w_i = \psi(r_i) = \psi(b_i - A_{i,:}\mathbf{x})$; ψ being a convex function. This problem is usually solved by an iteratively reweighted least squares algorithm.
2. In orthogonal distance fitting, instead of minimizing the residuals one minimizes the orthogonal distances between the fitting function F and the data points. Important examples are fitting of a circle, an arc, or an ellipse to data points.

Examples:

1. Given $f_1(t) = 1$ and $f_2(t) = t$, find the least squares fit to the data points (1, 0.75), (2, 1.13), and (3, 1.39). We get the A, $\mathbf{b}$, and $\mathbf{x}_0$ from Example 52.1.1, and

$$F(\mathbf{x}_0, t) = 0.45 + 0.32t.$$

   If the third data point is changed to (3, 13.9), then the least squares solution changes to $\mathbf{x}_0 = (\,-7.890,\ \ 6.575)^T$, and the least squares fit becomes $F(\mathbf{x}_0, t) = -7.890 + 6.575t$; this illustrates the sensitivity to outliers.

52.3 Geometric and Algebraic Aspects

Definitions:

The columns of $A \in \mathbb{R}^{m\times n}$ span the **range of** A, while the **nullspace** or **kernel** of A is the set of solutions to the homogeneous system $A\mathbf{x} = \mathbf{0}$:

$$\text{range}(A) = \{\mathbf{z} = A\mathbf{x} \mid \mathbf{x} \in \mathbb{R}^n\}, \qquad \ker(A) = \{\mathbf{x} \in \mathbb{R}^n \mid A\mathbf{x} = \mathbf{0}\}.$$

The four **fundamental subspaces** associated with Problem LS are range(A), $\ker(A^T)$, $\ker(A)$, and range(A^T). (See Section 2.4 for more information.)

Facts:

The first three facts can be found in [Str88, Sect. 2.4]; the remaining facts are discussed in [Bjo96, Chap. 1]. p denotes the rank of A: $p = \text{rank}(A)$.

1. If $p = n < m$, then the vector $\mathbf{0}$ of all zeros is the only element in $\ker(A)$.
2. The spaces range(A) and $\ker(A^T)$ are subspaces of $\mathbb{R}^m$ with dimensions p and $m-p$, respectively. The two spaces are orthogonal complements, i.e., $\mathbf{y}^T\mathbf{z} = 0$ for any pair $(\mathbf{y} \in \text{range}(A),\ \mathbf{z} \in \ker(A^T))$, and $\text{range}(A) \oplus \ker(A^T) = \mathbb{R}^m$.
3. The spaces $\ker(A)$ and range(A^T) are subspaces of $\mathbb{R}^n$ with dimensions $n-p$ and p, respectively. The two spaces are orthogonal complements.
4. The least squares residual vector $\mathbf{r}_0 = \mathbf{b} - A\mathbf{x}_0$ is an element in $\ker(A^T)$. Combining this with the definition of $\mathbf{r}$, we get the so-called **augmented system** associated with Problem LS:
$$\begin{bmatrix} I & A \\ A^T & 0 \end{bmatrix} \begin{bmatrix} \mathbf{r} \\ \mathbf{x} \end{bmatrix} = \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix}.$$
If $p = n$, then the augmented system is nonsingular and the solution components are $\mathbf{r}_0$ and $\mathbf{x}_0$.
5. The vector $A\mathbf{x}_0$ is the orthogonal projection of $\mathbf{b}$ onto range(A).
6. The vector $\mathbf{r}_0$ is the orthogonal projection of $\mathbf{b}$ onto $\ker(A^T)$.
7. If $p < n$, then the columns in A can be reordered such that $A\,\Pi = \left[\widetilde{A}\widehat{A}\right]$, where Π is a permutation matrix and the submatrix $\widetilde{A}$ has p columns, range$(A) = \text{range}(\widetilde{A})$. The permutation is not unique.
8. The orthogonal projectors onto range(A) and $\ker(A)$ are given by $AA^\dagger$ and $I - A^\dagger A$, respectively.

Examples:

1. Figure 52.1 illustrates Facts 5 and 6 in the case $m = 3$, $n = p = 2$.
2. For the problem in Example 52.1.1, both range(A) and $\ker(A^T)$ are subspaces of $\mathbb{R}^3$ given

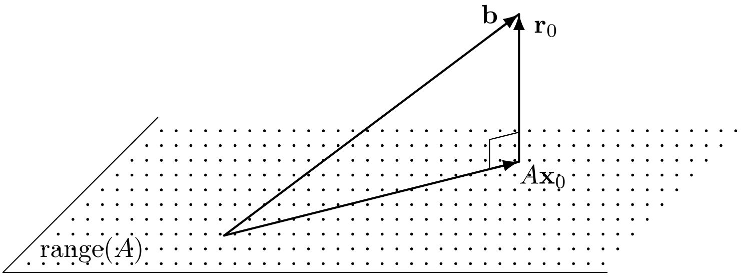

FIGURE 52.1 Illustration of Facts 5 and 6

by, respectively,

$$\text{range}(A) = \alpha \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} + \beta \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}, \qquad \ker(A^T) = \gamma \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix},$$

with $\alpha, \beta, \gamma \in \mathbb{R}$.

3. Fact 4 can be used to derive the normal equations:

$$\mathbf{r} = \mathbf{b} - A\mathbf{x} \in \ker(A^T) \quad \Rightarrow \quad A^T(\mathbf{b} - A\mathbf{x}) = \mathbf{0} \ .$$

52.4 Orthogonal Factorizations

(See Section 5.5 and Section 51.5 for additional information on orthogonal factorizations.)

Definitions:

The real matrix Q is **orthogonal** if it is square and satisfies $Q^T Q = I$.

A **QR factorization** of a matrix $A \in \mathbb{R}^{m \times n}$ with $m \geq n$ has the form

$$A \ = \ Q\,R \ = \ Q \begin{bmatrix} \widehat{R} \\ 0 \end{bmatrix} \ = \ \widehat{Q}\,\widehat{R}\,,$$

where $Q \in \mathbb{R}^{m \times m}$ is orthogonal, $R \in \mathbb{R}^{m \times n}$, $\widehat{R} \in \mathbb{R}^{n \times n}$ is upper triangular, and $\widehat{Q} = Q_{:,1:n}$. The form $A = \widehat{Q}\widehat{R}$ is the so-called "reduced" (or "skinny") QR factorization.

The **singular value decomposition** (SVD) of $A \in \mathbb{R}^{m \times n}$ has the form

$$A = U\,\Sigma\,V^T \ ,$$

where $U \in \mathbb{R}^{m \times m}$ and $V \in \mathbb{R}^{n \times n}$ are orthogonal matrices and $\Sigma = \text{diag}(\sigma_1, \ldots, \sigma_r) \in \mathbb{R}^{m \times n}$ has diagonal elements

$$\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r \geq 0, \quad r = \min\{m, n\} \ .$$

Letting $\mathbf{u}_j$ and $\mathbf{v}_j$ denote the jth column in U and V, respectively, we can write

$$A = \sum_{j=1}^{r} \sigma_j \mathbf{u}_j \mathbf{v}_j^T \ .$$

For $k < r$ the matrix $\sum_{j=1}^{k} \sigma_j \mathbf{u}_j \mathbf{v}_j^T$ is called the **truncated SVD** approximation to A. (See Section 5.6 and Chapters 24 and 58 for more information about the singular value decomposition.)

Facts:

Except for Facts 1 and 8, see [Bjo96, Chap. 1]. Also see Section 52.5.

1. [Str88, Chap. 3]. A QR factorization preserves rank: $\text{rank}(R) = \text{rank}(\widehat{R}) = \text{rank}(A)$.
2. A QR factorization is not unique, but two factorizations $Q_1 R_1$ and $Q_2 R_2$ always satisfy $\widehat{R}_1 = D\,\widehat{R}_2$, where D is diagonal with $D_{ii} = \pm 1$.
3. The triangular factor $\widehat{R}$ and the upper triangular Cholesky factor C for the normal equations matrix $A^T A$ always satisfy $\widehat{R} = \widetilde{D}C$, where $\widetilde{D}$ is diagonal with $\widetilde{D}_{ii} = \pm 1$.
4. If A has full rank and has the QR factorization $A = QR$, then $\mathbf{x}_0$ can be found by back substitution in the upper triangular system $\widehat{R}\,\mathbf{x} = Q_{:,1:n}^T \mathbf{b}$.

5. If Q has not been saved, then we can use forward and back substitution to solve the seminormal equations: $\widehat{R}^T\widehat{R}\mathbf{x} = A^T\mathbf{b}$. For reasons of numerical stability, this must be followed by one step of iterative refinement; the complete process is called the *corrected seminormal equations* method.
6. Let $\operatorname{rank}(A) = p \le n \le m$ and $A = QR$. The columns in $Q_{:,1:p}$ and $Q_{:,p+1:m}$ are orthonormal bases of $\operatorname{range}(A)$ and $\ker(A^T)$, respectively.
7. Let $A = U\Sigma V^T$. Then $p = \operatorname{rank}(A)$ is equal to the number of strictly positive singular values: $\sigma_1 \ge \cdots \ge \sigma_p > 0$, $\sigma_{p+1} = \cdots = \sigma_{\min\{m,n\}} = 0$. The columns in $U_{:,1:p}$ and $U_{:,p+1:m}$ are orthonormal bases of $\operatorname{range}(A)$ and $\ker(A^T)$, respectively, and the columns in $V_{:,1:p}$ and $V_{:,p+1:n}$ are orthonormal bases of $\operatorname{range}(A^T)$ and $\ker(A)$, respectively.
8. [GV96, Chap. 12]. The TLS solution can be computed as follows: compute the SVD of the coefficient matrix A augmented with the right-hand side $\mathbf{b}$, i.e., $[\,A\,,\,\mathbf{b}\,] = \widetilde{U}\,\widetilde{\Sigma}\,\widetilde{V}^T$. If the smallest singular value $\widetilde{\sigma}_{n+1}$ is simple, and if $\beta = \widetilde{V}_{n+1,n+1} \ne 0$, then

$$\mathbf{x}_{\mathrm{T}} = -\beta^{-1}\widetilde{V}_{1:n,n+1}, \quad E_{\mathrm{T}} = -\widetilde{\sigma}_{n+1}\,\widetilde{U}_{:,n+1}\,\widetilde{V}^T_{1:n,n+1}, \quad \mathbf{r}_{\mathrm{T}} = -\widetilde{\sigma}_{n+1}\,\beta\,\widetilde{U}_{:,n+1}\ .$$

Examples:

1. For the problem from Example 52.1.1, we find $[\,A\,,\,\mathbf{b}\,] = \widetilde{U}\,\widetilde{\Sigma}\,\widetilde{V}^T$ with

$$\widetilde{\Sigma} = \operatorname{diag}\begin{bmatrix}4.515\\0.6198\\0.0429\end{bmatrix}, \quad \widetilde{U}_{:,3} = \begin{bmatrix}0.4248\\-0.8107\\0.4029\end{bmatrix}, \quad \widetilde{V}_{:,3} = \begin{bmatrix}0.3950\\0.2796\\-0.8751\end{bmatrix}.$$

Thus,

$$\mathbf{x}_{\mathrm{T}} = \begin{bmatrix}0.4513\\0.3195\end{bmatrix}, \quad E_{\mathrm{T}} = \begin{bmatrix}-0.0072 & -0.0051\\0.0137 & 0.0097\\-0.0068 & -0.0048\end{bmatrix}, \quad \mathbf{r}_{\mathrm{T}} = \begin{bmatrix}-0.015939\\0.030421\\-0.015118\end{bmatrix}.$$

In Example 52.1.1 we found $\mathbf{x}_0 = \begin{bmatrix}0.4500 & 0.3200\end{bmatrix}^T$. The difference between $\mathbf{x}_0$ and $\mathbf{x}_{\mathrm{T}}$ is small because the problem is almost consistent and A is well conditioned; see Section 52.6 The elements in $\mathbf{r}_{\mathrm{T}}$ are about 80% of the elements in $\mathbf{r}_0$ given in Example 52.1.1.

52.5 Least Squares Algorithms

Definitions:

By least squares algorithms we mean algorithms for computing the least squares solution efficiently and stably on a computer. The algorithms should take into account the size of the matrix and, if applicable, also its structure.

Facts:

For real systems the following facts can be found in, e.g., [Bjo96], [Bjo04], and [LH95].

1. The algorithm that is least sensitive to the influence of rounding errors is based on the QR factorization of A:
   (a) Compute the reduced QR factorization $A = \widehat{Q}\widehat{R}$.
   (b) Compute the vector $\boldsymbol{\beta} = \widehat{Q}^T\mathbf{b}$ (can be computed during the QR factorization algorithm without forming $\widehat{Q}$ explicitly).

   (c) Compute $\mathbf{x} = \widehat{R}^{-1}\boldsymbol{\beta}$ via back substitution.

   The use of this algorithm was first suggested in [Gol65].

2. If A is well conditioned, the normal equations can be used instead:
   (a) Compute the normal equation system $M = A^T A$ and $\mathbf{d} = A^T\mathbf{b}$.
   (b) Compute the Cholesky factorization $M = C^T C$ and $\mathbf{y} = C^{-T}\mathbf{d}$ (the vector $\mathbf{y}$ can be computed during the Cholesky algorithm).
   (c) Compute $\mathbf{x} = C^{-1}\mathbf{y}$ via back substitution.
3. If A or $A^T A$ is a Toeplitz matrix, use an algorithm that utilizes this structure to obtain the computational complexity $O(mn)$.
4. If A is large and sparse, use a sparse QR factorization algorithm that avoids storing the matrix Q. If solving a system with the same A but a different right-hand side, use the corrected seminormal equations.
5. Alternatively, if A is large and sparse, it may be preferable to use the augmented system approach because it may lead to less fill-in. Then a symmetric indefinite solver, such as the LDL^T factorization, must be used, cf. [GV96, Sect. 4.4].
6. If A is large and the matrix-vector multiplications with A and A^T can be computed easily, then use the conjugate gradient algorithm on the normal equations. Several implementations are available; CGLS is the classical formulation; LSQR is more accurate for ill-conditioned matrices.

52.6 Sensitivity

Definitions:

For $A \in \mathbb{R}^{m\times n}$ with $p = \text{rank}(A) \leq \min(m,n)$ the **condition number** for the least squares problem is given by $\kappa(A) = \sigma_1/\sigma_p$, where $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p > 0$ are the nonzero singular values of A.

Let $\mathbf{x}_{0\text{M}}$ and $\widetilde{\mathbf{x}}_{0\text{M}}$ denote the minimum-norm least squares solutions to the problems $\min \|\mathbf{b} - A\mathbf{x}\|_2$ and $\min \|\widetilde{\mathbf{b}} - \widetilde{A}\mathbf{x}\|_2$, the latter being a perturbation of the former. Define the quantities

$$\delta_A = \|\widetilde{A} - A\|_2, \qquad \delta_b = \|\widetilde{\mathbf{b}} - \mathbf{b}\|_2, \qquad \eta = \frac{\delta_A}{\sigma_p} = \kappa(A)\,\frac{\delta_A}{\|A\|_2}\ .$$

Facts:

(See, e.g., [Bjo96, Sect. 1.4] or [LH95, Chap. 9].)

1. If $\eta < 1$, then the rank is not changed by the perturbation $\text{rank}(\widetilde{A}) = \text{rank}(A)$.
2. If $\eta < 1$, then the relative perturbation in $\widetilde{\mathbf{x}}_{0\text{M}}$ is bounded as

$$\frac{\|\widetilde{\mathbf{x}}_{0\text{M}} - \mathbf{x}_{0\text{M}}\|_2}{\|\mathbf{x}_{0\text{M}}\|_2} \leq \frac{\kappa(A)}{1-\eta}\left(\frac{\delta_A}{\|A\|_2} + \frac{\delta_b + \eta\|\mathbf{r}_0\|_2}{\|A\|_2\|\mathbf{x}_{0\text{M}}\|_2}\right) + \eta, \qquad \mathbf{r}_0 = \mathbf{b} - A\mathbf{x}_{0\text{M}}\ .$$

   If $\text{rank}(A) = n$, then the last term η is omitted. If the problem is consistent, i.e., $\mathbf{r}_0 = \mathbf{0}$, then the relative error can be expected to grow linearly with κ. For $\mathbf{r}_0 \neq \mathbf{0}$ the contribution $\eta\|\mathbf{r}_0\|_2$ and the definition of η show that the relative error may grow as $\kappa(A)^2$.
3. The condition number for the normal equations matrix is $\kappa(A^T A) = \kappa(A)^2$. Due to the finite computer precision, information may be lost when the normal equations are formed; see, e.g., [Bjo96, Sect. 2.2] and Example 2.

4. *Component-wise perturbation theory* applies when component-wise perturbation bounds are available for the errors in A and $\mathbf{b}$; if

$$|\widetilde{A} - A| \leq \epsilon |A| \qquad \text{and} \qquad |\widetilde{\mathbf{b}} - \mathbf{b}| \leq \epsilon |\mathbf{b}| \ ,$$

where the absolute values and inequalities are interpreted componentwise, then

$$|\widetilde{\mathbf{x}} - \mathbf{x}| = \epsilon \, |A^{\dagger}| \, (|\mathbf{b}| + |A| \, |\mathbf{x}|) + \epsilon \, |(A^T A)^{-1}| \, |E^T| \, |\mathbf{r}|$$

and

$$\|\widetilde{\mathbf{x}} - \mathbf{x}\|_{\infty} \leq \epsilon \left\| |A^{\dagger}| \, (|A| \, |\mathbf{x}| + |\mathbf{b}|) \right\|_{\infty} + \epsilon \left\| |(A^T A)^{-1}| \, |A^T| \, |\mathbf{r}| \right\|_{\infty} .$$

See [Bjo96, Sects. 1.4.5–6] for further references about component-wise perturbation analysis and *a posteriori* error estimation.

Examples:

1. We consider the problem from Example 52.1.1 and two perturbed versions of it,

$$A = \begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix} 0.75 \\ 1.13 \\ 1.39 \end{bmatrix}, \qquad \widetilde{A} = \begin{bmatrix} 0.8 & 1.1 \\ 0.95 & 2 \\ 1.1 & 2.95 \end{bmatrix}, \quad \widetilde{\mathbf{b}} = \begin{bmatrix} 0.79 \\ 1.23 \\ 1.30 \end{bmatrix} .$$

The matrix has full rank, so the least squares solution is unique (and equal to the minimum-norm least squares solution). The vectors

$$\mathbf{x}_0 = \begin{bmatrix} 0.4500 \\ 0.3200 \end{bmatrix}, \qquad \widetilde{\mathbf{x}}_1 = \begin{bmatrix} 0.5967 \\ 0.2550 \end{bmatrix}, \qquad \widetilde{\mathbf{x}}_2 = \begin{bmatrix} 0.8935 \\ 0.1280 \end{bmatrix}$$

are the minimizers of $\|\mathbf{b} - A\mathbf{x}\|_2$, $\|\widetilde{\mathbf{b}} - A\mathbf{x}\|_2$, and $\|\widetilde{\mathbf{b}} - \widetilde{A}\mathbf{x}\|_2$, respectively.

The matrix has condition number $\kappa(A) = 6.793$, and $\eta = \kappa(A) * \|\widetilde{A} - A\|_2 / \|A\|_2 = 0.4230 < 1$. The relative errors and their upper bounds are

$$\frac{\|\widetilde{\mathbf{x}}_1 - \mathbf{x}_0\|_2}{\|\mathbf{x}_0\|_2} = 0.291 \ \leq \ \kappa(A) \, \frac{\|\widetilde{\mathbf{b}} - \mathbf{b}\|_2}{\|A\|_2 \|\mathbf{x}_0\|_2} = 0.423$$

$$\frac{\|\widetilde{\mathbf{x}}_2 - \mathbf{x}_0\|_2}{\|\mathbf{x}_0\|_2} = 0.875 \ \leq \ \frac{1}{1 - \eta} \left(\eta + \kappa(A) \, \frac{\|\widetilde{\mathbf{b}} - \mathbf{b}\|_2 + \eta \|\mathbf{b} - A\mathbf{x}_0\|_2}{\|A\|_2 \|\mathbf{x}_0\|_2} \right) = 1.575 \ .$$

2. Consider the following matrix A and the corresponding normal equation matrix:

$$A = \begin{bmatrix} 1 & 1 \\ \delta & 0 \\ 0 & \delta \end{bmatrix}, \qquad A^T A = \begin{bmatrix} 1{+}\delta^2 & 1 \\ 1 & 1{+}\delta^2 \end{bmatrix}.$$

If $|\delta| \leq \sqrt{\epsilon}$ (where ϵ is the machine precision), then the quantity $1 + \delta^2$ is represented by 1 on the computer and, therefore, the computed $A^T A$ is singular. If we use Householder transformations to compute the QR factorization, we get $R = \begin{bmatrix} -1 & -1 \\ 0 & \delta\sqrt{2} \end{bmatrix}$, so information about δ is preserved.

52.7 Up- and Downdating of QR Factorization

Definitions:

Given $A \in \mathbb{R}^{m\times n}$ with $m > n$ and its QR factorization, as well as a row vector $\mathbf{a}^T$ with $\mathbf{a} \in \mathbb{R}^n$, **updating** of the factorization means computing the QR factorization of the augmented matrix $\begin{bmatrix} A \\ \mathbf{a}^T \end{bmatrix} = \widetilde{A} = \widetilde{Q}\widetilde{R}$ from the QR factors of A. Similarly, **downdating** means computing the QR factors of A from those of $\widetilde{A}$. Up- and downdating algorithms require only $O(mn)$ flops (compared to the $O(mn^2)$ flops of recomputing the QR factors).

Facts:

The following facts can be found in Chapter 3 of [Bjo96].

1. The matrix R can be updated to $\widetilde{R}$ without knowledge of Q by means of a sequence of n Givens transformations $G_1, \ldots, G_n$.
2. The updating of Q to $\widetilde{Q}$ then takes the form
$$\widetilde{Q} = \begin{bmatrix} Q & 0 \\ 0 & 1 \end{bmatrix} G_1^T \cdots G_n^T \ .$$
3. Downdating of $\widetilde{R}$ to R requires the first row $\widetilde{Q}_{1,:}$ of $\widetilde{Q}$. Let $\widetilde{G}_1, \ldots, \widetilde{G}_{m-n}$ be Givens rotations such that $\widehat{R} = G_{m-n} \cdots G_1 \,(\, \widetilde{R} \quad \widetilde{Q}_{1,:}^T \,)$ is upper triangular. Then $R = \widehat{R}_{2:n+1,2:n}$.
4. If $\widetilde{Q}$ is not available, then its first row $\widetilde{Q}_{1,:}$ can be computed by the LINPACK/Saunders algorithm or via hyperbolic rotations. If A is available, the corrected seminormal equations provide a more accurate algorithm.
5. Up- and downdating algorithms are also available for the cases where a column is appended to or deleted from A.
6. Up- and downdating of the Cholesky factor under a rank-one modification $\widetilde{M} = M \pm \mathbf{a}\,\mathbf{a}^T$ is analytically equivalent to updating R from the QR factorization. In the downdating case the matrix $\widetilde{M}$ must be positive (semi)definite.

Examples:

1. Let
$$A = \begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \end{bmatrix} = Q\,R = \begin{bmatrix} 0.5774 & -0.7071 & -0.4082 \\ 0.5774 & 0 & 0.8165 \\ 0.5774 & 0.7071 & -0.4082 \end{bmatrix} \begin{bmatrix} 1.732 & 3.464 \\ 0 & 1.414 \\ 0 & 0 \end{bmatrix} .$$
If $\mathbf{a}^T = (\,1 \;\; 4\,)$, then
$$\widetilde{A} = \begin{bmatrix} 1 & 1 \\ 1 & 2 \\ 1 & 3 \\ 1 & 4 \end{bmatrix} = \widetilde{Q}\,\widetilde{R} \qquad \text{with} \qquad \widetilde{R} = \begin{bmatrix} 2 & 5 \\ 0 & 2.236 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} .$$
The updated factor $\widetilde{R}$ is computed by augmenting R with $\mathbf{a}^T$ and applying two left Givens rotations G_1 and G_2 to row pairs (1,4) and (2,4), respectively:
$$\begin{bmatrix} R \\ a^T \end{bmatrix} = \begin{bmatrix} 1.732 & 3.464 \\ 0 & 1.414 \\ 0 & 0 \\ 1 & 4 \end{bmatrix} \xrightarrow{G_1} \begin{bmatrix} 2 & 5 \\ 0 & 1.414 \\ 0 & 0 \\ 0 & 1.732 \end{bmatrix} \xrightarrow{G_2} \begin{bmatrix} 2 & 5 \\ 0 & 2.236 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} .$$

52.8 Damped Least Squares

Definitions:

The **damped least squares** solution is the solution to the problem $\big(A^TA + \alpha I\big)\mathbf{x} = A^T\mathbf{b}$, where $\alpha > 0$ and A and $\mathbf{b}$ are real. Damped least squares is also known as **ridge regression** and **Tikhonov** (or **Phillips**) **regularization**.

Facts:

(See, e.g., [Han98] for further details.)

1. The two formulations
$$\min\{\|\mathbf{b} - A\mathbf{x}\|_2^2 + \alpha\|\mathbf{x}\|_2^2\} \qquad \text{and} \qquad \min\left\|\begin{bmatrix}\mathbf{b}\\ \mathbf{0}\end{bmatrix} - \begin{bmatrix}A\\ \sqrt{\alpha}\,I\end{bmatrix}\mathbf{x}\right\|_2$$
are analytically equivalent.
2. The damping (controlled by the parameter α) reduces the variance of the solution, at the cost of introducing bias.
3. If $\mathrm{Cov}(\mathbf{b}) = I$, then the covariance matrix for the damped least squares solution $\mathbf{x}_\alpha$ is
$$\mathrm{Cov}(\mathbf{x}_\alpha) = \big(A^TA + \alpha I\big)^{-1}A^TA\big(A^TA + \alpha I\big)^{-1} = V\,\Sigma^2\,(\Sigma^2 + \alpha I)^{-2}V^T\ ,$$
where Σ and V are from the SVD of A. Hence,
$$\|\mathrm{Cov}(\mathbf{x}_\alpha)\|_2 = \max_i\big\{\sigma_i^2/(\sigma_i^2 + \alpha)^2\big\} \le (4\alpha)^{-1}\ ,$$
while $\|\mathrm{Cov}(\mathbf{x}_0)\|_2 = \|(A^TA)^{-1}\|_2 = \sigma_n^{-2}$, which can be much larger.
4. The expected value of $\mathbf{x}_\alpha$ is
$$\mathcal{E}(\mathbf{x}_\alpha) = \big(A^TA + \alpha I\big)^{-1}A^TA\,\mathbf{x}_0\ ,$$
which introduces a bias because $\mathcal{E}(\mathbf{x}_\alpha) \ne \mathcal{E}(\mathbf{x}_0)$ when $\alpha > 0$.
5. The damped least squares problem can take the more general form
$$\min\big\{\|\mathbf{b} - A\mathbf{x}\|_2^2 + \alpha\|B\mathbf{x}\|_2^2\big\} \qquad \Leftrightarrow \qquad (A^TA + \alpha B^TB)\,\mathbf{x} = A^T\mathbf{b}\ ,$$
where $\|B\cdot\|_2$ defines a (semi)norm. The solution to this problem is unique when the nullspaces of A and B intersect trivially.
6. [Han98, Chap. 7]. Some algorithms for computing α are the discrepancy principle, generalized cross validation, and the L-curve criterion.

Examples:

1. Let $\delta = 10^{-5}$ and consider the matrix and vectors
$$A = \begin{bmatrix}1 & 1\\ 1 & 1+\delta\\ 1 & 1+2\delta\end{bmatrix}, \qquad \mathbf{x}_0 = \begin{bmatrix}1\\ 1\end{bmatrix}, \qquad \mathbf{b} = A\,\mathbf{x}_0, \qquad \widetilde{\mathbf{b}} = \mathbf{b} + \begin{bmatrix}0\\ 0\\ \delta\end{bmatrix}.$$
Obviously $\mathbf{x}_0$ is the least squares solution to $A\mathbf{x} + \mathbf{r} = \mathbf{b}$ with $\mathbf{r}_0 = \mathbf{0}$. The minimizer of $\|\widetilde{\mathbf{b}} - A\mathbf{x}\|_2$ is $\widetilde{\mathbf{x}}_0 = (\,0.5 \;\; 1.5\,)^T$, showing that for this problem the least squares solution is very sensitive to perturbations (the condition number is $\kappa(A) = 2.4{\cdot}10^5$). Using $\alpha = 10^{-8}$, we obtain the damped least squares solutions

$$\mathbf{x}_\alpha = \begin{bmatrix} 0.999995 \\ 1.000005 \end{bmatrix} \qquad \text{and} \qquad \widetilde{\mathbf{x}}_\alpha = \begin{bmatrix} 0.995 \\ 1.005 \end{bmatrix}.$$

Comparing the damped and the undamped least squares solutions $\widetilde{\mathbf{x}}_\alpha$ and $\widetilde{\mathbf{x}}_0$ to the perturbed least squares problem, we see that $\widetilde{\mathbf{x}}_\alpha$ is a better approximation to the unperturbed solution $\mathbf{x}_0$ than $\widetilde{\mathbf{x}}_0$.

52.9 Rank Revealing Decompositions

Definitions:

A **rank revealing decomposition** is a two-sided orthogonal decomposition of the form

$$A = U\,\widehat{R}\,V^T = U \begin{bmatrix} R \\ 0 \end{bmatrix} V^T,$$

where U and V are orthogonal, and R is upper triangular and reveals the (numerical) rank of A in the size of its diagonal elements.

The **numerical rank** k_τ of A, with respect to the threshold τ, is defined as

$$k_\tau = \min \operatorname{rank}(A+E) \quad \text{subject to} \quad \|E\|_2 \le \tau.$$

Facts:

(See, e.g., [Bjo96, Sects. 1.7.3–6], [Han98, Sect. 2.2], and [Ste98, Chap. 5].)

1. [GV96, p. 73] The numerical rank k_τ is equal to the number of singular values greater than τ, i.e., $\sigma_{k_\tau} > \tau \ge \sigma_{k_\tau+1}$.
2. The singular value decomposition is rank revealing with the middle matrix $R = \Sigma$. The SVD is difficult to update.
3. If A is exactly rank deficient with $\operatorname{rank}(A) = p$, then there always exists a *pivoted QR factorization* $A\,\Pi = Q\widehat{R}$ with $\widehat{R}$ of the form

   $$\widehat{R} = \begin{bmatrix} R_{11} & R_{12} \\ 0 & 0 \end{bmatrix}, \qquad R_{11} \in \mathbb{R}^{p\times p}, \qquad \operatorname{rank}(\widehat{R}) = \operatorname{rank}(R_{11}) = p\ ,$$

   and a *complete orthogonal decomposition* of the form $A = U\,\widehat{R}\,V^T$, where

   $$\widehat{R} = \begin{bmatrix} R_{11} & 0 \\ 0 & 0 \end{bmatrix}, \qquad R_{11} \in \mathbb{R}^{p\times p}, \qquad \operatorname{rank}(\widehat{R}) = \operatorname{rank}(R_{11}) = p\ .$$

   The pseudoinverse of A is $A^\dagger = V_{:,1:p}R_{11}^{-1}U_{:,1:p}^T$.
4. A basic solution can be computed from the pivoted QR factorization as $\mathbf{x}_{0\mathrm{B}} = \Pi\, R_{11}^{-1}Q_{:,1:p}^T\mathbf{b}$. The minimum-norm least squares solution is given in terms of the complete orthogonal decomposition as $\mathbf{x}_{0\mathrm{M}} = V_{:,1:p}R_{11}^{-1}U_{:,1:p}^T\mathbf{b}$.
5. The *rank revealing QR* (RRQR) *decomposition* is a pivoted QR factorization $A\,\Pi = Q\,\widehat{R}$ such that

   $$\sigma_i/c_i \le \sigma_i(R_{1:i,1:i}) \le \sigma_i \le \|R_{1:i,1:i}\|_2 \le c_i\sigma_i, \qquad i = 1,\dots,n,$$

   where σ_i is the ith singular value of A,

   $$c_i = \sqrt{i(n-i) + \min(i, n-i)}\ ,$$

   and $\sigma_i(R_{1:i,1:i})$ denotes the smallest singular value of $R_{1:i,1:i}$. The RRQR factorization can be used to estimate the numerical rank k_τ. The RRQR factorization is not unique.

6. The *URV decomposition* is a two-sided orthogonal decomposition $A = U\widehat{R}V^T$, such that, for $k = 1, \ldots, n$,

$$\sigma_i \breve{c}_k \le \sigma_i(R_{1:i,1:i}) \le \sigma_i, \quad i = 1, \ldots, k$$

and

$$\sigma_i \le \sigma_{i-k}(R_{k+1:n,k+1:n}) \le \sigma_i / \breve{c}_k, \quad i = k+1, \ldots, n,$$

where

$$\breve{c}_k = \left(1 - \frac{\|R_{k+1:n,k+1:n}\|_2^2}{\sigma_k(R_{1:i,1:i})^2 - \|R_{k+1:n,k+1:n}\|_2^2}\right)^{1/2}.$$

There is also a ULV decomposition with a lower triangular middle matrix; both can be used to estimate the numerical rank of A.

7. The RRQR, URV, and ULV decompositions can be updated, at slightly more cost than the QR factorization.

Examples:

1. The rank of A is revealed by the zero element in the (3,3) position of R:

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 3 & 4 \\ 3 & 4 & 5 \\ 4 & 5 & 6 \end{bmatrix} = QR \qquad \text{with} \qquad R = \begin{bmatrix} 5.477 & 7.303 & 9.129 \\ 0 & 0.816 & 1.633 \\ 0 & 0 & 0 \end{bmatrix}.$$

Here the QR factorization is rank revealing ($U = Q$ and $V = I$).

2. Pivoting must be used to ensure that a QR factorization is rank revealing. The "standard column pivoting" often works well in connection with Householder transformations; here the pivot column in each stage is chosen to maximize the norm of the leading column of the submatrix $A^{(k)}_{k:m,k:n}$ to be reduced. Example:

$$A = \begin{bmatrix} 4 & 2 & 2 \\ 2 & 1 & 2 \\ 0 & 0 & 1 \end{bmatrix},$$

$$A^{(1)} = H_1 A = \begin{bmatrix} -4.4721 & -2.2361 & -2.6833 \\ 0 & 0 & 0.8944 \\ 0 & 0 & \end{bmatrix},$$

$$A^{(1)}\Pi = \begin{bmatrix} -4.4721 & -2.6833 & -2.2361 \\ 0 & 0.8944 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \quad \Pi = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix},$$

$$\widehat{R} = A^{(2)} = H_2 A^{(1)}\Pi = \begin{bmatrix} -4.4721 & -2.6833 & -2.2361 \\ 0 & -1.3416 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

3. The standard column pivoting strategy is not guaranteed to reveal the numerical rank; hence, the development of the RRQR and URV decompositions.

53.1 Introduction

Let A be an n by n nonsingular matrix and $\mathbf{b}$ be an n-vector. Assume that A and $\mathbf{b}$ are given. As discussed in Chapter 51, the solution of the system of linear equations $A\mathbf{x} = \mathbf{b}$ using Gaussian elimination, where $\mathbf{x}$ is an unknown n-vector to be computed, requires $O(n^3)$ operations, which typically include additions, subtractions, multiplications, and divisions. Computing the solution also requires $O(n^2)$ words of storage. The computational complexity is based on the assumption that every element of the matrix has to be stored and operated on. However, linear systems that arise in many scientific and engineering applications can be large; that is, n can be large. It is not uncommon for n to be over hundreds of thousands or even millions. Fortunately, for these linear systems, it is often the case that most of the elements in the matrix A will be zero.

Following is a simple example that illustrates where the zero elements come from. Consider Laplace's equation defined on a unit square:

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0.$$

Assume that u is known along the boundary. Suppose the square domain is discretized into a $(k+2)$ by $(k+2)$ mesh with evenly spaced mesh points. Let $h = \frac{1}{k+1}$ be the spacing between two mesh points in the x- and y-directions. See Figure 53.1. We will denote the mesh points by (x_i, y_j), $0 \leq i, j \leq k+1$. The solution at (x_i, y_j) will be denoted by $u_{i,j} = u(x_i, y_j)$. To solve Laplace's equation numerically, the partial derivatives at (x_i, y_j), $1 \leq i, j \leq k$, will be approximated, for example, using second-order centered difference approximations:

$$\left.\frac{\partial^2 u}{\partial x^2}\right|_{(x_i,y_j)} = \frac{u_{i-1,j} - 2u_{i,j} + u_{i+1,j}}{h^2} + O(h^2),$$

$$\left.\frac{\partial^2 u}{\partial y^2}\right|_{(x_i,y_j)} = \frac{u_{i,j-1} - 2u_{i,j} + u_{i,j+1}}{h^2} + O(h^2).$$

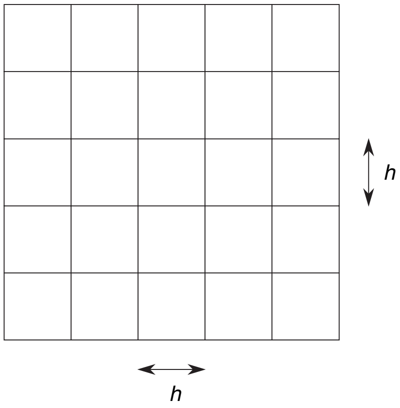

FIGURE 53.1 Discretization of a unit square.

Here, it is assumed that $u_{0,j}$, $u_{k+1,j}$, $u_{i,0}$, $u_{i,k+1}$ are given by the boundary condition, for $1 \leq i, j \leq k$. Using the difference approximations, Laplace's equation at each mesh point (x_i, y_j), $1 \leq i, j \leq k$, is approximated by the following linear equation:

$$u_{i-1,j} + u_{i,j-1} - 4u_{i,j} + u_{i+1,j} + u_{i,j+1} = 0, \qquad \text{for } 1 \leq i, j \leq k.$$

This leads to a system of k^2 linear equations in k^2 unknowns. The solution to the linear system provides the approximate solution $u_{i,j}$, $1 \leq i, j \leq k$, at the mesh points. Note that each equation has at most five unknowns. Thus, the coefficient matrix of the linear system, which is k^2 by k^2 and has k^4 elements, has at most $5k^2$ nonzero elements. It is therefore crucial, for the purpose of efficiency (both in terms of operations and storage), to take advantage of the zero elements as much as possible when solving the linear system. The goal is to compute the solution without storing and operating on most of the zero elements of the matrix. This chapter will discuss some of the techniques for exploiting the zero elements in Gaussian elimination.

Throughout this chapter, the matrices are assumed to be real. However, most of the discussions are also applicable to complex matrices, with the exception of those on real symmetric positive definite matrices. The discussions related to real symmetric positive definite matrices are applicable to Hermitian positive definite matrices (which are complex but not symmetric).

53.2 Sparse Matrices

Definitions:

A matrix A is **sparse** if substantial savings in either operations or storage can be achieved when the zero elements of A are exploited during the application of Gaussian elimination to A.

The number of nonzero elements in a matrix A is denoted by $\boldsymbol{nnz}(A)$.

Facts: [DER89], [GL81]

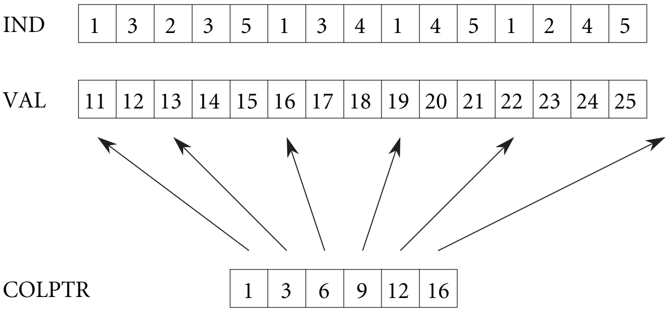
1. Let A be an n by n sparse matrix. It often takes much fewer than n^2 words to store the nonzero elements in A.
2. Let T be a given n by n sparse triangular matrix, $\mathbf{b}$ be a given n-vector, and $\mathbf{x}$ be an unknown n-vector. The number of operations required to solve the triangular system of linear equations $T\mathbf{x} = \mathbf{b}$ is $O(\boldsymbol{nnz}(T))$.

Examples:

1. Consider the following n by n matrix T:

$$T = \begin{bmatrix} t_{1,1} & t_{1,2} & & & & & \\ t_{2,1} & t_{2,2} & t_{2,3} & & & & \\ & t_{3,2} & t_{3,3} & t_{3,4} & & & \\ & & \ddots & \ddots & \ddots & & \\ & & & t_{n-2,n-3} & t_{n-2,n-2} & t_{n-2,n-1} & \\ & & & & t_{n-1,n-2} & t_{n-1,n-1} & t_{n-1,n} \\ & & & & & t_{n,n-1} & t_{n,n} \end{bmatrix},$$

where $t_{i,i} \neq 0$ $(1 \leq i \leq n)$, $t_{i,i+1} \neq 0$ and $t_{i+1,i} \neq 0$ $(1 \leq i \leq n-1)$, and all other elements of T are zero. The matrix T is an example of a tridiagonal matrix and is considered sparse. If Gaussian elimination is applied to T with partial pivoting for numerical stability, $t_{i,i+2}$, $1 \leq i \leq n-2$, may become nonzero due to the possibility of row interchanges. Thus, in the worst case, there will be at most $5n$ nonzero elements in the triangular factorization (counting the 1s on the diagonal of the lower triangular factor). The number of operations required in Gaussian elimination is at most $5n$.



IND	1	3	2	3	5	1	3	4	1	4	5	1	2	4	5
VAL	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25

COLPTR	1	3	6	9	12	16

FIGURE 53.2 An example of a compressed column storage scheme.

2. Typically only the nonzero elements of a sparse matrix have to be stored. One of the common ways to store an n by n sparse matrix A is the *compressed column storage* (CCS) scheme. The nonzero elements are stored in an array (e.g., VAL) column by column, along with an integer array (e.g., IND) that stores the corresponding row indices. Another integer array (e.g., COLPTR) will be used to point to the beginnings of the column sequences. To be specific, if $p = \text{COLPTR}(k)$, then $\text{VAL}(p)$ contains the first member in the sequence of nonzero elements in column k of A. Thus, the numerical values and the corresponding row indices in column k of A are stored in $\text{VAL}(s)$ and $\text{IND}(s)$, for $s = p$ $(= \text{COLPTR}(k))$, $p+1$, $p+2, \cdots$, $\text{COLPTR}(k+1)-1$. Note that $\text{COLPTR}(n+1)$ is one more than the number of nonzero elements in A, which is useful for indicating the end of the set of nonzero elements. Suppose that A is given below:

$$A = \begin{bmatrix} 11 & 0 & 16 & 19 & 22 \\ 0 & 13 & 0 & 0 & 23 \\ 12 & 14 & 17 & 0 & 0 \\ 0 & 0 & 18 & 20 & 24 \\ 0 & 15 & 0 & 21 & 25 \end{bmatrix}.$$

The CCS scheme for storing the nonzero elements is depicted in Figure 53.2. For example, since COLPTR(4) = 9 and COLPTR(5) = 12, the values of the nonzero elements in column 4 and the corresponding row indices are found in VAL(s) and IND(s), where $s = 9$, 10, and 11. For this matrix, COLPTR(6) = 16.

3. The *compressed row storage* (CRS) scheme is another possibility of storing the nonzero elements of a sparse matrix. It is very similar to the CCS scheme, except that the nonzero elements are stored by rows.
4. Let $A = [a_{i,j}]$ be an n by n sparse matrix. Let $\mathbf{b} = [b_i]$ and $\mathbf{c} = [c_i]$ be n-vectors. The following algorithm computes the product $\mathbf{c} = A\mathbf{b}$, with the assumption that the nonzero elements of A are stored using the CRS scheme.

```
for $i = 1, 2, \cdots, n$ do
    $c_i \leftarrow 0$
    for $s = \text{ROWPTR}(i), \text{ROWPTR}(i) + 1, \cdots, \text{ROWPTR}(i + 1) - 1$ do
        $c_i \leftarrow c_i + \text{VAL}(s) b_{\text{IND}(s)}$
```

5. Let $A = [a_{i,j}]$ be an n by n sparse matrix. Let $\mathbf{b} = [b_i]$ and $\mathbf{c} = [c_i]$ be n-vectors. The following algorithm computes the product $\mathbf{c} = A\mathbf{b}$, with the assumption that the nonzero elements of A are stored using the CCS scheme.

```
for $i = 1, 2, \cdots, n$ do
    $c_i \leftarrow 0$
for $i = 1, 2, \cdots, n$ do
    for $s = \text{COLPTR}(i), \text{COLPTR}(i) + 1, \cdots, \text{COLPTR}(i + 1) - 1$ do
        $c_{\text{IND}(s)} \leftarrow c_{\text{IND}(s)} + \text{VAL}(s) b_i$
```

53.3 Sparse Matrix Factorizations

Mathematically, computing a triangular factorization of a sparse matrix using Gaussian elimination is really no different from that of a dense matrix. However, the two are very different algorithmically. Sparse triangular factorizations can be quite complicated because of the need to preserve the zero elements and to avoid operating on the zero elements as much as possible.

Definitions:

Let A be a sparse matrix. An element is a **fill element** in the factorization if it is zero in A but becomes nonzero during Gaussian elimination.

The **sparsity structure** of a matrix $A = [a_{i,j}]$, denoted by Struct(A), refers to the set $\{(i, j) : a_{i,j} \neq 0\}$.

Consider applying Gaussian elimination to a matrix A with row and column pivoting:

$$A = P_1 M_1 P_2 M_2 \cdots P_{n-1} M_{n-1} U Q_{n-1} \cdots Q_2 Q_1,$$

where P_i and Q_i $(1 \leq i \leq n-1)$ are, respectively, the row and column permutations due to pivoting, M_i $(1 \leq i \leq n-1)$ is a Gauss transformation (see Chapter 51), and U is the upper triangular factor. Let $L = M_1 + M_2 + \cdots + M_{n-1} - (n-2)I$, where I is the identity matrix. Note that L is a lower triangular matrix. The matrix $F = L + U - I$ is referred to as the **fill matrix**.

The matrix A is said to have a **zero-free diagonal** if all the diagonal elements of A are nonzero. The zero-free diagonal is also known as a **maximum transversal**.

No **exact numerical cancellation** between two numbers u and v means that $u + v$ (or $u - v$) is nonzero regardless of the values of u and v.

Facts: [DER89], [GL81]

In the following discussion, A is a sparse nonsingular matrix and F is its fill matrix.

1. [Duf81], [DW88] There exists a (row) permutation matrix P_r such that P_rA has a zero-free diagonal. Similarly, there exists a (column) permutation matrix P_c such that AP_c has a zero-free diagonal.
2. It is often true that there are more nonzero elements in F than in A.
3. The sparsity structure of F depends on the sparsity structure of A, as well as the pivot sequence needed to maintain numerical stability in Gaussian elimination. This means that Struct(F) is known only during numerical factorization. As a result, the storage scheme cannot be created in advance to accommodate the fill elements that occur during Gaussian elimination.
4. If A is symmetric and positive definite, then pivoting for numerical stability is not needed during Gaussian elimination. Assume that exact numerical cancellations do not occur during Gaussian elimination. Then Struct(A) $\subseteq$ Struct(F).
5. Let A be symmetric and positive definite. Assume that exact numerical cancellations do not occur during Gaussian elimination. Then Struct(F) is determined solely by Struct(A). This implies that Struct(F) can be computed before any numerical factorization proceeds. Knowing Struct(F) in advance allows an efficient storage scheme for the nonzero elements in the triangular factor to be set up prior to numerical factorization.
6. [GN85] Suppose that A is an n by n nonsymmetric matrix. Consider applying Gaussian elimination to a matrix A with partial pivoting:

$$A = P_1 M_1 P_2 M_2 \cdots P_{n-1} M_{n-1} U,$$

   where P_i $(1 \leq i \leq n-1)$, is a row permutation due to pivoting, M_i $(1 \leq i \leq n-1)$ is a Gauss transformation, and U is the upper triangular factor. Let F denote the corresponding fill matrix; that is, $F = M_1 + M_2 + \cdots + M_{n-1} + U - (n-1)I$. The matrix product A^TA is symmetric and positive definite and, hence, has a Cholesky factorization $A^TA = L_C L_C^T$. Assume that A has a zero-free diagonal. Then Struct(F) $\subseteq$ Struct($L_C + L_C^T$). This result holds for *every* legitimate sequence of pivots $\{P_1, P_2, \cdots, P_{n-1}\}$. Thus, Struct($L_C$) and Struct($L_C^T$) can serve as *upper bounds* on Struct(L) and Struct(U), respectively. When A is irreducible, then Struct(L_C^T) is a *tight* bound on Struct(U): for a given $(i,j) \in$ Struct(L_C^T), there is an assignment of numerical values to the nonzero elements of A so that $U_{i,j}$ is nonzero; this is referred to as a *one-at-a-time* result [GN93]. However, Struct(L_C) is *not* a tight bound on Struct(L). A tight bound on Struct(L) can be found in [GN87] and [GN93].

Examples:

Some of the properties of sparse matrices, such as zero-free diagonals and reducible/irreducible matrices, depend only on the sparsity structures of the matrices; the actual values of the nonzero elements are irrelevant. As a result, for the examples illustrating such properties, only the sparsity structures will be taken into consideration. The numerical values will not be shown. Nonzero elements will be indicated by ×.

1. Following is an example of a reducible matrix:

$$A = \begin{bmatrix} \times & \times & \times & \times & \times & & \times & & & \\ & & & & \times & & \times & \times & \times & \\ & \times & \times & & \times & & & & & \\ & \times & & \times & & \times & & & \times & \times \\ & \times & & & \times & & & & \times & \\ & \times & \times & & & & & & & \times \\ \times & \times & \times & \times & & & \times & & \times & \times \\ & \times & & & \times & & & & \times & \\ \times & & & & \times & & & & \times & \times \\ & & & & & & & & & \times \end{bmatrix}.$$

The matrix A can be put into a block upper triangular form using the following permutations:

$$\pi_r = [2, 4, 7, 1, 9, 6, 8, 5, 3, 10],$$
$$\pi_c = [8, 6, 4, 7, 1, 3, 9, 5, 2, 10].$$

Here, $\pi_r(i) = j$ means that row i of the permuted matrix comes from row j of the original matrix. Similarly, $\pi_c(i) = j$ means that column i of the permuted matrix comes from column j of the original matix. When π_r and π_c are applied to the identity matrix (separately), the corresponding permutation matrices are obtained:

$$P_r = \begin{bmatrix} & \times & & & & & & & & \\ & & & \times & & & & & & \\ & & & & & & \times & & & \\ \times & & & & & & & & & \\ & & & & & & & & \times & \\ & & & & & \times & & & & \\ & & & & & & & \times & & \\ & & & & \times & & & & & \\ & & \times & & & & & & & \\ & & & & & & & & & \times \end{bmatrix}, P_c = \begin{bmatrix} & & & & \times & & & & & \\ & & & & & & & & \times & \\ & & & & & \times & & & & \\ & & \times & & & & & & & \\ & & & & & & & \times & & \\ & \times & & & & & & & & \\ & & & \times & & & & & & \\ \times & & & & & & & & & \\ & & & & & & \times & & & \\ & & & & & & & & & \times \end{bmatrix}.$$

The permuted matrix P_rAP_c is shown below:

$$P_rAP_c = \left[\begin{array}{c|c|cc|c|cccc|c} \times & & & \times & & & \times & \times & & \\ \hline & \times & \times & & & & \times & & \times & \times \\ \hline & & \times & \times & \times & \times & \times & & \times & \times \\ & & \times & \times & \times & \times & & \times & \times & \\ \hline & & & & \times & & \times & \times & & \times \\ \hline & & & & & \times & & & \times & \times \\ & & & & & & \times & \times & \times & \\ & & & & & & \times & \times & \times & \\ & & & & & \times & & \times & \times & \\ \hline & & & & & & & & & \times \end{array}\right].$$

The block triangular form has four 1×1 blocks, one 2×2 block, and one 4×4 block on the diagonal.

2. The advantage of the block triangular form is that only the diagonal blocks have to be factored in the solution of a linear system. As an example, suppose that A is lower block triangular:

$$A = \begin{bmatrix} A_{1,1} & & & \\ A_{2,1} & A_{2,2} & & \\ \vdots & \vdots & \ddots & \\ A_{m,1} & A_{m,2} & \cdots & A_{m,m} \end{bmatrix}.$$

Here, m is the number of blocks on the diagonal of A. Consider the solution of the linear system $A\mathbf{x} = \mathbf{b}$. Suppose $\mathbf{b}$ and $\mathbf{x}$ are partitioned according to the block structure of A:

$$\mathbf{b} = \begin{bmatrix} \mathbf{b}_1 \\ \mathbf{b}_2 \\ \vdots \\ \mathbf{b}_m \end{bmatrix} \quad \text{and} \quad \mathbf{x} = \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_m \end{bmatrix}.$$

Then the solution can be obtained using a block substitution scheme:

$$A_{k,k}\mathbf{x}_k = \mathbf{b}_k - \sum_{i=1}^{k-1} A_{k,i}\mathbf{x}_i, \quad \text{for } 1 \leq i \leq m.$$

Note that only the diagonal blocks $A_{k,k}$, $1 \leq k \leq m$, have to be factored; Gaussian elimination does not have to be applied to the entire matrix A. This can result in substantial savings in storage and operations.

3. In this example, the matrix A has zero elements on the diagonal:

$$A = \begin{bmatrix} & & & & \times & & \times & \times & & \times \\ & & & \times & & & & & & \times \\ & & & \times & \times & & & \times & & \times \\ & & \times & & \times & & \times & & \times & \\ & \times & & & & \times & \times & \times & \times & \times \\ & \times & & & & & \times & & \times & \times \\ & & \times & \times & & & & \times & \times & \times \\ & & \times & \times & \times & \times & \times & \times & & \\ & & & & & \times & & & \times & \\ \times & \times & & & & \times & & & & \times \end{bmatrix}.$$

The following permutation matrix P, when applied to the columns of A, will produce a matrix with a zero-free diagonal:

$$P = \begin{bmatrix} & & & & & & & & & \times \\ & & & & & \times & & & & \\ & & & & & & & \times & & \\ & \times & & & & & & & & \\ & & & \times & & & & & & \\ & & & & & & & & \times & \\ \times & & & & & & & & & \\ & & \times & & & & & & & \\ & & & & \times & & & & & \\ & & & & & & \times & & & \end{bmatrix}.$$

The sparsity structure of the permuted matrix is shown below:

$$AP = \begin{bmatrix} \times & & \times & \times & & & \times & & & \\ & \times & & & & & \times & & & \\ & \times & \times & \times & & & \times & & & \\ \times & & & \times & \times & & & \times & & \\ \times & & \times & & \times & \times & \times & & \times & \\ \times & & & & \times & \times & \times & & & \\ & \times & \times & & \times & & \times & \times & & \\ \times & \times & \times & \times & & & & \times & \times & \\ & & & & \times & & & & \times & \\ & & & & & \times & \times & & \times & \times \end{bmatrix}.$$

The permutation matrix P is obtained by applying the following permutation π to the columns of the identity matrix:

$$\pi = [7, 4, 8, 5, 9, 2, 10, 3, 6, 1].$$

Again, $\pi(i) = j$ means that column i of the permuted matrix comes from column j of the original matrix.

4. Consider the following matrix:

$$A = \begin{bmatrix} 10 & 0 & 1 & 0 & 1 & 0 & 0 \\ 1 & 10 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 10 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 10 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 10 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 10 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 10 \end{bmatrix},$$

which is diagonally dominant. The matrix can be factored without pivoting for stability. The triangular factors are given below:

$$L = \begin{bmatrix} 1 & & & & & & \\ \frac{1}{10} & 1 & & & & & \\ 0 & 0 & 1 & & & & \\ 0 & 0 & \frac{1}{10} & 1 & & & \\ 0 & \frac{1}{10} & \frac{1}{1000} & 0 & 1 & & \\ \frac{1}{10} & 0 & -\frac{1}{100} & 0 & -\frac{10}{991} & 1 & \\ 0 & 0 & 0 & 0 & \frac{100}{991} & \frac{1}{99199} & 1 \end{bmatrix}, \; U = \begin{bmatrix} 10 & 0 & 1 & 0 & 1 & 0 & 0 \\ & 10 & -\frac{1}{10} & 0 & \frac{9}{10} & 0 & 0 \\ & & 10 & 0 & 0 & 1 & 0 \\ & & & 10 & 0 & -\frac{1}{10} & 1 \\ & & & & \frac{991}{100} & -\frac{1}{1000} & 1 \\ & & & & & \frac{99199}{9910} & \frac{10}{991} \\ & & & & & & \frac{981980}{99199} \end{bmatrix}.$$

Note that A has 18 nonzero elements, whereas $L+U$ has 26 nonzero elements, showing that there are more nonzero elements in the fill matrix than in A.

5. Consider the matrix A in the previous example. Suppose $\hat{A} = [\hat{a}_{i,j}]$ is obtained from A by swapping the $(1,1)$ and $(2,1)$ elements:

$$\hat{A} = \begin{bmatrix} 1 & 0 & 1 & 0 & 1 & 0 & 0 \\ 10 & 10 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 10 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 10 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 10 & 0 & 1 \\ 1 & 0 & 0 & 0 & 0 & 10 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 10 \end{bmatrix}.$$

When Gaussian elimination with partial pivoting is applied to $\hat{A}$, rows 1 and 2 will be interchanged at step 1 of the elimination since $|\hat{a}_{2,1}| > |\hat{a}_{1,1}|$. It can be shown that no more interchanges are needed in the subsequent steps. The triangular factors are given by

$$\hat{L} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ \frac{1}{10} & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{10} & 1 & 0 & 0 & 0 \\ 0 & -1 & \frac{1}{10} & 0 & 1 & 0 & 0 \\ \frac{1}{10} & 1 & -\frac{1}{10} & 0 & -\frac{10}{109} & 1 & 0 \\ 0 & 0 & 0 & 0 & \frac{10}{109} & \frac{10}{10999} & 1 \end{bmatrix}, \; \hat{U} = \begin{bmatrix} 10 & 10 & 0 & 0 & 1 & 0 & 0 \\ 0 & -1 & 1 & 0 & \frac{9}{10} & 0 & 0 \\ 0 & 0 & 10 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 10 & 0 & -\frac{1}{10} & 1 \\ 0 & 0 & 0 & 0 & \frac{109}{10} & -\frac{1}{10} & 1 \\ 0 & 0 & 0 & 0 & 0 & \frac{10999}{1090} & \frac{10}{109} \\ 0 & 0 & 0 & 0 & 0 & 0 & \frac{108980}{10999} \end{bmatrix}.$$

Even though A (in the previous example) and $\hat{A}$ have the same sparsity structures, their fill matrices have different numbers of nonzero elements. There are 27 nonzero elements in the fill matrix of $\hat{A}$. While this example is small, it illustrates that the occurrence of fill elements in Gaussian elimination generally depends on both the sparsity structure and the values of the nonzero elements of the matrix.

6. Consider the example in the last two examples again. Note that A has a zero-free diagonal. Both A and $\hat{A}$ have the same sparsity structure. The sparsity structure of $A^T A$ is the same as that of $\hat{A}^T \hat{A}$:

$$A^T A = \begin{bmatrix} \times & \times & \times & & \times & \times & \\ \times & \times & & & \times & & \times \\ \times & & \times & \times & \times & \times & \times \\ & & \times & \times & & & \times \\ \times & \times & \times & & \times & & \times \\ \times & & \times & & & \times & \\ & \times & \times & \times & \times & & \times \end{bmatrix}.$$

(Again, × denotes a nonzero element.) The Cholesky factor L_C of the symmetric positive definite matrix $A^T A$ has the form:

$$L_C = \begin{bmatrix} \times & & & & & & \\ \times & \times & & & & & \\ \times & \times & \times & & & & \\ & & \times & \times & & & \\ \times & \times & \times & \times & \times & & \\ \times & \times & \times & \times & \times & \times & \\ & \times & \times & \times & \times & \times & \times \end{bmatrix}.$$

Note that $\text{Struct}(L) \neq \text{Struct}(\hat{L})$, but $\text{Struct}(L) \subset \text{Struct}(L_C)$ and $\text{Struct}(\hat{L}) \subset \text{Struct}(L_C)$. Similarly, $\text{Struct}(U) \neq \text{Struct}(\hat{U})$, but $\text{Struct}(U) \subset \text{Struct}(L_C^T)$ and $\text{Struct}(\hat{U}) \subset \text{Struct}(L_C^T)$. This example illustrates that when A has a zero-free diagonal the sparsity structure of the Cholesky factor of $A^T A$ indeed contains the sparsity structure of L (or U^T), irrespective of the choice of the pivot sequence.

7. It is shown in an earlier example that fill elements do occur in Gaussian elimination of sparse matrices. In order to allow for these fill elements during Gaussian elimination, the simple storage schemes (CCS or CRS) may not be sufficient. More sophisticated storage schemes are often needed. The choice of a storage scheme depends on the choice of the factorization algorithm. There are many implementations of sparse Gaussian elimination, such as *profile methods*, *left-looking methods*, *right-looking methods*, and *frontal/multifrontal methods* [DER89], [GL81]. Describing these implementations is beyond the scope of this chapter. Following is a list of pointers to some of the implementations.

   (a) Factorization of sparse symmetric positive definite matrices: [NP93], [RG91].

   (b) Factorization of sparse symmetric indefinite matrices: [AGL98], [DR83], [DR95], [Duf04], [Liu87a], [Liu87b].

   (c) Factorization of sparse nonsymmetric matrices: [DEG+99], [Duf77], [DR96], [GP88].

8. A column-oriented example of a *right-looking* sparse Gaussian elimination:
Let $A = [a_{ij}]$ be an n by n sparse nonsingular matrix. For simplicity, we will use $\text{cdiv}(\rho, \mathbf{v})$ to denote the task of dividing the elements of the vector $\mathbf{v}$ by a scalar ρ, assuming that $\rho \neq 0$; i.e., $\mathbf{v} \leftarrow \frac{1}{\rho}\mathbf{v}$. We will also use $\text{cmod}(\rho, \mathbf{u}, \mathbf{v})$ to denote the task of subtracting from the vector $\mathbf{v}$ the product of ρ and $\mathbf{u}$; i.e., $\mathbf{v} \leftarrow \mathbf{v} - \rho\mathbf{u}$. We further assume that the diagonal elements are nonzero and that they remain so throughout the factorization. The following is a simple description of a right-looking sparse Gaussian elimination, using MATLAB notation.

```
for $k = 1, 2, \cdots, n$ do
    cdiv( $a_{k,k}$ , $a_{k+1:n,k}$ )
    for $j = k+1, k+2, \cdots, n$ do
        if $a_{k,j} \neq 0$ then cmod( $a_{k,j}$ , $a_{k+1:n,k}$ , $a_{k+1:n,j}$ )
```

In an actual implementation, sparsity must be exploited in performing the cdiv and cmod tasks for efficiency. Also, the storage scheme should be designed so that the nonzero elements can be accessed efficiently.

9. A column-oriented example of a *left-looking* sparse Gaussian elimination:
Let $A = [a_{i,j}]$ be an n by n sparse nonsingular matrix. We will use the same notation and make the same assumption as in the previous example. The following is a simple description of a left-looking sparse Gaussian elimination.

```
for $k = 1, 2, \cdots, n$ do
    for $j = 1, 2, \cdots, k-1$ do
        if $a_{j,k} \neq 0$ then cmod( $a_{j,k}$ , $a_{k:n,j}$ , $a_{k:n,k}$ )
    cdiv( $a_{k,k}$ , $a_{k+1:n,k}$ )
```

53.4 Modeling and Analyzing Fill

A key component of sparse Gaussian elimination is the exploitation of the sparsity structure of the given matrix and its triangular factors. Graphs are useful in understanding and analyzing how fill elements are introduced in sparse Gaussian elimination. Some basic graph-theoretical tools and results are described in this section. Others can be found in [EL92], [GL81], [GL93], [GNP94], [Liu86], [Liu90], and [Sch82].

In this and the next sections, all graphs (bipartite graphs, directed graphs, and undirected graphs) are simple. That is, loops and multiple edges are not allowed. More information on graphs can be found in Chapter 39 (graphs), Chapter 40 (digraphs), and Chapter 41 (bipartite graphs).

Definitions:

Consider an n by n sparse nonsymmetric matrix $A = [a_{i,j}]$. Let $R = \{r_1, r_2, \cdots, r_n\}$ be a set of "row" vertices associated with the rows of A. Similarly, let $C = \{c_1, c_2, \cdots, c_n\}$ be a set of "column" vertices associated with the columns of A. The **bipartite graph** or **bigraph** of A, denoted by $H(A) = (R, C, E)$, can be associated with the sparsity structure of A. There is an edge $\{r_i, c_j\} \in E$ if and only if $a_{i,j} \neq 0$.

Suppose A has a zero-free diagonal, and assume that the pivots are always chosen from the diagonal. Then the sparsity structure of A can be represented by a **directed graph** or **digraph**, denoted by $\Gamma(A) = (X, E)$. Here, $X = \{x_1, x_2, \cdots, x_n\}$, with x_i, $1 \leq i \leq n$, representing column i and row i of A. There is a directed edge or arc $(x_i, x_j) \in E$ if and only if $a_{i,j} \neq 0$, for $i \neq j$. (The nonzero elements on the diagonal of A are not represented.)

Consider the case where $A = [a_{i,j}]$ is n by n, symmetric and positive definite. Assume that the pivots are always chosen from the diagonal. Then an **undirected graph** or **graph** (when the context is clear) $G(A) = (X, E)$ can be used to represent the sparsity structure of A. Let $X = \{x_1, x_2, \cdots, x_n\}$, with x_i representing row i and column i of A. There is an (undirected) edge $\{x_i, x_j\} \in E$ if and only if $a_{i,j} \neq 0$ (and, hence, $a_{j,i} \neq 0$), for $i \neq j$. (The nonzero elements on the diagonal of A are not represented.)

A **path** in a graph (which can be a bigraph, digraph, or undirected graph) is a sequence of *distinct* vertices $(x_{s_1}, x_{s_2}, \cdots, x_{s_t})$ such that there is an edge between every pair of consecutive vertices. For bigraphs and undirected graphs, $\{x_{s_p}, x_{s_{p+1}}\}$, $1 \leq p \leq t-1$, is an (undirected) edge. For digraphs, the path is a directed path, and $(x_{s_p}, x_{s_{p+1}})$, $1 \leq p \leq t-1$, is an arc.

Let A be an n by n matrix. After k ($1 \leq k \leq n$) steps of Gaussian elimination (using a right-looking formulation), the matrix remaining to be factored is the trailing submatrix that consists of the elements in the last $(n-k)$ rows and the last $(n-k)$ columns of A. The graph (bipartite, digraph, or undirected graph) associated with this $(n-k)$ by $(n-k)$ trailing matrix is the k-th **elimination graph**.

Facts:

1. [PM83] Let $H^{(0)}$, $H^{(1)}$, $H^{(2)}$, $\cdots$, $H^{(n)}$ be the sequence of elimination bigraphs associated with the Gaussian elimination of an n by n sparse nonsymmetric matrix $A = [a_{i,j}]$. The initial bigraph $H^{(0)}$ is the bigraph of A. Each elimination bigraph can be obtained from the previous one through a simple transformation. Suppose that

the nonzero element $a_{s,t}$ is chosen as the pivot at step k, $1 \leq k \leq n$. Then the edge corresponding to $a_{s,t}$ (i.e., $\{r_s, c_t\}$) is removed from $H^{(k-1)}$, together with all the edges incident to r_s and c_t. The vertices r_s and c_t are also removed from $H^{(k-1)}$. To obtain the next elimination bigraph $H^{(k)}$ from the modified $H^{(k-1)}$, an edge $\{r, c\}$ is added if there is a path (r, c_t, r_s, c) in the original $H^{(k-1)}$ and if $\{r, c\}$ is not already in $H^{(k-1)}$. The new edges added to create $H^{(k)}$ correspond to the fill elements introduced when $a_{s,t}$ is used to eliminate row s and column t. The bigraph $H^{(k)}$ represents the sparsity structure of the matrix remaining to be factored after row s and column t are eliminated.

2. [RT78] Let A be an n by n sparse nonsymmetric matrix. Suppose that A has a zero-free diagonal and assume that pivots are restricted to the diagonal. Then Gaussian elimination can be modeled using elimination digraphs. Let $\Gamma^{(0)}$, $\Gamma^{(1)}$, $\Gamma^{(2)}$, $\cdots$, $\Gamma^{(n)}$ be the sequence of elimination digraphs. The initial digraph $\Gamma^{(0)}$ is the digraph of A. Each elimination digraph can be obtained from the previous one through a simple transformation. Without loss of generality, assume that Gaussian elimination proceeds from row/column 1 to row/column n. Consider step k, $1 \leq k \leq n$. Vertex x_k is removed from $\Gamma^{(k-1)}$, together with all the arcs of the form (x_k, u) and (v, x_k), where u and v are vertices in $\Gamma^{(k-1)}$. To obtain the next elimination digraph $\Gamma^{(k)}$ from the modified $\Gamma^{(k-1)}$, an arc (r, c) is added if there is a directed path (r, x_k, c) in the original $\Gamma^{(k-1)}$ and if (r, c) is not already in $\Gamma^{(k-1)}$. The new arcs added to create $\Gamma^{(k)}$ correspond to the fill elements introduced by Gaussian elimination at step k. The digraph $\Gamma^{(k)}$ represents the sparsity structure of the matrix remaining to be factored after k steps of Gaussian elimination.
3. [Ros72] For an n by n symmetric positive definite matrix A, the elimination graphs associated with Gaussian elimination can be represented by (undirected) graphs. Let the elimination graphs be denoted by $G^{(0)}$, $G^{(1)}$, $G^{(2)}$, $\cdots$, and $G^{(n)}$. The initial graph $G^{(0)}$ is the graph of A. Each elimination graph can be obtained from the previous one through a simple transformation. Without loss of generality, assume that Gaussian elimination proceeds from row/column 1 to row/column n. Consider step k, $1 \leq k \leq n$. Vertex x_k is removed from $G^{(k-1)}$, together with all its incident edges. To obtain the next elimination graph $G^{(k)}$ from the modified $G^{(k-1)}$, an (undirected) edge $\{r, c\}$ is added if there is a path (r, x_k, c) in the original $G^{(k-1)}$ and if $\{r, c\}$ is not already in $G^{(k-1)}$. The new edges added to create $G^{(k)}$ correspond to the fill elements introduced by Gaussian elimination at step k. The graph $G^{(k)}$ represents the sparsity structure of the matrix remaining to be factored after k steps of Gaussian elimination.
4. [GL80b], [RTL76] Consider an n by n symmetric positive definite matrix A. Let $G = (X, E)$ be the (undirected) graph of A and let $X = \{x_1, x_2, \cdots, x_n\}$. Denote the Cholesky factor of A by L. For $i > j$, the (i, j) element of L is nonzero if and only if there is a path $(x_i, x_{s_1}, x_{s_2}, \cdots, x_{s_t}, x_j)$ in G such that $s_p < j$ $(< i)$, for $1 \leq p \leq t$. Such a path is sometimes referred to as a *fill path*. Note that t can be zero, which corresponds to $\{x_i, x_j\} \in E$.
5. We have focused on the use of elimination graphs to model and analyze sparse Gaussian elimination in this chapter. There are other tools and techniques that are also useful for this purpose. Some of the tools include, for example, *elimination trees* for symmetric positive definite matrices [Liu90] and *elimination directed acyclic graphs* for nonsymmetric matrices [EL92].

Examples:

1. As one may observe, the operations involved in the generation of the elimination bigraphs, digraphs, and graphs are very similar. Thus, only one example will be illustrated here.

Consider the nonsymmetric matrix $A = [a_{i,j}]$ in Figure 53.3. The bigraph H of A is depicted in Figure 53.4.

$$A = \begin{bmatrix} \times & & \times & & & \times & \\ & & & \times & & & \\ & & \times & & & & \\ \times & & & \times & \times & & \\ & \times & & & & & \times \\ & & \times & & & \times & \times \\ \times & & & & \times & & \end{bmatrix}.$$

FIGURE 53.3 A sparse nonsymmetric matrix A.

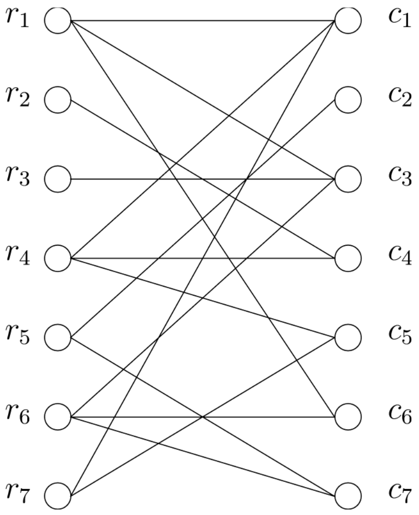


FIGURE 53.4 The bigraph of the matrix A in Figure 53.3.

Suppose that $a_{1,1}$ is used to eliminate row 1 and column 1. After the first step of Gaussian elimination, the remaining matrix is shown in Figure 53.5. Following the recipe given above, the edges $\{r_1, c_1\}$, $\{r_1, c_3\}$, $\{r_1, c_6\}$, $\{r_4, c_1\}$, and $\{r_7, c_1\}$ are to be removed from the bigraph H in Figure 53.4. Then r_1 and c_1 are also removed from the bigraph H. The new bigraph is obtained by adding to H the following edges:

(a) $\{r_4, c_3\}$ (because of the path (r_4, c_1, r_1, c_3) in the original H).

(b) $\{r_4, c_6\}$ (because of the path (r_4, c_1, r_1, c_6) in the original H).

(c) $\{r_7, c_3\}$ (because of the path (r_7, c_1, r_1, c_3) in the original H).

(d) $\{r_7, c_6\}$ (because of the path (r_7, c_1, r_1, c_6) in the original H).

The new bigraph is shown in Figure 53.6, in which the new edges are shown as dashed lines. Note that the new bigraph is exactly the bigraph of A'.

$$A' = \begin{bmatrix} & & \times & & & \\ & \times & & & & \\ & + & \times & \times & + & \\ \times & & & & & \times \\ & \times & & & \times & \times \\ & + & & \times & + & \end{bmatrix}.$$

FIGURE 53.5 The remaining matrix after the first step of Gaussian elimination on the matrix A in Figure 53.3.

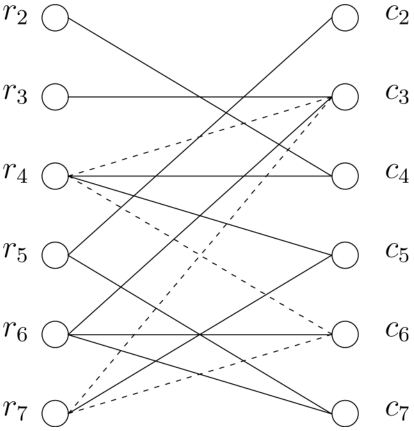

FIGURE 53.6 The bigraph of the matrix A' in Figure 53.5.

2. Let $A = [a_{i,j}]$ be a symmetric and positive definite matrix:

$$A = \begin{bmatrix} \times & & \times & & & & & \times \\ & \times & \times & & \times & & & \\ \times & \times & \times & & & & & \\ & & & \times & \times & & \times & \\ & \times & & \times & \times & \times & & \\ & & & & \times & \times & & \times \\ & & & \times & & & \times & \\ \times & & & & & \times & & \times \end{bmatrix}.$$

Assume that exact numerical cancellations do not occur. Then the sparsity structure of the Cholesky factor $L = [\ell_{i,j}]$ of A is given below:

$$L = \begin{bmatrix} \times & & & & & & & \\ & \times & & & & & & \\ \times & \times & \times & & & & & \\ & & & \times & & & & \\ & \times & + & \times & \times & & & \\ & & & & \times & \times & & \\ & & & \times & + & + & \times & \\ \times & & + & & + & \times & + & \times \end{bmatrix}.$$

The symbol + represents a fill element. The (undirected) graph G of A is shown in Figure 53.7. There are several fill paths in G. The fill path $(x_5, x_2, x_3, x_1, x_8)$ corresponds to the fill element $\ell_{8,5}$ in L. Another example is the fill path (x_7, x_4, x_5, x_6), which corresponds to the fill element $\ell_{7,6}$ in L.

53.5 Effect of Reorderings

Let A be a sparse nonsingular matrix. As noted above, the occurrence of fill elements in Gaussian elimination generally depends on the values of the nonzero elements in A (which affect the choice of pivots if numerical stability is a concern) and the sparsity structure of A. This section will consider some techniques that will help preserve the sparsity structure in the factorization of A.

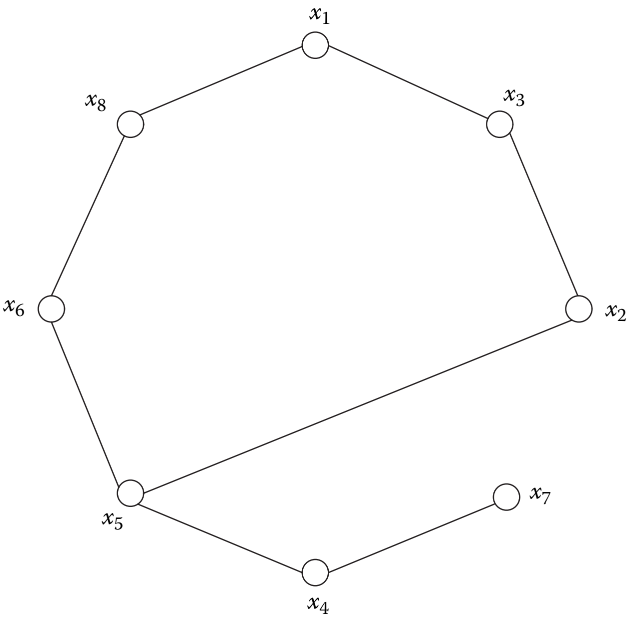

FIGURE 53.7 An example illustrating fill paths.

Definitions:

Let A be an n by n sparse matrix. Suppose that G is a graph associated with A as described in the previous section; the graph can be a bipartite graph, directed graph, or undirected graph, depending on whether A is nonsymmetric or symmetric and whether the pivots are chosen to be on the diagonal. The **fill graph** G^F of A is G, together with all the additional edges corresponding to the fill elements that occur during Gaussian elimination.

An **elimination ordering** (or **elimination sequence**) for the rows (or columns) of a matrix is a bijection $\alpha : \{1, 2, \cdots, n\} \to \{1, 2, \cdots, n\}$. It specifies the order in which the rows (or columns) of the matrix are eliminated during Gaussian elimination.

A **perfect elimination ordering** is an elimination ordering that does not produce any fill elements during Gaussian elimination.

Consider an n by n sparse matrix A. Let f_i and ℓ_i be the column indices of the *first* and *last* nonzero elements in row i of A, respectively. The **envelope** of A is the set

$$\{(i, j) : f_i \leq j \leq \ell_i, \quad \text{for } 1 \leq i \leq n\}.$$

That is, all the elements between the first and last nonzero elements of every row are in the envelope.

The **profile** of a matrix is the number of elements in the envelope.

Facts:

The problem of reordering a sparse matrix is combinatorial in nature. The facts stated below are some of fundamental ones. Others can be found in, for example, [GL81] and [Gol04].

1. [GL81] An elimination ordering for the rows/columns of the matrix corresponds to a permutation of the rows/columns.
2. [DER89], [GL81] The choice of an elimination ordering will affect the number of fill elements in the triangular factors.
3. [GL81], [Ros72] When A is sparse symmetric positive definite, an elimination ordering α fulfilling certain criterion (e.g., reducing the number of fill elements or the number of operations) can be determined by analyzing the sparsity structure of A and how the sparsity changes during Gaussian elimination. The elimination ordering provides a symmetric permutation of A. Let P denote the permutation matrix corresponding to α. Let G^F be the fill graph of the matrix PAP^T. It is known that G^F is a chordal graph. The ordering α is a perfect elimination ordering for G^F.
4. [Yan81] For sparse symmetric positive definite matrices, finding the optimal elimination ordering (i.e., an elimination ordering that minimizes the number of fill elements in the Cholesky factor) is NP-complete. This implies that almost all reordering techniques are heuristic in nature.
5. [DER89] When A is a sparse nonsymmetric matrix, the elimination orderings for the rows and columns of A generally have to be chosen to preserve the sparsity structure and to maintain numerical stability.
6. [GN85] Suppose that A is a sparse nonsymmetric matrix. If partial pivoting (by rows) is used to maintain numerical stability, then an elimination ordering for the columns of A can be chosen to preserve the sparsity structure.

Examples:

1. Consider the following two diagonally dominant matrices:

$$A = \begin{bmatrix} 7 & 1 & -1 & 1 & -1 \\ -1 & 7 & 0 & 0 & 0 \\ 1 & 0 & 7 & 0 & 0 \\ -1 & 0 & 0 & 7 & 0 \\ 1 & 0 & 0 & 0 & 7 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 7 & 0 & 0 & 0 & 1 \\ 0 & 7 & 0 & 0 & -1 \\ 0 & 0 & 7 & 0 & 1 \\ 0 & 0 & 0 & 7 & -1 \\ -1 & 1 & -1 & 1 & 7 \end{bmatrix}.$$

Applying Gaussian elimination to A produces the following triangular factors:

$$A = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ -\frac{1}{7} & 1 & 0 & 0 & 0 \\ \frac{1}{7} & -\frac{1}{50} & 1 & 0 & 0 \\ -\frac{1}{7} & \frac{1}{50} & -\frac{1}{51} & 1 & 0 \\ \frac{1}{7} & -\frac{1}{50} & \frac{1}{51} & -\frac{1}{52} & 1 \end{bmatrix} \begin{bmatrix} 7 & 1 & -1 & 1 & -1 \\ 0 & \frac{50}{7} & -\frac{1}{7} & \frac{1}{7} & -\frac{1}{7} \\ 0 & 0 & \frac{357}{50} & -\frac{7}{50} & \frac{7}{50} \\ 0 & 0 & 0 & \frac{364}{51} & -\frac{7}{51} \\ 0 & 0 & 0 & 0 & \frac{371}{52} \end{bmatrix}.$$

Applying Gaussian elimination to B, on the other hand, produces the following triangular factors:

$$B = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ -\frac{1}{7} & \frac{1}{7} & -\frac{1}{7} & \frac{1}{7} & 1 \end{bmatrix} \begin{bmatrix} 7 & 0 & 0 & 0 & 1 \\ 0 & 7 & 0 & 0 & -1 \\ 0 & 0 & 7 & 0 & 1 \\ 0 & 0 & 0 & 7 & -1 \\ 0 & 0 & 0 & 0 & \frac{53}{7} \end{bmatrix}.$$

The two matrices A and B have the *same* numbers of nonzero elements, but their respective triangular factors have *very different* numbers of fill elements. In fact, the triangular factors of B have *no* fill elements. Note that B can be obtained by permuting the rows and columns of A. Let P be the following permutation matrix:

$$P = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

Then $B = PAP^T$; that is, B is obtained by *reversing* the order of the rows and columns in A. This example illustrates that permuting the rows and columns of a sparse matrix may have a drastic effect on the sparsity structures of the triangular factors in Gaussian elimination.

2. A popular way to exploit the sparsity structure of a sparse matrix during Gaussian elimination is to find elimination orderings so that the nonzero elements in the permuted matrix are near the diagonal. This can be accomplished, for example, by permuting the matrix so that it has a small envelope or profile. The Cuthill–McKee algorithm [CM69] and the reverse Cuthill–McKee algorithms [Geo71], [LS76] are well-known heuristics for producing reorderings that reduce the profile of a sparse symmetric matrix. The permuted matrix can be factored using the *envelope* or *profile* method [GL81], which is similar to the factorization methods for band matrices. The storage scheme for the profile method is very simple. The permuted matrix is stored by rows. If the symmetric matrix is positive definite, then for every row of the permuted matrix, all the elements between the first nonzero element and the diagonal elements are stored. It is easy to show that the fill elements in the triangular factor can only occur inside the envelope of the lower triangular part of the permuted matrix.
3. Although the profile method is easy to implement, it is not designed to reduce the number of fill elements in Gaussian elimination. The nested dissection algorithm [Geo73], which is based on a divide-and-conquer idea, is a well-known heuristic for preserving the sparsity structure. Let A be a symmetric positive definite matrix, and let $G = (X, E)$ be the (undirected) graph of A. Without loss of generality, assume that G is connected. Let $S \subseteq X$. Suppose that S is removed from G. Also assume that all edges incident to every vertex in S are removed from G. Denote the remaining graph by $G(X\backslash S)$. If S is chosen so that $G(X\backslash S)$ contains two or more disconnected components, then the set S is referred to as a *separator*. Consider the following reordering strategy: renumber the vertices of the disconnected components of $G(X\backslash S)$ first, and renumber the vertices of S last. Now pick a vertex x in one component and a vertex y in another component. The renumbering scheme ensures that there is *no* fill path between x and y in G. This is a heuristic way to limit the creation of fill elements. The renumbering corresponds to a symmetric permutation of the rows and columns of the matrix. Consider the example in Figure 53.8. The removal of the vertices in S (together with the incident edges) divides the mesh into two joint meshes (labeled G_1 and G_2). Suppose that the mesh points in G_1 are renumbered before those in G_2. Then the matrix on the right in Figure 53.8 shows the sparsity structure of the permuted matrix. Note the block structure of the permuted matrix. The blocks A_1 and A_2 correspond to mesh points in G_1 and G_2, respectively. The block A_S corresponds to the mesh points in S. The nonzero elements in the off-diagonal blocks C_1/C_2 correspond to the edges between G_1/G_2 and S. The unlabeled blocks are entirely zero. This is referred to as the "dissection" strategy. When the strategy is applied recursively to the disconnected components, more zero (but smaller) blocks will be created in A_1 and A_2. The resulting reordering is called a "nested dissection" ordering. It can be shown that, when the nested dissection algorithm is applied to a k by k mesh (like the example in the Introduction), the number of nonzero elements in the Cholesky factor will be $O(k^2 \log k)$ and the number

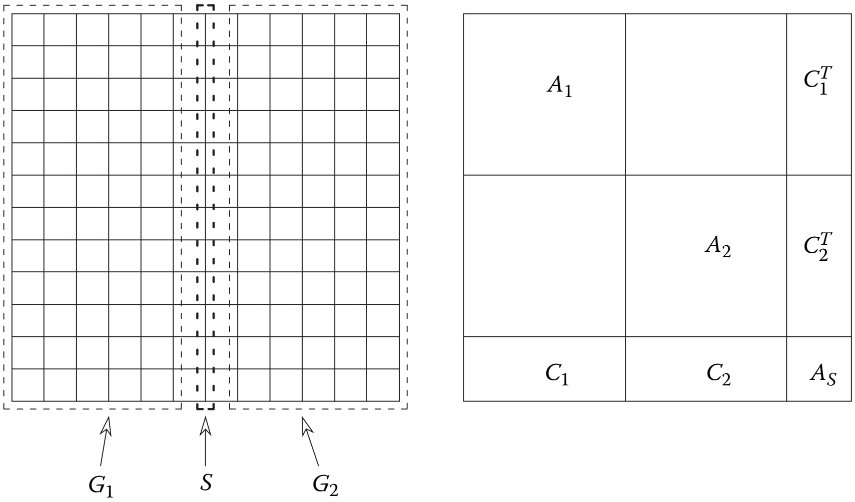

FIGURE 53.8 An example of the dissection strategy.

of operations required to compute the Cholesky factor will be $O(k^3)$. Incidentally, for the k by k mesh, it has been proved that the number of nonzero elements in the Cholesky factor and the number of operations required to compute the triangular factorization are at least $O(k^2 \log k)$ and $O(k^3)$, respectively [HMR73], [Geo73]. Thus, nested dissection orderings are optimal asymptotically. In recent years, higher quality nested dissection orderings have been obtained for general sparse symmetric matrices by using more sophisticated graph partitioning techniques to generate the separators [HR98], [PSL90], [Sch01].

4. The nested dissection algorithm is a "top-down" algorithm since it identifies the vertices (i.e., rows/columns) to be reordered last. The minimum degree algorithm [TW67] is a "bottom-up" algorithm for reordering rows and columns of a symmetric positive definite matrix. It is a heuristic that is best described using the elimination graphs. Let $G^{(0)}$ be the (undirected) graph of a sparse symmetric positive definite matrix. The minimum degree algorithm picks the vertex x_m with the *smallest* degree (i.e., the smallest number of incident edges) to be eliminated; that is, x_m is to be reordered as the first vertex. Then x_m, together with all the edges incident to x_m, are eliminated from $G^{(0)}$ to generate the next elimination graph $G^{(1)}$. This process is repeated until all the vertices are eliminated. The order in which the vertices are eliminated is a minimum degree ordering. Note that if several vertices have the minimum degree in the current elimination graph, then ties have to be broken. It is well known that the quality of a minimum degree ordering can be influenced by the choice of the tie-breaking strategy [BS90]. Several efficient implementations of the minimum degree algorithm are available [ADD96], [GL80b], [GL80a], [Liu85]. An excellent survey of the minimum degree algorithm can be found in [GL89]. It should be noted that the minimum degree algorithm is a heuristic for minimizing the number of operations in sparse Gaussian elimination, since the square of the degree of a vertex in an elimination graph is the number of nonzero elements involved in the rank-1 update when the row and column corresponding to that vertex are eliminated.
5. The minimum deficiency algorithm [TW67] is another bottom-up heuristic, but it is intended to minimize the number of fill elements introduced in sparse Gaussian elimination. It is similar to the minimum degree algorithm, except that the vertex whose elimination would introduce the *fewest* fill elements will be eliminated at each step. In general, the minimum deficiency algorithm is much more expensive to implement than the minimum degree algorithm. This is because the former one needs the *look-ahead* to predict the number of fill elements that would be introduced. However, inexpensive approximations to the minimum deficiency algorithms have been proposed recently [NR99], [RE98].

6. For an n by n sparse nonsymmetric matrix $A = [a_{i,j}]$, there are analogs of the minimum degree and minimum deficiency algorithms. The Markowitz scheme [Mar57] is the nonsymmetric version of the minimum degree algorithm for sparse nonsymmetric matrices. Recall that $\boldsymbol{nnz}(A_{i,1:n})$ is the number of nonzero elements in row i of A and $\boldsymbol{nnz}(A_{1:n,j})$ is the number of nonzero elements in column j of A. For each nonzero $a_{i,j}$ in A, define its "Markowitz" cost to be the product $[\boldsymbol{nnz}(A_{i,1:n})-1][\boldsymbol{nnz}(A_{1:n,j})-1]$, which would be the number of nonzero elements in the rank-1 update if $a_{i,j}$ were chosen as pivot. At each step of Gaussian elimination, the nonzero element that has the *smallest* Markowitz cost will be chosen as the pivot. After the elimination, the Markowitz costs of all the nonzero elements, including the fill elements, are updated to reflect the change in the sparsity structure before proceeding to the next step. If A is symmetric and positive definite, and if pivots are chosen from the diagonal, then the Markowitz scheme is the same as the minimum degree algorithm.
7. The Markowitz scheme for sparse nonsymmetric matrices attempts to preserve the sparsity structure by minimizing the number of nonzero elements in the rank-1 update at each step of Gaussian elimination. This process depends entirely on the sparsity structure of the matrix. However, the resulting pivots may not lead to a numerically stable factorization. For example, the magnitude of a pivot may be too small compared to the magnitudes of the other nonzero elements in the matrix. To enhance numerical stability, a modified Markowitz scheme is often used. Denote the matrix to be factored by $A = [a_{i,j}]$. Let $s = \max\{|a_{i,j}| : a_{i,j} \neq 0\}$. Let τ be a given tolerance; e.g., τ can be 0.01 or 0.001. Without loss of generality, consider the first step of Gaussian elimination of A. Instead of considering all nonzero elements in A, let $C = \{a_{i,j} : |a_{i,j}| \geq \tau\, s\}$. Thus, C is the subset of nonzero elements whose magnitudes are larger than or equal to $\tau\, s$; it is the set of candidate pivots. Then the pivot search is limited to applying the Markowitz scheme to the nonzero elements in C. This is a compromise between preserving sparsity and maintaining numerical stability. The two parameters τ and s are usually fixed throughout the entire Gaussian elimination process. The modified scheme is often referred to as the *threshold pivoting* scheme [Duf77].
8. As noted earlier, if Gaussian elimination with partial pivoting is used to factor a sparse nonsymmetric matrix A, then the columns may be permuted to preserve sparsity. Suppose that A has a zero-free diagonal, and let L_C be the Cholesky factor of the symmetric positive definite matrix $A^T A$. Since $\text{Struct}(L) \subseteq \text{Struct}(L_C)$ and $\text{Struct}(U) \subseteq \text{Struct}(L_C^T)$, a possibility is to make sure that L_C is sparse. In other words, one can choose a permutation P_{L_C} for $A^T A$ to reduce the number of nonzero elements in the Cholesky factor of $P_{L_C}^T (A^T A) P_{L_C}$. Note that $P_{L_C}^T (A^T A) P_{L_C} = (AP_{L_C})^T (AP_{L_C})$. Thus, P_{L_C} can be applied to the columns of A [GN85], [GN87].

Given an n by n nonsingular matrix A and an n-vector $\mathbf{b}$, the linear system $A\mathbf{x} = \mathbf{b}$ can always be solved for $\mathbf{x}$ by Gaussian elimination. The work required is approximately $2n^3/3$ operations (additions, subtractions, multiplications, and divisions), and, in general, n^2 words of storage are required. This is often acceptable if n is of moderate size, say $n \leq 1000$, but for much larger values of n, say, $n \approx 10^6$, both the work and storage for Gaussian elimination may become prohibitive.

Where do such large linear systems arise? They may occur in many different areas, but one important source is the numerical solution of partial differential equations (PDEs). Solutions to PDEs can be approximated by replacing derivatives by finite difference quotients. For example, to solve the equation

$$\frac{\partial}{\partial x}\left(a(x,y,z)\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(a(x,y,z)\frac{\partial u}{\partial y}\right) + \frac{\partial}{\partial z}\left(a(x,y,z)\frac{\partial u}{\partial z}\right) = f(x,y,z) \quad \text{in } \Omega$$
$$u = g \quad \text{on boundary of } \Omega,$$

on a three-dimensional region Ω, where a, f, and g are given functions with a bounded away from 0, one might first divide the region Ω into small subregions of width h in each direction, and then replace each partial derivative by a centered difference approximation; e.g.,

$$\begin{aligned}\frac{\partial}{\partial x}\left(a\frac{\partial u}{\partial x}\right)(x,y,z) \approx \frac{1}{h^2}[&a(x+h/2,y,z)(u(x+h,y,z)-u(x,y,z))\\ &-a(x-h/2,y,z)(u(x,y,z)-u(x-h,y,z))],\end{aligned}$$

with similar approximations for $\partial/\partial y(a\partial u/\partial y)$ and $\partial/\partial z(a\partial u/\partial z)$. If the resulting finite difference approximation to the differential operator is set equal to the right-hand side value $f(x_i, y_j, z_k)$ at each of the interior mesh points (x_i, y_j, z_k), $i = 1, \ldots, n_1$, $j = 1, \ldots, n_2$, $k = 1, \ldots, n_3$, then this gives a system of $n = n_1 n_2 n_3$ linear equations for the n unknown values of u at these mesh points. If u_{ijk} denotes the approximation to $u(x_i, y_j, z_k)$, then the equations are

$$\begin{aligned}
\frac{1}{h^2}[&a(x_i + h/2, y_j, z_k)(u_{i+1,j,k} - u_{ijk}) - a(x_i - h/2, y_j, z_k)(u_{ijk} - u_{i-1,j,k}) \\
&+ a(x_i, y_j + h/2, z_k)(u_{i,j+1,k} - u_{ijk}) - a(x_i, y_j - h/2, z_k)(u_{ijk} - u_{i,j-1,k}) \\
&+ a(x_i, y_j, z_k + h/2)(u_{i,j,k+1} - u_{ijk}) - a(x_i, y_j, z_k - h/2)(u_{ijk} - u_{i,j,k-1})] \\
&\quad = f(x_i, y_j, z_k).
\end{aligned}$$

The formula must be modified near the boundary of the region, where known boundary values are added to the right-hand side. Still the result is a system of linear equations for the unknown interior values of u. If $n_1 = n_2 = n_3 = 100$, then the number of equations and unknowns is $100^3 = 10^6$.

Notice, however, that the system of linear equations is *sparse*; each equation involves only a few (in this case seven) of the unknowns. The actual form of the system matrix A depends on the numbering of equations and unknowns. Using the *natural ordering*, equations and unknowns are ordered first by i, then j, then k. The result is a *banded* matrix, whose bandwidth is approximately $n_1 n_2$, since unknowns in any z plane couple only to those in the same and adjacent z planes. This results in some savings for Gaussian elimination. Only entries inside the band need be stored because these are the only ones that *fill in* (become nonzero, even if originally they were zero) during the process. The resulting work is about $2(n_1 n_2)^2 n$ operations, and the storage required is about $n_1 n_2 n$ words. Still, this is too much when $n_1 = n_2 = n_3 = 100$. Different orderings can be used to further reduce fill in, but another option is to use iterative methods.

Because the matrix is so sparse, matrix-vector multiplication is very cheap. In the above example, the product of the matrix with a given vector can be accomplished with just $7n$ multiplications and $6n$ additions. The nonzeros of the matrix occupy only $7n$ words and, in this case, they are so simple that they hardly need to be stored at all. If the linear system $Ax = b$ could be solved iteratively, using only matrix-vector multiplication and, perhaps, solution of some much simpler linear systems such as diagonal or sparse triangular systems, then a tremendous savings might be achieved in both work and storage.

This section describes how to solve such systems iteratively. While iterative methods are appropriate for sparse systems like the one above, they also may be useful for *structured systems*. If matrix-vector multiplication can be performed rapidly, and if the structure of the matrix is such that it is not necessary to store the entire matrix but only certain parts or values in order to carry out the matrix-vector multiplication, then iterative methods may be faster and require less storage than Gaussian elimination or other methods for solving $A\mathbf{x} = \mathbf{b}$.

54.1 Krylov Subspaces and Preconditioners

Definitions:

An **iterative method** for solving a linear system $A\mathbf{x} = \mathbf{b}$ is an algorithm that starts with an initial guess $\mathbf{x_0}$ for the solution and successively modifies that guess in an attempt to obtain improved approximate solutions $\mathbf{x_1}, \mathbf{x_2}, \ldots$.

The **residual** at step k of an iterative method for solving $A\mathbf{x} = \mathbf{b}$ is the vector $\mathbf{r_k} \equiv \mathbf{b} - A\mathbf{x_k}$, where $\mathbf{x_k}$ is the approximate solution generated at step k. The initial residual is $\mathbf{r_0} \equiv \mathbf{b} - A\mathbf{x_0}$, where $\mathbf{x_0}$ is the initial guess for the solution.

The **error** at step k is the difference between the true solution $A^{-1}\mathbf{b}$ and the approximate solution $\mathbf{x_k}$: $\mathbf{e_k} \equiv A^{-1}\mathbf{b} - \mathbf{x_k}$.

A **Krylov space** is a space of the form span$\{\mathbf{q}, A\mathbf{q}, A^2\mathbf{q}, \ldots, A^{k-1}\mathbf{q}\}$, where A is an n by n matrix and $\mathbf{q}$ is an n-vector. This space will be denoted as $K_k(A, \mathbf{q})$.

A **preconditioner** is a matrix M designed to improve the performance of an iterative method for solving the linear system $A\mathbf{x} = \mathbf{b}$. Linear systems with coefficient matrix M should be easier to solve than the original linear system, since such systems will be solved at each iteration.

The matrix $M^{-1}A$ (for **left preconditioning**) or AM^{-1} (for **right preconditioning**) or $L^{-1}AL^{-*}$ (for **Hermitian preconditioning**, when $M = LL^*$) is sometimes referred to as the **preconditioned iteration matrix**.

Another name for a preconditioner is a **splitting**; that is, if A is written in the form $A = M - N$, then this is referred to as a splitting of A, and iterative methods based on this splitting are equivalent to methods using M as a preconditioner.

A **regular splitting** is one for which M is nonsingular with $M^{-1} \geq 0$ (elementwise) and $M \geq A$ (elementwise).

Facts:

The following facts and general information on Krylov spaces and preconditioners can be found, for example, in [Axe95], [Gre97a], [Hac94], [Saa03], and [Vor03].

1. An iterative method may obtain the exact solution at some stage (in which case it might be considered a direct method), but it may still be thought of as an iterative method because the user is interested in obtaining a good approximate solution before the exact solution is reached.
2. Each iteration of an iterative method usually requires one or more matrix-vector multiplications, using the matrix A and possibly its Hermitian transpose A^*. An iteration may also require the solution of a preconditioning system $M\mathbf{z} = \mathbf{r}$.
3. The residual and error vector at step k of an iterative method are related by $\mathbf{r_k} = A\mathbf{e_k}$.
4. All of the iterative methods to be described in this chapter generate approximate solutions $\mathbf{x_k}$, $k = 1, 2, \ldots$, such that $\mathbf{x_k} - \mathbf{x_0}$ lies in the Krylov space span$\{\mathbf{z_0}, C\mathbf{z_0}, \ldots, C^{k-1}\mathbf{z_0}\}$, where $\mathbf{z_0}$ is the initial residual, possibly multiplied by a preconditioner, and C is the preconditioned iteration matrix.
5. The *Jacobi*, *Gauss-Seidel*, and *SOR (successive overrelaxation)* methods use the simple iteration
$$\mathbf{x_k} = \mathbf{x_{k-1}} + M^{-1}(\mathbf{b} - A\mathbf{x_{k-1}}), \quad k = 1, 2, \ldots,$$
with different preconditioners M. For the Jacobi method, M is taken to be the diagonal of A, while for the Gauss-Seidel method, M is the lower triangle of A. For the SOR method, M is of the form $\omega^{-1}D - L$, where D is the diagonal of A, $-L$ is the strict lower triangle of A, and ω is a relaxation parameter. Subtracting each side of this equation from the true solution $A^{-1}\mathbf{b}$, we find that the error at step k is
$$\mathbf{e_k} = (I - M^{-1}A)\mathbf{e_{k-1}} = \ldots = (I - M^{-1}A)^k\mathbf{e_0}.$$
Subtracting each side of this equation from $\mathbf{e_0}$, we find that $\mathbf{x_k}$ satisfies
$$\begin{aligned}\mathbf{e_0} - \mathbf{e_k} = \mathbf{x_k} - \mathbf{x_0} &= [I - (I - M^{-1}A)^k]\mathbf{e_0} \\ &= \left[\sum_{j=1}^{k} \binom{k}{j} (-1)^{j-1}(M^{-1}A)^{j-1}\right] \mathbf{z_0},\end{aligned}$$
where $\mathbf{z_0} = M^{-1}A\mathbf{e_0} = M^{-1}\mathbf{r_0}$. Thus, $\mathbf{x_k} - \mathbf{x_0}$ lies in the Krylov space

$$\operatorname{span}\{\mathbf{z_0}, (M^{-1}A)\mathbf{z_0}, \ldots, (M^{-1}A)^{k-1}\mathbf{z_0}\}.$$

6. Standard *multigrid methods* for solving linear systems arising from partial differential equations are also of the form $\mathbf{x_k} = \mathbf{x_{k-1}} + M^{-1}\mathbf{r_{k-1}}$. For these methods, computing $M^{-1}\mathbf{r_{k-1}}$ involves restricting the residual to a coarser grid or grids, solving (or iterating) with the linear system on those grids, and then prolonging the solution back to the finest grid.

Applications:

1. Figure 54.1 shows the convergence of the Jacobi, Gauss–Seidel, and SOR (with $\omega = 1.9$) iterative methods for the problem described at the beginning of this chapter, using a mildly varying coefficient $a(x, y, z) = 1 + x + 3yz$ on the unit cube $\Omega = [0, 1] \times [0, 1] \times [0, 1]$ with homogeneous Dirichlet boundary conditions, $u = 0$ on $\partial\Omega$. The right-hand side function f was chosen so that the solution to the differential equation would be $u(x, y, z) = x(1 - x)y^2(1 - y)z(1 - z)^2$. The region was discretized using a $50 \times 50 \times 50$ mesh, and the natural ordering of nodes was used, along with a zero initial guess.

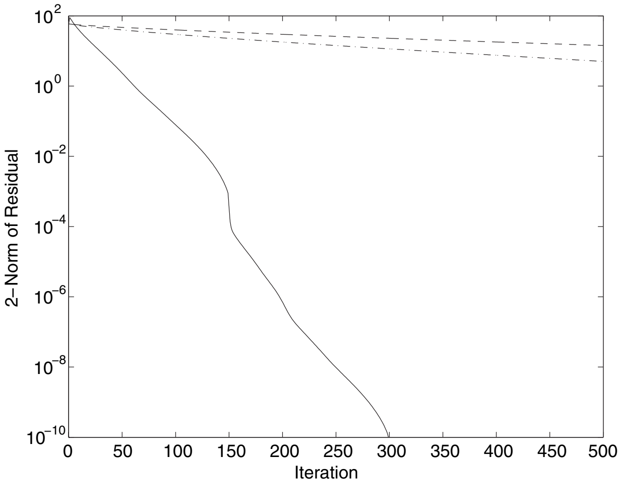

FIGURE 54.1 Convergence of iterative methods for the problem given in the introduction with $a(x, y, z) = 1 + x + 3yz$, $h = 1/50$. Jacobi (dashed), Gauss–Seidel (dash-dot), and SOR with $\omega = 1.9$ (solid).

54.2 Optimal Krylov Space Methods for Hermitian Problems

Throughout this section, we let A and b denote the already preconditioned matrix and right-hand side vector, and we assume that A is Hermitian. Note that if the original coefficient matrix is Hermitian, then this requires Hermitian positive definite preconditioning (preconditioner of the form $M = LL^*$ and preconditioned matrix of the form $L^{-1}AL^{-*}$) in order to maintain this property.

Definitions:

The **Minimal Residual (MINRES)** algorithm generates, at each step k, the approximation $\mathbf{x_k}$ with $\mathbf{x_k} - \mathbf{x_0} \in K_k(A, \mathbf{r_0})$ for which the 2-norm of the residual, $\|\mathbf{r_k}\| \equiv \langle \mathbf{r_k}, \mathbf{r_k} \rangle^{1/2}$, is minimal.

The **Conjugate Gradient (CG)** algorithm for Hermitian positive definite matrices generates, at each step k, the approximation $\mathbf{x_k}$ with $\mathbf{x_k} - \mathbf{x_0} \in K_k(A, \mathbf{r_0})$ for which the A-norm of the error, $\|\mathbf{e_k}\|_A \equiv \langle \mathbf{e_k}, A\mathbf{e_k}\rangle^{1/2}$, is minimal. (Note that this is sometimes referred to as the $A^{1/2}$-norm of the error, e.g., in Chapter 50 of this book.)

The **Lanczos** algorithm for Hermitian matrices is a short recurrence for constructing an orthonormal basis for a Krylov space.

Facts:

The following facts can be found in any of the general references [Axe95], [Gre97a], [Hac94], [Saa03], and [Vor03].

1. The Lanczos algorithm [Lan50] is implemented as follows:

```
Lanczos Algorithm. (For Hermitian matrices $A$)

Given $\mathbf{q_1}$ with $\|\mathbf{q_1}\| = 1$, set $\beta_0 = 0$.
For $j = 1, 2, \ldots,$
    $\tilde{\mathbf{q}}_{\mathbf{j+1}} = A\mathbf{q_j} - \beta_{j-1}\mathbf{q_{j-1}}$. Set $\alpha_j = \langle \tilde{\mathbf{q}}_{\mathbf{j+1}}, \mathbf{q_j}\rangle$,   $\tilde{\mathbf{q}}_{\mathbf{j+1}} \longleftarrow \tilde{\mathbf{q}}_{\mathbf{j+1}} - \alpha_j \mathbf{q_j}$.
    $\beta_j = \|\tilde{\mathbf{q}}_{\mathbf{j+1}}\|$,   $\mathbf{q_{j+1}} = \tilde{\mathbf{q}}_{\mathbf{j+1}}/\beta_j$.
```

2. It can be shown by induction that the Lanczos vectors $\mathbf{q_1}, \mathbf{q_2}, \ldots$ produced by the above algorithm are orthogonal. Gathering the first k vectors together as the columns of an n by k matrix Q_k, this recurrence can be written succinctly in the form

$$AQ_k = Q_k T_k + \beta_k \mathbf{q_{k+1}} \boldsymbol{\xi_k}^T,$$

where $\boldsymbol{\xi_k} \equiv (0, \ldots, 0, 1)^T$ is the kth unit vector and T_k is the tridiagonal matrix of recurrence coefficients:

$$T_k \equiv \begin{pmatrix} \alpha_1 & \beta_1 & & \\ \beta_1 & \ddots & \ddots & \\ & \ddots & \ddots & \beta_{k-1} \\ & & \beta_{k-1} & \alpha_k \end{pmatrix}.$$

The above equation is sometimes written in the form

$$AQ_k = Q_{k+1}\underline{T}_k,$$

where $\underline{T}_k$ is the $k+1$ by k matrix whose top k by k block is T_k and whose bottom row is zero except for the last entry which is β_k.

3. If the initial vector $\mathbf{q_1}$ in the Lanczos algorithm is taken to be $\mathbf{q_1} = \mathbf{r_0}/\|\mathbf{r_0}\|$, then the columns of Q_k span the Krylov space $K_k(A, \mathbf{r_0})$. Both the MINRES and CG algorithms take the approximation $\mathbf{x_k}$ to be of the form $\mathbf{x_0} + Q_k\mathbf{y_k}$ for a certain vector $\mathbf{y_k}$. For the MINRES algorithm, $\mathbf{y_k}$ is the solution of the $k+1$ by k least squares problem

$$\min_{\mathbf{y}} \|\beta\boldsymbol{\xi_1} - \underline{T}_k\mathbf{y}\|,$$

where $\beta \equiv \|\mathbf{r_0}\|$ and $\boldsymbol{\xi_1} \equiv (1, 0, \ldots, 0)^T$ is the first unit vector. For the CG algorithm, $\mathbf{y_k}$ is the solution of the k by k tridiagonal system

$$T_k\mathbf{y} = \beta\boldsymbol{\xi_1}.$$

4. The following algorithms are standard implementations of the CG and MINRES methods.

```
Conjugate Gradient Method (CG).
 (For Hermitian Positive Definite Problems)
Given an initial guess $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$ and set $\mathbf{p_0} = \mathbf{r_0}$.
For $k = 1, 2, \ldots$,
    Compute $A\mathbf{p_{k-1}}$.
    Set $\mathbf{x_k} = \mathbf{x_{k-1}} + a_{k-1}\mathbf{p_{k-1}}$,   where   $a_{k-1} = \frac{\langle \mathbf{r_{k-1}}, \mathbf{r_{k-1}} \rangle}{\langle \mathbf{p_{k-1}}, A\mathbf{p_{k-1}} \rangle}$ .
    Compute $\mathbf{r_k} = \mathbf{r_{k-1}} - a_{k-1}A\mathbf{p_{k-1}}$.
    Set $\mathbf{p_k} = \mathbf{r_k} + b_{k-1}\mathbf{p_{k-1}}$, where $b_{k-1} = \frac{\langle \mathbf{r_k}, \mathbf{r_k} \rangle}{\langle \mathbf{r_{k-1}}, \mathbf{r_{k-1}} \rangle}$ .
```

```
Minimal Residual Algorithm (MINRES). (For Hermitian Problems)
Given $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$ and set $\mathbf{q_1} = \mathbf{r_0}/\|\mathbf{r_0}\|$.
Initialize $\xi = (1, 0, \ldots, 0)^T$, $\beta = \|\mathbf{r_0}\|$.
For $k = 1, 2, \ldots$,
    Compute $\mathbf{q_{k+1}}$, $\alpha_k \equiv T(k,k)$, and $\beta_k \equiv T(k+1,k) \equiv T(k,k+1)$ using
      the Lanczos algorithm.
    Apply rotations $F_{k-2}$ and $F_{k-1}$ to the last column of $T$; that is,
        $\begin{pmatrix} T(k-2,k) \\ T(k-1,k) \end{pmatrix} \leftarrow \begin{pmatrix} c_{k-2} & s_{k-2} \\ -\bar{s}_{k-2} & c_{k-2} \end{pmatrix} \begin{pmatrix} 0 \\ T(k-1,k) \end{pmatrix}$,  if $k > 2$,
        $\begin{pmatrix} T(k-1,k) \\ T(k,k) \end{pmatrix} \leftarrow \begin{pmatrix} c_{k-1} & s_{k-1} \\ -\bar{s}_{k-1} & c_{k-1} \end{pmatrix} \begin{pmatrix} T(k-1,k) \\ T(k,k) \end{pmatrix}$,  if $k > 1$.
    Compute the $k^{th}$ rotation, $c_k$ and $s_k$, to annihilate the $(k+1,k)$ entry of $T$:
    $c_k = |T(k,k)|/\sqrt{|T(k,k)|^2 + |T(k+1,k)|^2}$, $\bar{s}_k = c_k T(k+1,k)/T(k,k)$.
    Apply $k^{th}$ rotation to $\xi$ and to last column of $T$:
        $\begin{pmatrix} \xi(k) \\ \xi(k+1) \end{pmatrix} \leftarrow \begin{pmatrix} c_k & s_k \\ -\bar{s}_k & c_k \end{pmatrix} \begin{pmatrix} \xi(k) \\ 0 \end{pmatrix}$.
        $T(k,k) \leftarrow c_k T(k,k) + s_k T(k+1,k)$,   $T(k+1,k) \leftarrow 0$.
    Compute $\mathbf{p_{k-1}} = [\mathbf{q_k} - T(k-1,k)\mathbf{p_{k-2}} - T(k-2,k)\mathbf{p_{k-3}}]/T(k,k)$,
      where undefined terms are zero for $k \leq 2$.
    Set $\mathbf{x_k} = \mathbf{x_{k-1}} + a_{k-1}\mathbf{p_{k-1}}$, where $a_{k-1} = \beta\xi(k)$.
```

5. In exact arithmetic, both the CG and the MINRES algorithms obtain the exact solution in at most n steps, since the affine space $\mathbf{x_0} + K_n(A, \mathbf{r_0})$ contains the true solution.

Applications:

1. Figure 54.2 shows the convergence (in terms of the 2-norm of the residual) of the (unpreconditioned) CG and MINRES algorithms for the same problem used in the previous section.

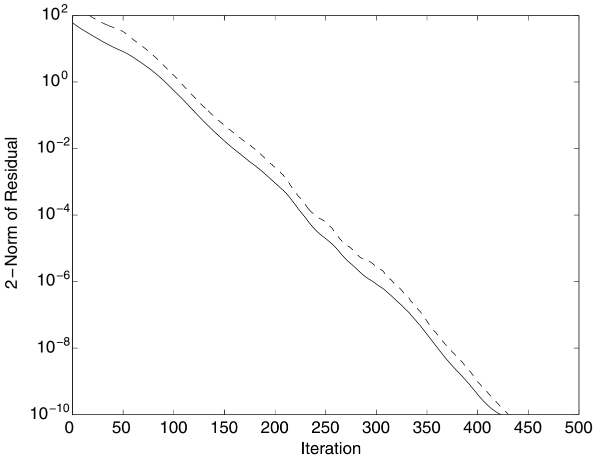

FIGURE 54.2 Convergence of MINRES (solid) and CG (dashed) for the problem given in the introduction with $a(x, y, z) = 1 + x + 3yz$, $h = 1/50$.

Note that the 2-norm of the residual decreases monotonically in the MINRES algorithm, but not in the CG algorithm. Had we instead plotted the A-norm of the error, then the CG convergence curve would have been below that for MINRES.

54.3 Optimal and Nonoptimal Krylov Space Methods for Non-Hermitian Problems

In this section, we again let A and $\mathbf{b}$ denote the already preconditioned matrix and right-hand side vector. The matrix A is assumed to be a general nonsingular n by n matrix.

Definitions:

The **Generalized Minimal Residual (GMRES)** algorithm generates, at each step k, the approximation $\mathbf{x_k}$ with $\mathbf{x_k} - \mathbf{x_0} \in K_k(A, \mathbf{r_0})$ for which the 2-norm of the residual is minimal.

The **Full Orthogonalization Method (FOM)** generates, at each step k, the approximation $\mathbf{x_k}$ with $\mathbf{x_k} - \mathbf{x_0} \in K_k(A, \mathbf{r_0})$ for which the residual is orthogonal to the Krylov space $K_k(A, \mathbf{r_0})$.

The **Arnoldi algorithm** is a method for constructing an orthonormal basis for a Krylov space that requires saving all of the basis vectors and orthogonalizing against them at each step.

The **restarted GMRES algorithm**, GMRES(j), is defined by simply restarting GMRES every j steps, using the latest iterate as the initial guess for the next GMRES cycle. Sometimes partial information from the previous GMRES cycle is retained and used after the restart.

The **non-Hermitian (or two-sided) Lanczos algorithm** uses a pair of three-term recurrences involving A and A^* to construct **biorthogonal** bases for the Krylov spaces $K_k(A, \mathbf{r_0})$ and $K_k(A^*, \hat{\mathbf{r}}_\mathbf{0})$, where $\hat{\mathbf{r}}_\mathbf{0}$ is a given vector with $\langle \mathbf{r_0}, \hat{\mathbf{r}}_\mathbf{0} \rangle \neq 0$. If the vectors $\mathbf{v_1}, \ldots, \mathbf{v_k}$ are the basis vectors for $K_k(A, \mathbf{r_0})$, and $\mathbf{w_1}, \ldots, \mathbf{w_k}$ are the basis vectors for $K_k(A^*, \hat{\mathbf{r}}_\mathbf{0})$, then $\langle \mathbf{v_i}, \mathbf{w_j} \rangle = 0$ for $i \neq j$.

In the **BiCG** (biconjugate gradient) method, the approximate solution $\mathbf{x_k}$ is chosen so that the residual $\mathbf{r_k}$ is orthogonal to $K_k(A^*, \hat{\mathbf{r}}_\mathbf{0})$.

In the **QMR** (quasi-minimal residual) algorithm, the approximate solution $\mathbf{x_k}$ is chosen to minimize a quantity that is related to (but not necessarily equal to) the residual norm.

The **CGS** (conjugate gradient squared) algorithm constructs an approximate solution $\mathbf{x_k}$ for which $\mathbf{r_k} = \varphi_k^2(A)\mathbf{r_0}$, where $\varphi_k(A)$ is the kth degree polynomial constructed in the BiCG algorithm; that is, the BiCG residual at step k is $\varphi_k(A)\mathbf{r_0}$.

The **BiCGSTAB** algorithm combines CGS with a one or more step residual norm minimizing method to smooth out the convergence.

The **IDR** (induced dimension reduction) method also produces a residual polynomial that is the product of the BiCG polynomial with a locally minimizing one. Residuals are forced to be in a sequence of nested subspaces.

Facts:

1. The Arnoldi algorithm [Arn51] is implemented as follows:

Arnoldi Algorithm.

```
Given $\mathbf{q_1}$ with $\|\mathbf{q_1}\| = 1$.
For $j = 1, 2, \ldots,$
  $\mathbf{\tilde{q}_{j+1}} = A\mathbf{q_j}$.
  For $i = 1, \ldots, j,$
    $h_{ij} = \langle \mathbf{\tilde{q}_{j+1}}, \mathbf{q_i} \rangle, \quad \mathbf{\tilde{q}_{j+1}} \longleftarrow \mathbf{\tilde{q}_{j+1}} - h_{ij}\mathbf{q_i}$.
  $h_{j+1,j} = \|\mathbf{\tilde{q}_{j+1}}\|, \quad \mathbf{q_{j+1}} = \mathbf{\tilde{q}_{j+1}}/h_{j+1,j}$.
```

2. Unlike the Hermitian case, if A is non-Hermitian then there is no known algorithm for finding the optimal approximations from successive Krylov spaces, while performing only $O(n)$ operations per iteration. In fact, a theorem due to Faber and Manteuffel [FM84] shows that for most non-Hermitian matrices A there is no short recurrence that generates these optimal approximations for successive values $k = 1, 2, \ldots$. Hence, the current options for non-Hermitian problems are either to perform extra work ($O(nk)$ operations at step k) and use extra storage ($O(nk)$ words to perform k iterations) to find optimal approximations from the successive Krylov subspaces or to settle for nonoptimal approximations. The (full) GMRES (generalized minimal residual) algorithm [SS86] finds the approximation for which the 2-norm of the residual is minimal, at the cost of this extra work and storage, while other non-Hermitian iterative methods (e.g., BiCG [Fle75], CGS [Son89], QMR [FN91], BiCGSTAB [Vor92], IDR [SG08], and restarted GMRES [SS86], [Mor95], [DeS99]) generate nonoptimal approximations.
3. Similar to the MINRES algorithm, the GMRES algorithm uses the Arnoldi iteration defined above to construct an orthonormal basis for the Krylov space $K_k(A, \mathbf{r_0})$.

   If Q_k is the n by k matrix with the orthonormal basis vectors $\mathbf{q_1}, \ldots, \mathbf{q_k}$ as columns, then the Arnoldi iteration can be written simply as

$$AQ_k = Q_k H_k + h_{k+1,k}\mathbf{q_{k+1}}\xi_{\mathbf{k}}{}^T = Q_{k+1}\underline{H}_k.$$

   Here H_k is the k by k upper Hessenberg matrix with (i, j) entry equal to h_{ij}, and $\underline{H}_k$ is the $k+1$ by k matrix whose upper k by k block is H_k and whose bottom row is zero except for the last entry, which is $h_{k+1,k}$.

   If $\mathbf{q_1} = \mathbf{r_0}/\|\mathbf{r_0}\|$, then the columns of Q_k span the Krylov space $K_k(A, \mathbf{r_0})$, and the GMRES approximation is taken to be of the form $\mathbf{x_k} = \mathbf{x_0} + Q_k\mathbf{y_k}$ for some vector $\mathbf{y_k}$. To minimize the 2-norm of the residual, the vector $\mathbf{y_k}$ is chosen to solve the least squares problem

$$\min_{\mathbf{y}} \|\beta\xi_{\mathbf{1}} - \underline{H}_k\mathbf{y}\|, \quad \beta \equiv \|\mathbf{r_0}\|.$$

The GMRES algorithm [SS86] can be implemented as follows:

Generalized Minimal Residual Algorithm (GMRES).

```
Given $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$ and set $\mathbf{q_1} = \mathbf{r_0}/\|\mathbf{r_0}\|$.
Initialize $\xi = (1, 0, \ldots, 0)^T$, $\beta = \|\mathbf{r_0}\|$.
For $k = 1, 2, \ldots$,
    Compute $\mathbf{q_{k+1}}$ and $h_{i,k} \equiv H(i,k)$, $i = 1, \ldots, k+1$, using the Arnoldi algorithm.
    Apply rotations $F_1, \ldots, F_{k-1}$ to the last column of $H$; that is,
    For $i = 1, \ldots, k-1$,
        $\begin{pmatrix} H(i,k) \\ H(i+1,k) \end{pmatrix} \leftarrow \begin{pmatrix} c_i & s_i \\ -\bar{s}_i & c_i \end{pmatrix} \begin{pmatrix} H(i,k) \\ H(i+1,k) \end{pmatrix}.$
    Compute the $k^{th}$ rotation, $c_k$ and $s_k$, to annihilate the $(k+1,k)$ entry of $H$:
    $c_k = |H(k,k)|/\sqrt{|H(k,k)|^2 + |H(k+1,k)|^2}$, $\bar{s}_k = c_k H(k+1,k)/H(k,k)$.
    Apply $k^{th}$ rotation to $\xi$ and to last column of $H$:
        $\begin{pmatrix} \xi(k) \\ \xi(k+1) \end{pmatrix} \leftarrow \begin{pmatrix} c_k & s_k \\ -\bar{s}_k & c_k \end{pmatrix} \begin{pmatrix} \xi(k) \\ 0 \end{pmatrix}$
        $H(k,k) \leftarrow c_k H(k,k) + s_k H(k+1,k), \quad H(k+1,k) \leftarrow 0.$
    If residual norm estimate $\beta|\xi(k+1)|$ is sufficiently small, then
        Solve upper triangular system $H_{k \times k}\ \mathbf{y_k} = \beta\ \xi_{k \times 1}$.
        Compute $\mathbf{x_k} = \mathbf{x_0} + Q_k \mathbf{y_k}$.
```

4. The (full) GMRES algorithm described above may be impractical because of increasing storage and work requirements, if the number of iterations needed to solve the linear system is large. In this case, the restarted GMRES algorithm or one of the algorithms based on the non-Hermitian Lanczos process may provide a reasonable alternative. The BiCGSTAB algorithm [Vor92] and the IDR algorithm [SG08] are often among the most effective iteration methods for solving non-Hermitian linear systems. The BiCGSTAB algorithm can be written as follows:

BiCGSTAB.

```
Given $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$ and set $\mathbf{p_0} = \mathbf{r_0}$.
Choose $\mathbf{\hat{r}_0}$ such that $\langle \mathbf{r_0}, \mathbf{\hat{r}_0} \rangle \neq 0$.
For $k = 1, 2, \ldots$,
    Compute $A\mathbf{p_{k-1}}$.
    Set $\mathbf{x_{k-1/2}} = \mathbf{x_{k-1}} + a_{k-1}\mathbf{p_{k-1}}$, where $a_{k-1} = \frac{\langle \mathbf{r_{k-1}}, \mathbf{\hat{r}_0} \rangle}{\langle A\mathbf{p_{k-1}}, \mathbf{\hat{r}_0} \rangle}$.
    Compute $\mathbf{r_{k-1/2}} = \mathbf{r_{k-1}} - a_{k-1} A\mathbf{p_{k-1}}$.
    Compute $A\mathbf{r_{k-1/2}}$.
    Set $\mathbf{x_k} = \mathbf{x_{k-1/2}} + \omega_k \mathbf{r_{k-1/2}}$, where $\omega_k = \frac{\langle \mathbf{r_{k-1/2}}, A\mathbf{r_{k-1/2}} \rangle}{\langle A\mathbf{r_{k-1/2}}, A\mathbf{r_{k-1/2}} \rangle}$.
    Compute $\mathbf{r_k} = \mathbf{r_{k-1/2}} - \omega_k A\mathbf{r_{k-1/2}}$.
    Compute $\mathbf{p_k} = \mathbf{r_k} + b_k(\mathbf{p_{k-1}} - \omega_k A\mathbf{p_{k-1}})$, where $b_k = \frac{a_{k-1}}{\omega_k} \frac{\langle \mathbf{r_k}, \mathbf{\hat{r}_0} \rangle}{\langle \mathbf{r_{k-1}}, \mathbf{\hat{r}_0} \rangle}$.
```

5. The non-Hermitian Lanczos algorithm can break down if $\langle \mathbf{v_i}, \mathbf{w_i} \rangle = 0$, but neither $\mathbf{v_i}$ nor $\mathbf{w_i}$ is zero. In this case *look-ahead* strategies have been devised to skip steps at which the Lanczos vectors are undefined. See, for instance, [PTL85], [Nac91], and [FN91]. These look-ahead procedures are used in the QMR algorithm.
6. When A is Hermitian and $\mathbf{\hat{r}_0} = \mathbf{r_0}$, the BiCG method reduces to the CG algorithm, while the QMR method reduces to the MINRES algorithm.
7. The question of which iterative method to use is, of course, an important one. Unfortunately, there is no straightforward answer. It is problem dependent and may depend also on the type of machine being used. If matrix-vector multiplication is very expensive (e.g., if A is dense and has no special properties to enable fast matrix-vector multiplication), then full GMRES is probably the method of choice because it requires the fewest matrix-vector multiplications to reduce the residual norm to a desired level. If matrix-vector multiplication is not so expensive or if storage becomes a problem for full GMRES, then a restarted GMRES algorithm, some variant of the QMR method, or some variant of BiCGSTAB or IDR may be a reasonable alternative. With a sufficiently good preconditioner, each of these iterative methods can be expected to find a good approximate solution quickly. In fact, with a sufficiently good preconditioner M, an even simpler iteration method such as $\mathbf{x_k} = \mathbf{x_{k-1}} + M^{-1}(\mathbf{b} - A\mathbf{x_{k-1}})$ may converge in just a few iterations, and this avoids the cost of inner products and other things in the more sophisticated Krylov space methods.

Applications:

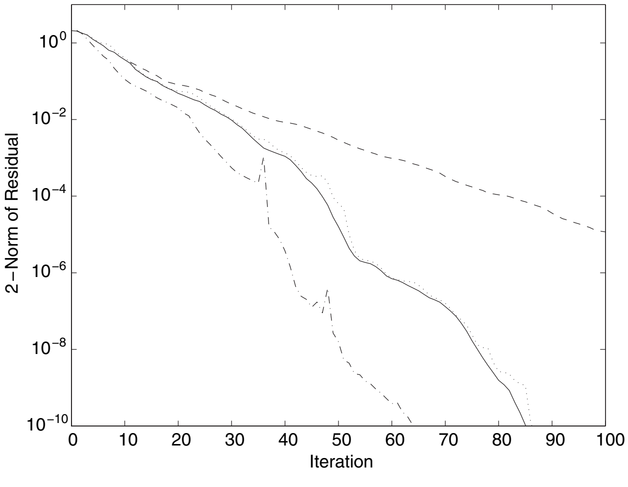

FIGURE 54.3 Convergence of full GMRES (solid), restarted GMRES (restarted every 10 steps) (dashed), QMR (dotted), and BiCGSTAB (dash-dot) for a problem from neutron transport. For GMRES (full or restarted), the number of matrix-vector multiplications is the same as the number of iterations, while for QMR and BiCGSTAB, the number of matrix-vector multiplications is *twice* the number of iterations.

1. To illustrate the behavior of iterative methods for solving non-Hermitian linear systems, we have taken a simple problem involving the Boltzmann transport equation in one dimension:

$$\mu \frac{\partial \psi}{\partial x} + \sigma_T \psi - \sigma_s \phi = f, \quad x \in [a, b], \quad \mu \in [-1, 1],$$

where

$$\phi(x) = \frac{1}{2} \int_{-1}^{1} \psi(x, \mu')\, d\mu',$$

with boundary conditions

$$\psi(b,\mu)=\psi_b(\mu),\quad -1\le\mu<0,$$
$$\psi(a,\mu)=\psi_a(\mu),\quad 0<\mu\le 1.$$

The difference method used is described in [Gre97a], and a test problem from [ML82] was solved. Figure 54.3 shows the convergence of full GMRES, restarted GMRES (restarted every 10 steps), QMR, and BiCGSTAB. One should keep in mind that each iteration of the QMR algorithm requires *two* matrix-vector multiplications, one with A and one with A^*. Still, the QMR approximation at iteration k lies in the k-dimensional affine space $\mathbf{x_0}+\text{span}\{\mathbf{r_0},A\mathbf{r_0},\ldots,A^{k-1}\mathbf{r_0}\}$. Each iteration of the BiCGSTAB algorithm requires *two* matrix-vector multiplications with A, and the approximate solution generated at step k lies in the $2k$-dimensional affine space $\mathbf{x_0}+\text{span}\{\mathbf{r_0},A\mathbf{r_0},\ldots,A^{2k-1}\mathbf{r_0}\}$. The full GMRES algorithm finds the optimal approximation from this space at step $2k$. Thus, the GMRES residual norm at step $2k$ is guaranteed to be less than or equal to the BiCGSTAB residual norm at step k, and each requires the *same* number of matrix-vector multiplications to compute.

54.4 Preconditioners

Definitions:

An **incomplete Cholesky decomposition** is a preconditioner for a Hermitian positive definite matrix A of the form $M=LL^*$, where L is a sparse lower triangular matrix. The entries of L are chosen so that certain entries of LL^* match those of A. If L is taken to have the same sparsity pattern as the lower triangle of A, then its entries are chosen so that LL^* matches A in the positions where A has nonzeros.

A **modified incomplete Cholesky decomposition** is a preconditioner of the same form $M=LL^*$ as the incomplete Cholesky preconditioner, but the entries of L are modified so that instead of having M match as many entries of A as possible, the preconditioner M has certain other properties, such as the same row sums as A.

An **incomplete** ***LU*** **decomposition** is a preconditioner for a general matrix A of the form $M=LU$, where L and U are sparse lower and upper triangular matrices, respectively. The entries of L and U are chosen so that certain entries of LU match the corresponding entries of A.

A **sparse approximate inverse** is a sparse matrix M^{-1} constructed to approximate A^{-1}.

A **multigrid** preconditioner is a preconditioner designed for problems arising from partial differential equations discretized on grids. Solving the preconditioning system $Mz=r$ entails *restricting* the residual to coarser grids, performing relaxation steps for the linear system corresponding to the same differential operator on the coarser grids, and *prolonging* solutions back to finer grids.

An **algebraic multigrid** preconditioner is a preconditioner that uses principles similar to those used for PDE problems on grids, when the "grid" for the problem is unknown or nonexistent and only the matrix is available.

Facts:

1. If A is an M-matrix, then for every subset S of off-diagonal indices, there exists a lower triangular matrix $L=[l_{ij}]$ with unit diagonal and an upper triangular matrix $U=[u_{ij}]$ such that $A=LU-R$, where

$$l_{ij}=0\ \text{ if } (i,j)\in S,\quad u_{ij}=0\ \text{ if } (i,j)\in S,\quad \text{and}\quad r_{ij}=0\ \text{ if } (i,j)\notin S.$$

The factors L and U are unique and the splitting $A=LU-R$ is a regular splitting [Var60, MV77]. The idea of generating such approximate factorizations was considered by a number of people, one of the first of whom was Varga [Var60]. The idea became popular when it was used by Meijerink and van der Vorst to generate preconditioners for the conjugate gradient method and related iterations [MV77]. It has proved a successful technique in a range of applications and is now widely used with many variations. For example, instead of specifying the sparsity pattern of L, one might begin to compute the entries of the exact L-factor and set entries to 0 if they fall below some threshold (see, e.g., [Mun80]).

2. For a real symmetric positive definite matrix A arising from a standard finite difference or finite element approximation for a second order self-adjoint elliptic partial differential equation on a grid with spacing h, the condition number of A is $O(h^{-2})$. When A is preconditioned using the incomplete Cholesky decomposition LL^T, where L has the same sparsity pattern as the lower triangle of A, the condition number of the preconditioned matrix $L^{-1}AL^{-T}$ is still $O(h^{-2})$, but the constant multiplying h^{-2} is smaller. When A is preconditioned using the modified incomplete Cholesky decomposition, the condition number of the preconditioned matrix is $O(h^{-1})$ [DKR68, Gus78].
3. For a general matrix A, the incomplete LU decomposition can be used as a preconditioner in a non-Hermitian matrix iteration such as GMRES, QMR, or BiCGSTAB. At each step of the preconditioned algorithm one must solve a linear system $M\mathbf{z} = \mathbf{r}$. This is accomplished by first solving the lower triangular system $L\mathbf{y} = \mathbf{r}$ and then solving the upper triangular system $U\mathbf{z} = \mathbf{y}$.
4. One difficulty with incomplete Cholesky and incomplete LU decompositions is that the solution of the triangular systems may not parallelize well. In order to make better use of parallelism, sparse approximate inverses have been proposed as preconditioners. Here, a sparse matrix M^{-1} is constructed directly to approximate A^{-1}, and each step of the iteration method requires computation of a matrix-vector product $\mathbf{z} = M^{-1}\mathbf{r}$. For an excellent recent survey of all of these preconditioning methods, see [Ben02].
5. Multigrid methods have the very desirable property that for many problems arising from elliptic PDEs the number of cycles required to reduce the error to a desired fixed level is independent of the grid size. This is in contrast to methods such as ICCG and MICCG (incomplete and modified incomplete Cholesky decomposition used as preconditioners in the CG algorithm). Early developers of multigrid methods include Fedorenko [Fed61] and later Brandt [Bra77]. A very readable and up-to-date introduction to the subject can be found in [BHM00].
6. Algebraic multigrid methods represent an attempt to use principles similar to those used for PDE problems on grids, when the origin of the problem is not necessarily known and only the matrix is available. An example is the AMG code by Ruge and Stüben [RS87]. The AMG method attempts to achieve mesh-independent convergence rates, just like standard multigrid methods, without making use of the underlying grid. A related class of preconditioners are *domain decomposition* methods. (See [QV99] and [SBG96] for recent surveys.)

54.5 Preconditioned Algorithms

Facts:

1. It is easy to modify the algorithms of the previous sections to use left preconditioning: Simply replace A by $M^{-1}A$ and $\mathbf{b}$ by $M^{-1}\mathbf{b}$ wherever they appear. Since one need not actually compute M^{-1}, this is equivalent to solving linear systems with coefficient matrix M for the preconditioned quantities. For example, letting $\mathbf{z_k}$ denote the preconditioned residual $M^{-1}(\mathbf{b} - A\mathbf{x_k})$, the left-preconditioned BiCGSTAB algorithm is as follows:

Left-Preconditioned BiCGSTAB.

```
Given $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$, solve $M\mathbf{z_0} = \mathbf{r_0}$, and set $\mathbf{p_0} = \mathbf{z_0}$.
Choose $\hat{\mathbf{z}}_\mathbf{0}$ such that $\langle \mathbf{z_0}, \hat{\mathbf{z}}_\mathbf{0} \rangle \neq 0$.
For $k = 1, 2, \ldots$,
    Compute $A\mathbf{p_{k-1}}$ and solve $M\mathbf{q_{k-1}} = A\mathbf{p_{k-1}}$.
    Set $\mathbf{x_{k-1/2}} = \mathbf{x_{k-1}} + a_{k-1}\mathbf{p_{k-1}}$, where $a_{k-1} = \frac{\langle \mathbf{z_{k-1}}, \hat{\mathbf{z}}_\mathbf{0} \rangle}{\langle \mathbf{q_{k-1}}, \hat{\mathbf{z}}_\mathbf{0} \rangle}$.
    Compute $\mathbf{r_{k-1/2}} = \mathbf{r_{k-1}} - a_{k-1}A\mathbf{p_{k-1}}$ and $\mathbf{z_{k-1/2}} = \mathbf{z_{k-1}} - a_{k-1}\mathbf{q_{k-1}}$.
    Compute $A\mathbf{z_{k-1/2}}$ and solve $M\mathbf{s_{k-1/2}} = A\mathbf{z_{k-1/2}}$.
    Set $\mathbf{x_k} = \mathbf{x_{k-1/2}} + \omega_k\mathbf{z_{k-1/2}}$, where $\omega_k = \frac{\langle \mathbf{z_{k-1/2}}, \mathbf{s_{k-1/2}} \rangle}{\langle \mathbf{s_{k-1/2}}, \mathbf{s_{k-1/2}} \rangle}$.
    Compute $\mathbf{r_k} = \mathbf{r_{k-1/2}} - \omega_k A\mathbf{z_{k-1/2}}$ and $\mathbf{z_k} = \mathbf{z_{k-1/2}} - \omega_k\mathbf{s_{k-1/2}}$.
    Compute $\mathbf{p_k} = \mathbf{z_k} + b_k(\mathbf{p_{k-1}} - \omega_k\mathbf{q_{k-1}})$, where $b_k = \frac{a_{k-1}}{\omega_k}\frac{\langle \mathbf{z_k}, \hat{\mathbf{z}}_\mathbf{0} \rangle}{\langle \mathbf{z_{k-1}}, \hat{\mathbf{z}}_\mathbf{0} \rangle}$.
```

2. Right or Hermitian preconditioning requires a little more thought since we want to generate approximations $\mathbf{x_k}$ to the solution of the original linear system, not the modified one $AM^{-1}\mathbf{y} = \mathbf{b}$ or $L^{-1}AL^{-*}\mathbf{y} = L^{-1}\mathbf{b}$.
   If the CG algorithm is applied directly to the problem $L^{-1}AL^{-*}\mathbf{y} = L^{-1}\mathbf{b}$, then the iterates satisfy

$$\begin{aligned}
\mathbf{y_k} &= \mathbf{y_{k-1}} + a_{k-1}\hat{\mathbf{p}}_\mathbf{k-1}, \quad a_{k-1} = \frac{\langle \hat{\mathbf{r}}_\mathbf{k-1}, \hat{\mathbf{r}}_\mathbf{k-1} \rangle}{\langle \hat{\mathbf{p}}_\mathbf{k-1}, L^{-1}AL^{-*}\hat{\mathbf{p}}_\mathbf{k-1} \rangle}, \\
\hat{\mathbf{r}}_\mathbf{k} &= \hat{\mathbf{r}}_\mathbf{k-1} - a_{k-1}L^{-1}AL^{-*}\hat{\mathbf{p}}_\mathbf{k-1}, \\
\hat{\mathbf{p}}_\mathbf{k} &= \hat{\mathbf{r}}_\mathbf{k} + b_{k-1}\hat{\mathbf{p}}_\mathbf{k-1}, \quad b_{k-1} = \frac{\langle \hat{\mathbf{r}}_\mathbf{k}, \hat{\mathbf{r}}_\mathbf{k} \rangle}{\langle \hat{\mathbf{r}}_\mathbf{k-1}, \hat{\mathbf{r}}_\mathbf{k-1} \rangle}.
\end{aligned}$$

   Defining

$$\mathbf{x_k} \equiv L^{-*}\mathbf{y_k}, \quad \mathbf{r_k} \equiv L\hat{\mathbf{r}}_\mathbf{k}, \quad \mathbf{p_k} \equiv L^{-*}\hat{\mathbf{p}}_\mathbf{k},$$

   we obtain the following preconditioned CG algorithm for $A\mathbf{x} = \mathbf{b}$:

Preconditioned Conjugate Gradient Method (PCG).
(For Hermitian Positive Definite Problems, with Hermitian Positive Definite Preconditioners)

```
Given an initial guess $\mathbf{x_0}$, compute $\mathbf{r_0} = \mathbf{b} - A\mathbf{x_0}$ and solve
$M\mathbf{z_0} = \mathbf{r_0}$. Set $\mathbf{p_0} = \mathbf{z_0}$.
For $k = 1, 2, \ldots$,
    Compute $A\mathbf{p_{k-1}}$.
    Set $\mathbf{x_k} = \mathbf{x_{k-1}} + a_{k-1}\mathbf{p_{k-1}}$, where $a_{k-1} = \frac{\langle \mathbf{r_{k-1}}, \mathbf{z_{k-1}} \rangle}{\langle \mathbf{p_{k-1}}, A\mathbf{p_{k-1}} \rangle}$.
    Compute $\mathbf{r_k} = \mathbf{r_{k-1}} - a_{k-1}A\mathbf{p_{k-1}}$.
    Solve $M\mathbf{z_k} = \mathbf{r_k}$.
    Set $\mathbf{p_k} = \mathbf{z_k} + b_{k-1}\mathbf{p_{k-1}}$, where $b_{k-1} = \frac{\langle \mathbf{r_k}, \mathbf{z_k} \rangle}{\langle \mathbf{r_{k-1}}, \mathbf{z_{k-1}} \rangle}$.
```

Applications:

1. Figure 54.4 shows the convergence (in terms of the 2-norm of the residual) of the ICCG algorithm (CG with incomplete Cholesky decomposition as a preconditioner, where the sparsity

pattern of L was taken to match that of the lower triangle of A) and a multigrid method (using standard restriction and prolongation operators and the Gauss-Seidel algorithm for relaxation) for the same problem used in Sections 54.2 and 54.3. The horizontal axis represents iterations for ICCG or cycles for the multigrid method. Each multigrid V-cycle costs about twice as much as an ICCG iteration, since it performs two triangular solves and two matrix vector multiplications on each coarse grid, while doing one of each on the fine grid. There is also a cost for the restriction and prolongation operations. The grid size was taken to be 64^3 for the multigrid method since this enabled easy formation of coarser grids by doubling h. The coarsest grid, on which the problem was solved directly, was taken to be of size $4 \times 4 \times 4$. It should be noted that the number of multigrid cycles can be reduced by using the multigrid procedure as a preconditioner for the CG algorithm (although this would require a different relaxation method in order to maintain symmetry). The only added expense is the cost of inner products in the CG algorithm.

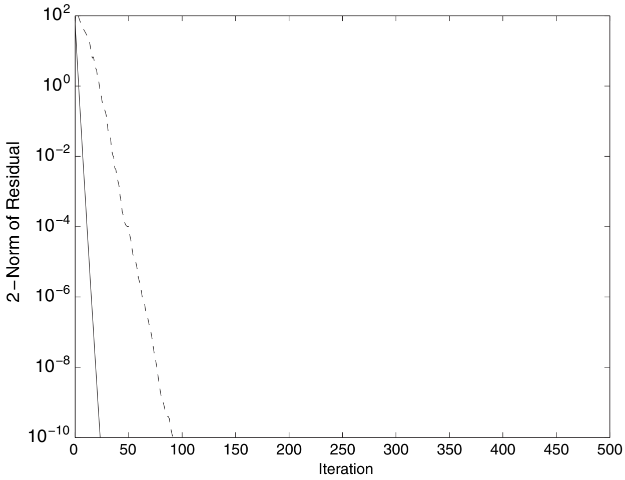

FIGURE 54.4 Convergence of ICCG (dashed) and multigrid (solid) for the problem given in the introduction with $a(x, y, z) = 1 + x + 3yz$, $h = 1/50$ (for ICCG), and $h = 1/64$ (for multigrid).

54.6 Convergence Rates of CG and MINRES

In this section, we again let A and $\mathbf{b}$ denote the already preconditioned matrix and right-hand side vector, and we assume that A is Hermitian (and also positive definite for CG).

Facts:

1. The CG error vector and the MINRES residual vector at step k can be written in the form

$$\mathbf{e_k} = P_k^C(A)\mathbf{e_0}, \quad \mathbf{r_k} = P_k^M(A)\mathbf{r_0},$$

where P_k^C and P_k^M are the kth degree polynomials with value 1 at the origin that minimize the A-norm of the error in the CG algorithm and the 2-norm of the residual in the MINRES algorithm, respectively. In other words, the error $\mathbf{e_k}$ in the CG approximation satisfies

$$\|\mathbf{e_k}\|_A = \min_{p_k} \|p_k(A)\mathbf{e_0}\|_A$$

and the residual $\mathbf{r_k}$ in the MINRES algorithm satisfies

$$\|\mathbf{r_k}\| = \min_{p_k} \|p_k(A)\mathbf{r_0}\|,$$

where the minimum is taken over all polynomials p_k of degree k or less with $p_k(0) = 1$.

2. Let an eigendecomposition of A be written as $A = U\Lambda U^*$, where U is a unitary matrix and $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ is a diagonal matrix of eigenvalues. If A is positive definite, define $A^{1/2}$ to be $U\Lambda^{1/2}U^*$. Then the A-norm of a vector $\mathbf{v}$ is just the 2-norm of the vector $A^{1/2}\mathbf{v}$. The equalities in Fact 1 imply

$$\begin{aligned}\|\mathbf{e_k}\|_A &= \min_{p_k} \|A^{1/2}p_k(A)\mathbf{e_0}\| = \min_{p_k} \|p_k(A)A^{1/2}\mathbf{e_0}\| \\ &= \min_{p_k} \|Up_k(\Lambda)U^*A^{1/2}\mathbf{e_0}\| \le \min_{p_k} \|p_k(\Lambda)\| \ \|\mathbf{e_0}\|_A,\end{aligned}$$

$$\|\mathbf{r_k}\| = \min_{p_k} \|Up_k(\Lambda)U^*\mathbf{r_0}\| \le \min_{p_k} \|p_k(\Lambda)\| \ \|\mathbf{r_0}\|.$$

These bounds are *sharp*; that is, for each step k there is an initial vector for which equality holds [Gre79, GG94, Jou96], but the initial vector that gives equality at step k may be different from the one that results in equality at some other step j.

The problem of describing the convergence of these algorithms therefore reduces to one in approximation theory — How well can one approximate zero on the set of eigenvalues of A using a kth degree polynomial with value 1 at the origin? While there is no simple expression for the maximum value of the minimax polynomial on a discrete set of points, this minimax polynomial can be calculated if the eigenvalues of A are known and, more importantly, this sharp upper bound provides intuition as to what constitute "good" and "bad" eigenvalue distributions. Eigenvalues tightly clustered around a single point (away from the origin) are good, for instance, because the polynomial $(1-z/c)^k$ is small in absolute value at all points near c. Widely spread eigenvalues, especially if they lie on both sides of the origin, are bad because a low degree polynomial with value 1 at the origin cannot be small at a large number of such points.

3. Since one usually has only limited information about the eigenvalues of A, it is useful to have error bounds that involve only a few properties of the eigenvalues. For example, in the CG algorithm for Hermitian positive definite problems, knowing only the largest and smallest eigenvalues of A, one can obtain an error bound by considering the minimax polynomial on the *interval* from λ_{min} to λ_{max}; i.e., the Chebyshev polynomial shifted to the interval and scaled to have value 1 at the origin. The result is

$$\frac{\|\mathbf{e_k}\|_A}{\|\mathbf{e_0}\|_A} \le 2\left[\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^k + \left(\frac{\sqrt{\kappa}+1}{\sqrt{\kappa}-1}\right)^k\right]^{-1} \le 2\left(\frac{\sqrt{\kappa}-1}{\sqrt{\kappa}+1}\right)^k,$$

where $\kappa = \lambda_{max}/\lambda_{min}$ is the ratio of largest to smallest eigenvalue of A.

If additional information is available about the interior eigenvalues of A, one often can improve on this estimate while maintaining a simpler expression than the sharp bound in Fact 2. Suppose, for example, that A has just a few eigenvalues that are much larger than the others, say, $\lambda_1 \le \cdots \le \lambda_{n-\ell} << \lambda_{n-\ell+1} \le \cdots \le \lambda_n$. Consider a polynomial p_k that is the product of a factor of degree ℓ that is zero at $\lambda_{n-\ell+1}, \ldots \lambda_n$ and the $(k-\ell)$th degree scaled and shifted Chebyshev polynomial on the interval

$[\lambda_1, \lambda_{n-\ell}]$:

$$p_k(x) = \left[T_{k-\ell}\left(\frac{2x - \lambda_{n-\ell} - \lambda_1}{\lambda_{n-\ell} - \lambda_1} \right) \Big/ T_{k-\ell}\left(\frac{-\lambda_{n-\ell} - \lambda_1}{\lambda_{n-\ell} - \lambda_1} \right) \right] \cdot \left(\prod_{i=n-\ell+1}^{n} \frac{\lambda_i - x}{\lambda_i} \right).$$

Since the second factor is zero at $\lambda_{n-\ell+1}, \ldots, \lambda_n$ and less than one in absolute value at each of the other eigenvalues, the maximum absolute value of this polynomial on $\{\lambda_1, \ldots, \lambda_n\}$ is less than the maximum absolute value of the first factor on $\{\lambda_1, \ldots, \lambda_{n-\ell}\}$. It follows that

$$\frac{\|\mathbf{e_k}\|_A}{\|\mathbf{e_0}\|_A} \leq 2 \left(\frac{\sqrt{\kappa_{n-\ell}} - 1}{\sqrt{\kappa_{n-\ell}} + 1} \right)^{k-\ell}, \quad \kappa_{n-\ell} \equiv \frac{\lambda_{n-\ell}}{\lambda_1}.$$

Analogous results hold for the 2-norm of the residual in the MINRES algorithm applied to a Hermitian positive definite linear system. For estimates of the convergence rate of the MINRES algorithm applied to indefinite linear systems see, for example, [Fis96].

54.7 Convergence Rate of GMRES

Facts:

1. Like MINRES for Hermitian problems, the GMRES algorithm for general linear systems produces a residual at step k whose 2-norm satisfies $\|\mathbf{r_k}\| = \min_{p_k} \|p_k(A)\mathbf{r_0}\|$, where the minimum is over all kth degree polynomials p_k with $p_k(0) = 1$. To derive a bound on this expression that is independent of the direction of $\mathbf{r_0}$, we could proceed as in the previous section by employing an eigendecomposition of A. To this end, assume that A is diagonalizable and let $A = V\Lambda V^{-1}$ be an eigendecomposition, where $\Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n)$ is a diagonal matrix of eigenvalues and the columns of V are right eigenvectors of A. Then it follows that

$$\|\mathbf{r_k}\| = \min_{p_k} \|V p_k(\Lambda) V^{-1} \mathbf{r_0}\| \leq \kappa(V) \min_{p_k} \|p_k(\Lambda)\| \cdot \|\mathbf{r_0}\|,$$

   where $\kappa(V) = \|V\| \cdot \|V^{-1}\|$ is the condition number of the eigenvector matrix V. We can assume that the columns of V have been scaled to make this condition number as small as possible. As in the Hermitian case, the polynomial that minimizes $\|V p_k(\Lambda) V^{-1}\mathbf{r_0}\|$ is not necessarily the one that minimizes $\|p_k(\Lambda)\|$, and it is not clear whether this bound is sharp. It turns out that if A is a normal matrix, then $\kappa(V) = 1$ and the bound is sharp [GG94, Jou96]. In this case, as in the Hermitian case, the problem of describing the convergence of GMRES reduces to a problem in approximation theory — How well can one approximate zero on the set of *complex* eigenvalues using a kth degree polynomial with value 1 at the origin?

   If the matrix A is nonnormal but has a fairly well-conditioned eigenvector matrix V, then the above bound, while not necessarily sharp, gives a reasonable estimate of the actual size of the residual. In this case again, it is A's eigenvalue distribution that essentially determines the behavior of GMRES.
2. In general, however, the behavior of GMRES cannot be determined from eigenvalues alone. In fact, it is shown in [GS94] and [GPS96] that *any* nonincreasing sequence of residual norms can be obtained with the GMRES method applied to a problem whose coefficient matrix has any desired eigenvalues. Thus, for example, eigenvalues

tightly clustered around 1 are not necessarily good for nonnormal matrices; one can construct a nonnormal matrix whose eigenvalues are equal to 1 or as tightly clustered around 1 as one might like, for which the GMRES algorithm makes no progress until step n (when it must find the exact solution).

The convergence behavior of the GMRES algorithm for nonnormal matrices is a topic of current research. The analysis must involve quantities other than the eigenvalues. Some partial results have been obtained in terms of the *field of values* [EES83, Eie93, BGT05], in terms of the *ϵ-pseudospectrum* [TE05], and in terms of the *polynomial numerical hull of degree k* [Gre02, Gre04].

54.8 Inexact Preconditioners and Finite Precision Arithmetic, Error Estimation and Stopping Criteria, Text and Reference Books

There are a number of topics of current or recent research that will not be covered in this chapter. Here we list a few of these with sample references.

Facts:

1. The effects of finite precision arithmetic on both the convergence rate and the ultimately attainable accuracy of iterative methods have been studied. Example papers include [DGR95, Gre89, Gre97b, GRS97, GS92, GS00, Pai76, Vor90], and [Woz80].
2. A related topic is inexact preconditioners. Suppose the preconditioning system $M\mathbf{z} = \mathbf{r}$ is solved inexactly, perhaps by using an iterative method inside the outer iteration for $A\mathbf{x} = \mathbf{b}$. How accurately should the preconditioning system be solved in order to obtain the best overall performance of the process? The answer is surprising. See [BF05, ES04], and [SS03] for recent discussions of this question.
3. Another related idea is the use of different preconditioners at different steps of the iteration, sometimes called *flexible* iterative methods. See, for example, [Saa93].
4. Finally, there is the important question of when an iterative method should be stopped. Sometimes one wishes to stop when the 2-norm of the error or the A-norm of the error in the CG method reaches a certain threshold. But one cannot compute these quantities directly. For discussions of estimating the A-norm of the error in the CG algorithm, as well as its connections to Gauss quadrature, see, for instance, [GM97, GS94, HS52], and [ST02]
5. A number of text and reference books on iterative methods are available. These include [Axe95, Gre97a, Hac94, Saa03], and [Vor03]

The eigenvalue decomposition (EVD) is an infinite iterative procedure — finding eigenvalues is equivalent to finding zeros of the characteristic polynomial, and, by the results of Abel and Galois, there is no algebraic formula for roots of the polynomial of degree greater than four. However, the number of arithmetic operations required to compute EVD to some prescribed accuracy is also finite — EVD of a general symmetric matrix requires $O(n^3)$ operations, while for matrices with special structure this number can be smaller. For example, the EVD of a tridiagonal matrix can be computed in $O(n^2)$ operations (see Sections 55.5 and 55.6).

Basic methods for the symmetric eigenvalue computations are the power method, the inverse iteration method, and the QR iteration method (see Section 55.1). Since direct application of those methods to a general symmetric matrix requires $O(n^4)$ operations, the most commonly used algorithms consist of two steps: the given matrix is first reduced to tridiagonal form, followed by the computation of the EVD of the tridiagonal matrix by QR iteration, the divide and conquer method, bisection and inverse iteration, or the method of multiple relatively robust representations. Two other methods are the Jacobi method, which does not require tridiagonalization, and the Lanczos method, which computes only a part of the tridiagonal matrix.

Design of an efficient algorithm must take into account the target computer, the desired speed and accuracy, the specific goal (whether all or some eigenvalues and eigenvectors are desired), and the matrix size and structure (small or large, dense or sparse, tridiagonal, etc.). For example, if only some eigenvalues and eigenvectors are required, one can use the methods of Sections 55.5, 55.6, and 55.8. If high relative accuracy is desired and the matrix is positive definite, the Jacobi method is the method of choice. If the matrix is sparse, the Lanczos method should be used. We shall cover the most commonly used algorithms, like those which are implemented in LAPACK (see Chapter 93) and MATLAB®(see Chapter 88). The algorithms provided in this chapter are intended to assist the reader in understanding the methods. Since the actual software is very complex, the reader is advised to use professional software in practice.

Efficient algorithms should be designed to use BLAS, and especially BLAS 3, as much as possible (see Chapter 92). The reasons are twofold: First, calling predefined standardized routines makes programs shorter and more easily readable, and second, processor vendors can optimize sets of standardized routines for their processor beyond the level given by compiler optimization. Examples of such optimized libraries are the *Intel Math Kernel Library* and *AMD Core Math Library.* Both libraries contain processor optimized BLAS, LAPACK, and FFT routines.

This chapter deals only with the computation of EVD of real symmetric matrices. The need to compute EVD of a complex Hermitian matrix (see Chapter 9) does not arise often in applications, and it is theoretically and numerically similar to the real symmetric case addressed here. All algorithms described in this chapter have their Hermitian counterparts (see e.g., [ABB99], [LSY98], and Chapters 88, 93, and 94).

The chapter is organized as follows: In Section 55.1, we describe basic methods for EVD computations. These methods are necessary to understand algorithms of Sections 55.3 to 55.6. In Section 55.2, we describe tridiagonalization by Householder reflections and Givens rotations. In Sections 55.3 to 55.6, we describe methods for computing the EVD of a tridiagonal matrix — QR iteration, the divide and conquer method, bisection and inverse iteration, and the method of multiple relatively robust representations, respectively. The Jacobi method is described in Section 55.7 and the Lanczos method is described in Section 55.8. For each method, we also describe the existing LAPACK or Matlab implementations. The respective timings of the methods are given in Section 55.9.

55.1 Basic Methods

The reader is referred to Sections 4.4, 9.1, 9.2, 9.3, 16.1, and 16.2 for more information on eigenvalues and their locations.

Definitions:

The **eigenvalue decomposition** (EVD) of a real symmetric matrix $A = [a_{ij}]$ is given by $A = U\Lambda U^T$, where U is a $n \times n$ real orthonormal matrix, $U^TU = UU^T = I_n$, and $\Lambda = \mathrm{diag}(\lambda_1, \ldots, \lambda_n)$ is a real diagonal matrix.

The numbers λ_i are the **eigenvalues** of A, the columns $\mathbf{u}_i$, $i = 1, \ldots, n$, of U are the **eigenvectors** of A, and $A\mathbf{u}_i = \lambda_i \mathbf{u}_i$, $i = 1, \ldots, n$.

If $|\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n|$, we say that λ_1 is the **dominant eigenvalue**.

Deflation is a process of reducing the size of the matrix whose EVD is to be determined, given that one eigenvector is known (see Fact 4 for details).

The **shifted matrix** of the matrix A is the matrix $A - \mu I$, where μ is the **shift**.

The simplest method for computing the EVD (also in the unsymmetric case) is the **power method**: given starting vector $\mathbf{x}_0$, the method computes the sequences

$$\nu_k = \mathbf{x}_k^T A\mathbf{x}_k, \qquad \mathbf{x}_{k+1} = A\mathbf{x}_k / \|A\mathbf{x}_k\|, \qquad k = 0, 1, 2, \ldots, \tag{55.1}$$

until convergence. Normalization of $\mathbf{x}_k$ can be performed in any norm and serves the numerical stability of the algorithm (avoiding overflow or underflow).

Inverse iteration is the power method applied to the inverse of a shifted matrix, starting from $\mathbf{x}_0$:

$$\nu_k = \mathbf{x}_k^T A\mathbf{x}_k, \quad \mathbf{v}_{k+1} = (A - \mu I)^{-1}\mathbf{x}_k, \quad \mathbf{x}_{k+1} = \mathbf{v}_{k+1} / \|\mathbf{v}_{k+1}\|, \quad k = 0, 1, 2, \ldots. \tag{55.2}$$

Given starting $n \times p$ matrix X_0 with orthonormal columns, the **orthogonal iteration** (also **subspace iteration**) forms the sequence of matrices

$$Y_{k+1} = AX_k, \qquad Y_{k+1} = X_{k+1}R_{k+1} \quad \text{(QR factorization)}, \qquad k = 0, 1, 2, \ldots, \tag{55.3}$$

where $X_{k+1}R_{k+1}$ is the reduced QR factorization of Y_{k+1} (X_{k+1} is an $n \times p$ matrix with orthonormal columns and R_{k+1} is an upper triangular $p \times p$ matrix).

Starting from the matrix $A_0 = A$, the **QR iteration** forms the sequence of matrices

$$A_k = Q_k R_k \quad \text{(QR factorization)}, \qquad A_{k+1} = R_k Q_k, \qquad k = 0, 1, 2, \ldots \tag{55.4}$$

Given the shift μ, the **shifted QR iteration** forms the sequence of matrices

$$A_k - \mu I = Q_k R_k \quad \text{(QR factorization)}, \quad A_{k+1} = R_k Q_k + \mu I, \quad k = 0, 1, 2, \ldots \tag{55.5}$$

Facts:

Facts 1 to 14 can be found in [GV96, Chap. 8.2], [Par80, Chap. 4, 5], [Ste01, Chaps. 2.1, 2.2.1, 2.2.2], and [Dem97, Chap. 4].

1. If λ_1 is the dominant eigenvalue and if $\mathbf{x}_0$ is not orthogonal to $\mathbf{u}_1$, then in Eq. (55.1) $\nu_k \to \lambda_1$ and $\mathbf{x}_k \to \mathbf{u}_1$. In other words, the power method converges to the dominant eigenvalue and its eigenvector.
2. The convergence of the power method is linear in the sense that
$$|\lambda_1 - \nu_k| = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right), \qquad \|\mathbf{u}_1 - \mathbf{x}_k\|_2 = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right).$$
More precisely,
$$|\lambda_1 - \nu_k| \approx \left|\frac{c_2}{c_1}\right| \left|\frac{\lambda_2}{\lambda_1}\right|^k,$$
where c_i is the coefficient of the i-th eigenvector in the linear combination expressing the starting vector $\mathbf{x}_0$.
3. Since λ_1 is not readily available, the convergence is in practice determined using residuals. If $\|A\mathbf{x}_k - \nu_k \mathbf{x}_k\|_2 \leq tol$, where tol is a user prescribed stopping criterion, then $|\lambda_1 - \nu_k| \leq tol$.
4. After computing the dominant eigenpair, we can perform deflation to reduce the given EVD to the one of size $n-1$. Let $Y = [\mathbf{u}_1 \quad X]$ be an orthogonal matrix. Then
$$\begin{bmatrix}\mathbf{u}_1 & X\end{bmatrix}^T A \begin{bmatrix}\mathbf{u}_1 & X\end{bmatrix} = \begin{bmatrix}\lambda_1 & 0 \\ 0 & A_1\end{bmatrix},$$
where $A_1 = X^T A X$.
5. The EVD of the shifted matrix $A - \mu I$ is given by $U(\Lambda - \mu I)U^T$. Sometimes we can choose shift μ such that the shifted matrix $A - \mu I$ has better ratio between the dominant eigenvalue and the absolutely closest one, than the original matrix. In this case, applying the power method to the shifted matrix will speed up the convergence.
6. Inverse iteration requires solving the system of linear equations $(A - \mu I)\mathbf{v}_{k+1} = \mathbf{x}_k$ for $\mathbf{v}_{k+1}$ in each step. At the beginning, we must compute the LU factorization of $A - \mu I$, which requires $2n^3/3$ operations and in each subsequent step we must solve two triangular systems, which requires $2n^2$ operations.
7. If μ is very close to some eigenvalue of A, then the eigenvalues of the shifted matrix satisfy $|\lambda_1| \gg |\lambda_2| \geq \cdots \geq |\lambda_n|$, so the convergence of the inverse iteration method is very fast.
8. If μ is very close to some eigenvalue of A, then the matrix $A - \mu I$ is nearly singular, so the solutions of linear systems may have large errors. However, these errors are almost entirely in the direction of the dominant eigenvector so the inverse iteration method is both fast and accurate.

9. We can further increase the speed of convergence of inverse iterations by substituting the shift μ with the Rayleigh quotient ν_k in each step, at the cost of computing new LU factorization each time. See Section 9.2 for more information about the Rayleigh quotient.
10. If

$$|\lambda_1| \geq \cdots \geq |\lambda_p| > |\lambda_{p+1}| \geq \cdots \geq |\lambda_n|,$$

then the subspace iteration given in Eq. (55.3) converges such that

$$X_k \to [\mathbf{u}_1, \ldots, \mathbf{u}_p], \qquad X_k^T A X_k \to \operatorname{diag}(\lambda_1, \ldots, \lambda_p),$$

at a speed which is proportional to $|\lambda_{p+1}/\lambda_p|^k$.
11. If $|\lambda_1| > |\lambda_2| > \cdots > |\lambda_n|$, then the sequence of matrices A_k generated by the QR iteration given in Eq. (55.4) converges to diagonal matrix Λ. However, this result is not of practical use, since the convergence may be very slow and each iteration requires $O(n^3)$ operations. Careful implementation, like the one described in Section 55.3, is needed to construct a useful algorithm.
12. The QR iteration is equivalent to orthogonal iteration starting with the matrix $X_0 = I$. More precisely, the matrices X_k from Eq. (55.3) and A_k from (Eq. 55.4) satisfy $X_k^T A X_k = A_k$.
13. Matrices A_k and A_{k+1} from Eq. (55.4) and Eq. (55.5) are orthogonally similar. In both cases

$$A_{k+1} = Q_k^T A_k Q_k.$$

14. The QR iteration method is essentially equivalent to the power method and the shifted QR iteration method is essentially equivalent to the inverse power method on the shifted matrix.
15. [Wil65, Chaps. 3, 5, 6, 7] [TB97, Chap. V] Let $U\Lambda U^T$ and $\tilde{U}\tilde{\Lambda}\tilde{U}^T$ be the exact and the computed EVDs of A, respectively, such that the diagonals of Λ and $\tilde{\Lambda}$ are in the same order. Numerical methods generally compute the EVD with the errors bounded by

$$|\lambda_i - \tilde{\lambda}_i| \leq \phi\epsilon\|A\|_2, \qquad \|\mathbf{u}_i - \tilde{\mathbf{u}}_i\|_2 \leq \psi\epsilon\frac{\|A\|_2}{\min_{j\neq i}|\lambda_i - \tilde{\lambda}_j|},$$

where ϵ is machine precision and ϕ and ψ are slowly growing polynomial functions of n which depend upon the algorithm used (typically $O(n)$ or $O(n^2)$). Such bounds are obtained by combining perturbation bounds, like, for example, those of Section 21.1, with the floating-point error analysis of the respective algorithms.
16. For some types of matrices it is possible to compute EVD more accurately than stated in Fact 15. Two examples of such matrices are "well-behaved" matrices and arrowhead matrices. Eigenvalue problems for "well-behaved" matrices satisfy relative perturbation bounds of Section 21.6. The EVD for such matrices can be computed with high relative accuracy as described in Sections 59.4 and 59.5. Arrowhead matrices have the form

$$A = \begin{bmatrix} D & \mathbf{z} \\ \mathbf{z}^T & \alpha \end{bmatrix},$$

where $D = \operatorname{diag}(d_1, \ldots, d_{n-1})$, $\mathbf{z} = \begin{bmatrix}\zeta_1 & \cdots & \zeta_{n-1}\end{bmatrix}$, and α is a scalar. For such matrices all eigenvalues and all components of each eigenvector can be computed to nearly full accuracy in $O(n^2)$ operations. See [JSB12] for details.

Examples:

1. The eigenvalue decomposition of the matrix

$$A = \begin{bmatrix} 4.5013 & 0.6122 & 2.1412 & 2.0390 \\ 0.6122 & 2.6210 & -0.4941 & -1.2164 \\ 2.1412 & -0.4941 & 1.1543 & -0.1590 \\ 2.0390 & -1.2164 & -0.1590 & -0.9429 \end{bmatrix}$$

computed by the MATLAB command `[U,Lambda]=eig(A)` is $A = U\Lambda U^T$ with (properly rounded to four decimal places)

$$U \begin{bmatrix} -0.3697 & 0.2496 & 0.1003 & -0.8894 \\ 0.2810 & -0.0238 & 0.9593 & -0.0153 \\ 0.3059 & -0.8638 & -0.1172 & -0.3828 \\ 0.8311 & 0.4370 & -0.2366 & -0.2495 \end{bmatrix}, \quad \Lambda = \begin{bmatrix} -2.3197 & 0 & 0 & 0 \\ 0 & 0.6024 & 0 & 0 \\ 0 & 0 & 3.0454 & 0 \\ 0 & 0 & 0 & 6.0056 \end{bmatrix}.$$

2. Let A, U, and Λ be as in the Example 1, and set $\mathbf{x}_0 = [1 \quad 1 \quad 1 \quad 1]^T$. The power method in Eq. (55.1) gives $\mathbf{x}_6 = [0.8893 \quad 0.0234 \quad 0.3826 \quad 0.2496]^T$. By setting $\mathbf{u}_1 = -U_{:,4}$ we have $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 0.0081$. Here (Fact 2), $c_2 = 0.7058$, $c_1 = -1.5370$, and

$$\left|\frac{c_2}{c_1}\right| \left|\frac{\lambda_2}{\lambda_1}\right|^6 = 0.0078.$$

Similarly, $\|\mathbf{u}_1 - \mathbf{x}_{50}\|_2 = 1.3857 \cdot 10^{-15}$. However, for a different (bad) choice of the starting vector, $\mathbf{x}_0 = [0 \quad 1 \quad 0 \quad 0]^T$, where $c_2 = 0.9593$ and $c_1 = -0.0153$, we have $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 0.7956$.

3. The deflation matrix Y and the deflated matrix A_1 (Fact 4) for the above example are equal to (correctly rounded):

$$Y = \begin{bmatrix} -0.8894 & -0.0153 & -0.3828 & -0.2495 \\ -0.0153 & 0.9999 & -0.0031 & -0.0020 \\ -0.3828 & -0.0031 & 0.9224 & -0.0506 \\ -0.2495 & -0.0020 & -0.0506 & 0.9670 \end{bmatrix},$$

$$A_1 = \begin{bmatrix} 6.0056 & 0 & 0 & 0 \\ 0 & 2.6110 & -0.6379 & -1.3154 \\ 0 & -0.6379 & 0.2249 & -0.8952 \\ 0 & -1.3154 & -0.8952 & -1.5078 \end{bmatrix}.$$

4. Let A and $\mathbf{x}_0$ be as in Example 2. For the shift $\mu = 6$, the inverse iteration method in Eq. (55.2) gives $\|\mathbf{u}_1 - \mathbf{x}_6\|_2 = 6.5187 \cdot 10^{-16}$, so the convergence is much faster than in Example 2 (Fact 7).

5. Let A be as in Example 1. Applying six steps of the QR iteration in Eq. (55.4) gives

$$A_6 = \begin{bmatrix} 6.0055 & -0.0050 & -0.0118 & -0.0000 \\ -0.0050 & 3.0270 & 0.3134 & 0.0002 \\ -0.0118 & 0.3134 & -2.3013 & -0.0017 \\ -0.0000 & 0.0002 & -0.0017 & 0.6024 \end{bmatrix}.$$

and applying six steps of the shifted QR iteration in Eq. (55.5) with $\mu = 6$ gives

$$A_6 = \begin{bmatrix} -2.3123 & 0.1452 & -0.0215 & -0.0000 \\ 0.1452 & 0.6623 & 0.4005 & 0.0000 \\ -0.0215 & 0.4005 & 2.9781 & -0.0000 \\ 0.0000 & 0.0000 & 0.0000 & 6.0056 \end{bmatrix}.$$

In this case both methods converge. The convergence toward the matrix where the eigenvalue nearest to the shift can be deflated is faster for the shifted iterations.

55.2 Tridiagonalization

The QR iteration in Eq. (55.4) and the shifted QR iteration in Eq. (55.5) require $O(n^3)$ operations (one QR factorization) for each step, which makes these algorithms highly unpractical. However, if the starting matrix is tridiagonal, one step of these iterations requires only $O(n)$ operations. As a consequence, the practical algorithm consists of three steps:

1. Reduce A to tridiagonal form T by orthogonal similarities, $X^TAX = T$.
2. Compute the EVD of T, $T = Q\Lambda Q^T$.
3. Multiply $U = XQ$.

The EVD of A is then $A = U\Lambda U^T$. Reduction to tridiagonal form can be performed by using Householder reflectors or Givens rotations and it is a finite process requiring $O(n^3)$ operations. Reduction to tridiagonal form is a considerable compression of data since an EVD of T can be computed very quickly. The EVD of T can be efficiently computed by various methods such as QR iteration, the divide and conquer method (DC), bisection and inverse iteration, or the method of multiple relatively robust representations (MRRR). These methods are described in subsequent sections.

Facts:

All the following facts, except Fact 6, can be found in [Par80, Chap. 7], [TB97, pp. 196–201], [GV96, Chap. 8.3.1], [Ste01, pp. 158–162], and [Wil65, pp. 345–367].

1. Tridiagonal form is not unique (see Examples 1 and 2).
2. The reduction of A to tridiagonal matrix by Householder reflections is performed as follows. Let us partition A as

   $$A = \left[\begin{array}{c|c} a_{11} & \mathbf{a}^T \\ \hline \mathbf{a} & B \end{array}\right].$$

   Let H be the appropriate Householder reflection (see Section 51.5), that is,

   $$\mathbf{v} = \mathbf{a} + \operatorname{sign}(a_{21})\|\mathbf{a}\|_2\mathbf{e}_1, \qquad H = I - 2\frac{\mathbf{v}\mathbf{v}^T}{\mathbf{v}^T\mathbf{v}},$$

   and let

   $$H_1 = \left[\begin{array}{c|c} 1 & \mathbf{0}^T \\ \hline \mathbf{0} & H \end{array}\right].$$

   Then

   $$H_1AH_1 = \left[\begin{array}{c|c} a_{11} & \mathbf{a}^TH \\ \hline H\mathbf{a} & HBH \end{array}\right] = \left[\begin{array}{c|c} a_{11} & \nu\mathbf{e}_1^T \\ \hline \nu\mathbf{e}_1 & A_1 \end{array}\right], \qquad \nu = -\operatorname{sign}(a_{21})\|\mathbf{a}\|_2.$$

   This step annihilates all elements in the first column below the first subdiagonal and all elements in the first row to the right of the first subdiagonal. Applying this procedure recursively yields the triangular matrix $T = X^TAX$, $X = H_1H_2\cdots H_{n-2}$.

3. H does not depend on the normalization of $\mathbf{v}$. The normalization $v_1 = 1$ is useful since $\mathbf{a}_{2:n}$ can be overwritten by $\mathbf{v}_{2:n}$ and v_1 does not need to be stored.
4. Forming H explicitly and then computing $A_1 = HBH$ requires $O(n^3)$ operations, which would ultimately yield an $O(n^4)$ algorithm. However, we do not need to form the matrix H explicitly — given $\mathbf{v}$, we can overwrite B with HBH in just $O(n^2)$ operations by using one matrix-vector multiplication and two rank-one updates.
5. The entire tridiagonalization algorithm is as follows:

```
Algorithm 1: Tridiagonalization by Householder reflections
Input: real symmetric $n \times n$ matrix $A$
Output: the main diagonal and sub- and superdiagonal of $A$ are overwritten by $T$,
        the Householder vectors are stored in the lower triangular part of $A$
        below the first subdiagonal
for $j = 1 : n-2$
    $\mu = \mathrm{sign}(a_{j+1,j})\|A_{j+1:n,j}\|_2$
    if $\mu \neq 0$, then
        $\beta = a_{j+1,j} + \mu$
        $\mathbf{v}_{j+2:n} = A_{j+2:n,j}/\beta$
    endif
    $a_{j+1,j} = -\mu$
    $a_{j,j+1} = -\mu$
    $v_{j+1} = 1$
    $\gamma = -2/\mathbf{v}_{j+1:n}^T\mathbf{v}_{j+1:n}$
    $\mathbf{w} = \gamma A_{j+1:n,j+1:n}\mathbf{v}_{j+1:n}$
    $\mathbf{q} = \mathbf{w} + \frac{1}{2}\gamma\mathbf{v}_{j+1:n}(\mathbf{v}_{j+1:n}^T\mathbf{w})$
    $A_{j+1:n,j+1:n} = A_{j+1:n,j+1:n} + \mathbf{v}_{j+1:n}\mathbf{q}^T + \mathbf{q}\mathbf{v}_{j+1:n}^T$
    $A_{j+2:n,j} = \mathbf{v}_{j+2:n}$
endfor
```

6. [DHS89] When symmetry is exploited in performing rank-2 update, Algorithm 1 requires $4n^3/3$ operations. Another important enhancement is the derivation of the block-version of the algorithm. Instead of performing rank-2 update on B, thus obtaining A_1, we can accumulate p transformations and perform rank-$2p$ update. In the first p steps, the algorithm is modified to update only columns and rows $1, \ldots, p$, which are needed to compute the first p Householder vectors. Then the matrix A is updated by $A - UV^T - VU^T$, where U and V are $n \times p$ matrices. This algorithm is rich in matrix–matrix multiplications (roughly one half of the operations is performed using BLAS 3 routines), but it requires extra workspace for U and V.
7. If the matrix X is needed explicitly, it can be computed from the stored Householder vectors by Algorithm 2. In order to minimize the operation count, the computation starts from the smallest matrix and the size is gradually increased; that is, the algorithm computes the sequence of matrices

$$H_{n-2}, \quad H_{n-3}H_{n-2}, \ldots, \quad X = H_1 \cdots H_{n-2}.$$

A column-oriented version is possible as well, and the operation count in both cases is $4n^3/3$. If the Householder matrices H_i are accumulated in the order in which they are generated, the operation count is $2n^3$.

```
Algorithm 2: Computation of the tridiagonalizing matrix $X$
Input: output from Algorithm 1
Output: matrix $X$ such that $X^TAX = T$, where $A$ is the input of Algorithm 1
        and $T$ is tridiagonal
$X = I_n$
for $j = n-2 : -1 : 1$
    $v_{j+1} = 1$
    $\mathbf{v}_{j+2:n} = A_{j+2:n,j}$
    $\gamma = -2/\mathbf{v}^T_{j+1:n}\mathbf{v}_{j+1:n}$
    $\mathbf{w} = \gamma X^T_{j+1:n,j+1:n}\mathbf{v}_{j+1:n}$
    $X_{j+1:n,j+1:n} = X_{j+1:n,j+1:n} + \mathbf{v}_{j+1:n}\mathbf{w}^T$
endfor
```

8. The error bounds for Algorithms 1 and 2 are as follows: The matrix $\tilde{T}$ computed by Algorithm 1 is equal to the matrix, which would be obtained by exact tridiagonalization of some perturbed matrix $A+E$ (backward error), where $\|E\|_2 \leq \psi\epsilon\|A\|_2$ and ψ is a slowly increasing function of n. The matrix $\tilde{X}$ computed by Algorithm 2 satisfies $\tilde{X} = X + F$, where $\|F\|_2 \leq \phi\epsilon$ and ϕ is a slowly increasing function of n.
9. Givens rotation parameters c and s are computed as in Fact 51.5.13. Tridiagonalization by Givens rotations is performed as follows:

```
Algorithm 3: Tridiagonalization by Givens rotations
Input: real symmetric $n \times n$ matrix $A$
Output: the matrix $X$ such that $X^TAX = T$ is tridiagonal, main diagonal
        and sub- and superdiagonal of $A$ are overwritten by $T$
$X = I_n$
for $j = 1 : n-2$
    for $i = j+2 : n$
        set $x = a_{j+1,j}$ and $y = a_{i,j}$
        compute $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$ via Fact 51.5.13
        $\begin{bmatrix} A_{j+1,j:n} \\ A_{i,j:n} \end{bmatrix} = G \begin{bmatrix} A_{j+1,j:n} \\ A_{i,j:n} \end{bmatrix}$
        $\begin{bmatrix} A_{j:n,j+1} & A_{j:n,i} \end{bmatrix} = \begin{bmatrix} A_{j:n,j+1} & A_{j:n,i} \end{bmatrix} G^T$
        $\begin{bmatrix} X_{1:n,j+1} & X_{1:n,i} \end{bmatrix} = \begin{bmatrix} X_{1:n,j+1} & X_{1:n,i} \end{bmatrix} G^T$
    endfor
endfor
```

10. Algorithm 3 requires $(n-1)(n-2)/2$ plane rotations, which amounts to $4n^3$ operations if symmetry is properly exploited. The operation count is reduced to $8n^3/3$ if fast rotations are used. Fast rotations are obtained by factoring out absolutely larger of c and s from G.
11. The Givens rotations in Algorithm 3 can be performed in different orderings. For example, the elements in the first column and row can be annihilated by rotations in the planes $(n-1, n)$, $(n-2, n-1)$, $\ldots (2, 3)$. Since Givens rotations act more selectively than Householder reflectors, they can be useful if A has some special structure. For example, Givens rotations are used to efficiently tridiagonalize symmetric band matrices (see Example 4).

12. Error bounds for Algorithm 3 are the same as the ones for Algorithms 1 and 2 (Fact 8), but with slightly different functions ψ and ϕ.

Examples:

1. Algorithms 1 and 2 applied to the matrix A from Example 55.1.1 give

$$T = \begin{bmatrix} 4.5013 & -3.0194 & 0 & 0 \\ -3.0194 & -0.3692 & 1.2804 & 0 \\ 0 & 1.2804 & 0.5243 & -0.9303 \\ 0 & 0 & -0.9303 & 2.6774 \end{bmatrix},$$

$$X = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & -0.2028 & 0.4417 & -0.8740 \\ 0 & -0.7091 & -0.6817 & -0.1800 \\ 0 & -0.6753 & 0.5833 & 0.4514 \end{bmatrix}.$$

2. Tridiagonalization is implemented in the Matlab function `T = hess(A)` (`[X,T] = hess(A)` if X is to be computed, as well). In fact, the function `hess` is more general and it computes the Hessenberg form of a general square matrix. For the same matrix A as above, the matrices T and X computed by `hess` are:

$$T = \begin{bmatrix} 2.6562 & 1.3287 & 0 & 0 \\ 1.3287 & 2.4407 & 2.4716 & 0 \\ 0 & 2.4716 & 3.1798 & 2.3796 \\ 0 & 0 & 2.3796 & -0.9429 \end{bmatrix}, \quad X = \begin{bmatrix} 0.4369 & 0.2737 & 0.8569 & 0 \\ 0.7889 & 0.3412 & -0.5112 & 0 \\ -0.4322 & 0.8993 & -0.0668 & 0 \\ 0 & 0 & 0 & 1.0000 \end{bmatrix}.$$

3. The block version of tridiagonal reduction is implemented in the LAPACK subroutine DSYTRD (file `dsytrd.f`). The computation of X is implemented in the subroutine DORGTR. The size of the required extra workspace (in elements) is $lwork = nb * n$, where nb is the optimal block size (here, $nb = 64$), and it is determined automatically by the subroutines. The timings are given in Section 55.9.
4. Computation of Givens rotation in Algorithm 3 is implemented in the Matlab functions `planerot` and `givens`, BLAS 1 subroutine DROTG, and LAPACK subroutine DLARTG. These implementations avoid unnecessary overflow or underflow by appropriately scaling x and y. Plane rotations (multiplications with G) are implemented in the BLAS 1 subroutine DROT. LAPACK subroutines DLAR2V, DLARGV, and DLARTV generate and apply multiple plane rotations. LAPACK subroutine DSBTRD tridiagonalizes a symmetric band matrix by using Givens rotations.

55.3 Implicitly Shifted QR Method

This method is named after the fact that, for a tridiagonal matrix, each step of the shifted QR iterations given by Eq. (55.5) can be elegantly implemented without explicitly computing the shifted matrix $A_k - \mu I$.

Definitions:

Wilkinson's shift μ is the eigenvalue of the bottom right 2×2 submatrix of T, which is closer to $t_{n,n}$.

Facts:

The following facts can be found in [GV96, pp. 417–422], [Ste01, pp. 163–171], [TB97, pp. 211–224], [Par80, Chap. 8], [Dem97, Chap. 5.3.1], and [Wil65, Chaps. 8.50, 8.54].

$T = [t_{ij}]$ is a real symmetric tridiagonal matrix of order n and $T = Q\Lambda Q^T$ is its EVD.

1. The stable formula for the Wilkinson's shift is

$$\mu = t_{n,n} - \frac{t_{n,n-1}^2}{\tau + \mathrm{sign}(\tau)\sqrt{\tau^2 + t_{n,n-1}^2}}, \qquad \tau = \frac{t_{n-1,n-1} - t_{n,n}}{2}.$$

2. The following recursive function implements the implicitly shifted QR method given by Eq. (55.5):

```
Algorithm 4: Implicitly shifted QR method for tridiagonal matrices
Input: real symmetric tridiagonal $n \times n$ matrix $T$
Output: the diagonal of $T$ is overwritten by its eigenvalues
function $T = QR\_iteration(T)$
  repeat      % one sweep
    compute a suitable shift $\mu$
    set $x = t_{11} - \mu$ and $y = t_{21}$
    compute $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$ via Fact 51.5.13
    $\begin{bmatrix} T_{1,1:3} \\ T_{2,1:3} \end{bmatrix} = G \begin{bmatrix} T_{1,1:3} \\ T_{2,1:3} \end{bmatrix}$
    $\begin{bmatrix} T_{1:3,1} & T_{1:3,2} \end{bmatrix} = \begin{bmatrix} T_{1:3,1} & T_{1:3,2} \end{bmatrix} G^T$
    for $i = 2 : n-1$
      set $x = t_{i,i-1}$ and $y = t_{i+1,i-1}$
      compute $G = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$ via Fact 51.5.13
      $\begin{bmatrix} T_{i,i-1:i+2} \\ T_{i+1,i-1:i+2} \end{bmatrix} = G \begin{bmatrix} T_{i,i-1:i+2} \\ T_{i+1,i-1:i+2} \end{bmatrix}$
      $\begin{bmatrix} T_{i-1:i+2,i} & T_{i-1:i+2,i+1} \end{bmatrix} = \begin{bmatrix} T_{i-1:i+2,i} & T_{i-1:i+2,i+1} \end{bmatrix} G^T$
    endfor
  until $|t_{i,i+1}| \leq \epsilon\sqrt{|t_{i,i} \cdot t_{i+1,i+1}|}$ for some $i$    % deflation
  set $t_{i+1,i} = 0$ and $t_{i,i+1} = 0$
  $T_{1:i,1:i} = QR\_iteration(T_{1:i,1:i})$
  $T_{i+1:n,i+1:n} = QR\_iteration(T_{i+1:n,i+1:n})$
```

3. Wilkinson's shift (Fact 1) is the most commonly used shift. With Wilkinson's shift, the algorithm always converges in the sense that $t_{n-1,n} \to 0$. The convergence is quadratic, that is, $|[T_{k+1}]_{n-1,n}| \leq c|[T_k]_{n-1,n}|^2$ for some constant c, where T_k is the matrix after the k-th sweep. Even more, the convergence is usually cubic. However, it can also happen that some $t_{i,i+i}$, $i \neq n-1$, becomes sufficiently small before $t_{n-1,n}$, so the practical program has to check for deflation at each step.
4. The plane rotation parameters at the start of the sweep are computed as if the shifted matrix $T - \mu I$ has been formed. Since the rotation is applied to the original T and not to $T - \mu I$, this creates new nonzero elements at the positions $(3, 1)$ and $(1, 3)$, the so-called **bulge**. The subsequent rotations simply chase the bulge out of the lower

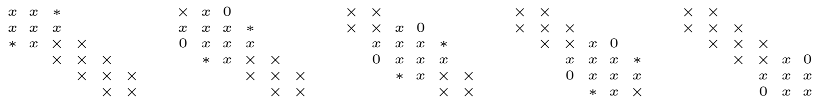

FIGURE 55.1 Chasing the bulge in one sweep of the implicit QR iteration for $n = 6$.

right corner of the matrix. The rotation in the $(2, 3)$ plane sets the elements $(3, 1)$ and $(1, 3)$ back to zero, but it generates two new nonzero elements at positions $(4, 2)$ and $(2, 4)$; the rotation in the $(3, 4)$ plane sets the elements $(4, 2)$ and $(2, 4)$ back to zero, but it generates two new nonzero elements at positions $(5, 3)$ and $(3, 5)$, etc. The procedure is illustrated in Figure 55.1: "x" denotes the elements that are transformed by the current plane rotation, "$*$" denotes the newly generated nonzero elements (the bulge), and 0 denotes the zeros that are reintroduced by the current plane rotation.

The effect of this procedure is the following. At the end of the first sweep, the resulting matrix T_1 is equal to the the matrix that would have been obtained by factorizing $T - \mu I = QR$ and computing $T_1 = RQ + \mu I$ as in Eq. (55.5).

5. Since the convergence of Algorithm 4 is quadratic (or even cubic), an eigenvalue is isolated after just a few steps, which requires $O(n)$ operations. This means that $O(n^2)$ operations are needed to compute all eigenvalues.
6. If the eigenvector matrix Q is desired, the plane rotations need to be accumulated similarly to the accumulation of X in Algorithm 3. This accumulation requires $O(n^3)$ operations (see Example 2 below and Fact 55.9.5). Another, usually faster, algorithm to compute Q is given in Fact 55.9.9.
7. The computed eigenvalue decomposition $T = Q\Lambda Q^T$ satisfies the error bounds from Fact 55.1.15 with A replaced by T and U replaced by Q. The deflation criterion implies $|t_{i,i+1}| \leq \epsilon \|T\|_F$, which is within these bounds.
8. Combining Algorithms 1, 2, and 4 we get the the following algorithm:

```
Algorithm 5: Real symmetric eigenvalue decomposition
Input: real symmetric $n \times n$ matrix $A$
Output: eigenvalue matrix $\Lambda$ and, optionally, eigenvector matrix $U$ of $A$
 if only eigenvalues are required, then
     Compute $T$ by Algorithm 1
     $T = QR\_iteration(T)$        % Algorithm 4
     $\Lambda = \mathrm{diag}(T)$
 else
     Compute $T$ by Algorithm 1
     Compute $X$ by Algorithm 2
     $T = QR\_iteration(T)$        % with rotations accumulated in $Q$
     $\Lambda = \mathrm{diag}(T)$
     $U = XQ$
 endif
```

9. The EVD computed by Algorithm 5 satisfies the error bounds given in Fact 55.1.15. However, the algorithm tends to perform better on matrices, which are graded downward, that is, on matrices that exhibit systematic decrease in the size of the matrix elements as we move along the diagonal. For such matrices, the tiny eigenvalues can usually be computed with higher relative accuracy (although counterexamples can be easily constructed). If the tiny eigenvalues are of interest, it should be checked whether

there exists a symmetric permutation that moves larger elements to the upper left corner, thus converting the given matrix to the one that is graded downward.

Examples:

1. For the matrix T from Example 55.2.1, after one sweep of Algorithm 4, we have

$$T = \begin{bmatrix} 2.9561 & 3.9469 & 0 & 0 \\ 3.9469 & 0.8069 & -0.7032 & 0 \\ 0 & -0.7032 & 0.5253 & 0.0091 \\ 0 & 0 & 0.0091 & 3.0454 \end{bmatrix}.$$

2. Algorithm 4 is implemented in the LAPACK subroutine DSTEQR. This routine can compute just the eigenvalues, or both eigenvalues and eigenvectors. To avoid double indices, the diagonal and subdiagonal entries of T are stored in one-dimensional vectors, $d_i = T_{ii}$ and $e_i = T_{i+1,i}$, respectively. The timings are given in Section 55.9.
3. Algorithm 5 is implemented in the Matlab routine `eig`. The command `Lambda = eig(A)` returns only the eigenvalues, `[U,Lambda]=eig(A)` returns the eigenvalues and the eigenvectors (see Example 55.1.1).
4. The LAPACK implementation of Algorithm 5 is given in the subroutine DSYEV. To compute only eigenvalues, DSYEV calls DSYTRD and DSTEQR without eigenvector option. To compute both eigenvalues and eigenvectors, DSYEV calls DSYTRD, DORGTR, and DSTEQR with the eigenvector option. The timings are given in Section 55.9.

55.4 Divide and Conquer Method

This is currently the fastest method for computing the EVD of a real symmetric tridiagonal matrix T. It is based on splitting the given tridiagonal matrix into two matrices, and then computing the EVDs of the smaller matrices and computing the final EVD from the two EVDs. The method was first introduced in [Cup81], but numerically stable and efficient implementation was first derived in [GE95].

Facts:

The following facts can be found in [Dem97, pp. 216–228], [Ste01, pp. 171–185], and [GE95]. $T = [t_{ij}]$ is a real symmetric tridiagonal matrix of order n and $T = U\Lambda U^T$ is its EVD.

1. Let T be partitioned as

$$T = \left[\begin{array}{cccc|cccc} d_1 & e_1 & & & & & & \\ e_1 & d_2 & e_2 & & & & & \\ & \ddots & \ddots & \ddots & & & & \\ & & e_{k-1} & d_k & e_k & & & \\ \hline & & & e_k & d_{k+1} & e_{k+1} & & \\ & & & & \ddots & \ddots & \ddots & \\ & & & & & e_{n-2} & d_{n-1} & e_{n-1} \\ & & & & & & e_{n-1} & d_n \end{array}\right] \equiv \begin{bmatrix} T_1 & e_k \mathbf{e}_k \mathbf{e}_1^T \\ e_k \mathbf{e}_1 \mathbf{e}_k^T & T_2 \end{bmatrix}.$$

We assume that T is unreduced, that is, $e_i \neq 0$ for all i. Further, we assume that

$e_i > 0$ for all i, which can be easily attained by diagonal similarity with a diagonal matrix of signs (see Example 1 below). Let

$$\hat{T}_1 = T_1 - e_k \mathbf{e}_k \mathbf{e}_k^T, \qquad \hat{T}_2 = T_2 - e_k \mathbf{e}_1 \mathbf{e}_1^T. \tag{55.6}$$

In other words, $\hat{T}_1$ is equal to T_1 except that d_k is replaced by $d_k - e_k$, and $\hat{T}_2$ is equal to T_2 except that d_{k+1} is replaced by $d_{k+1} - e_k$.

Let $\hat{T}_i = \hat{U}_i \hat{\Lambda}_i \hat{U}_i^T$, $i = 1, 2$, be the respective EVDs and let $\mathbf{v} = \begin{bmatrix} \hat{U}_1^T \mathbf{e}_k \\ \hat{U}_2^T \mathbf{e}_1 \end{bmatrix}$ ($\mathbf{v}$ consists of the last column of $\hat{U}_1^T$ and the first column of $\hat{U}_2^T$). Set $\hat{U} = \hat{U}_1 \oplus \hat{U}_2$ and $\hat{\Lambda} = \hat{\Lambda}_1 \oplus \hat{\Lambda}_2$. Then

$$T = \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix} \left[\begin{bmatrix} \hat{\Lambda}_1 & \\ & \hat{\Lambda}_2 \end{bmatrix} + e_k \mathbf{v}\mathbf{v}^T \right] \begin{bmatrix} \hat{U}_1^T & \\ & \hat{U}_2^T \end{bmatrix} = \hat{U}(\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T)\hat{U}^T. \tag{55.7}$$

If

$$\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T = X \Lambda X^T$$

is the EVD of the rank-one modification of the diagonal matrix $\hat{\Lambda}$, then $T = U \Lambda U^T$, where $U = \hat{U} X$ is the EVD of T. Thus, the original tridiagonal eigenvalue problem is reduced to two smaller tridiagonal eigenvalue problems and one eigenvalue problem for the rank-one update of a diagonal matrix.

2. If the matrix $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$ is permuted such that $\hat{\lambda}_1 \geq \cdots \geq \hat{\lambda}_n$, then λ_i and $\hat{\lambda}_i$ are interlaced, that is,

$$\lambda_1 \geq \hat{\lambda}_1 \geq \lambda_2 \geq \hat{\lambda}_2 \geq \cdots \geq \lambda_{n-1} \geq \hat{\lambda}_{n-1} \geq \lambda_n \geq \hat{\lambda}_n.$$

Moreover, if $\hat{\lambda}_{i-1} = \hat{\lambda}_i$ for some i, then one eigenvalue is obviously known exactly, that is, $\lambda_i = \hat{\lambda}_i$. In this case, λ_i can be deflated by applying to $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$ a plane rotation in the $(i-1, i)$ plane, where the Givens rotation parameters c and s are computed from v_{i-1} and v_i as in Fact 51.5.13.

3. If all $\hat{\lambda}_i$ are different, then the eigenvalues λ_i of $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$ are solutions of the so-called secular equation,

$$1 + e_k \sum_{i=1}^{n} \frac{v_i^2}{\hat{\lambda}_i - \lambda} = 0.$$

The eigenvalues can be computed by bisection, or by some faster zero finder of the Newton type, and they need to be computed as accurately as possible.

4. Once the eigenvalues λ_i of $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$ are known, the corresponding eigenvectors are

$$\mathbf{x}_i = (\hat{\Lambda} - \lambda_i I)^{-1} \mathbf{v}.$$

5. Each λ_i and $\mathbf{x}_i$ in Facts 3 and 4 is computed in $O(n)$ operations, respectively, so the overall computational cost for computing the EVD of $\hat{\Lambda} + e_k \mathbf{v}\mathbf{v}^T$ is $O(n^2)$.
6. The accuracy of the computed EVD is given by Fact 55.1.15. However, if some eigenvalues are too close, they may not be computed with sufficient relative accuracy. As a consequence, the eigenvectors computed by using Fact 4 may not be sufficiently orthogonal. One remedy to this problem is to solve the secular equation from Fact 3 in double of the working precision. A better remedy is based on the solution of the following inverse eigenvalue problem. If $\hat{\lambda}_1 > \cdots > \hat{\lambda}_n$ and $\lambda_1 > \hat{\lambda}_1 > \lambda_2 > \hat{\lambda}_2 > \cdots > \lambda_{n-1} > \hat{\lambda}_{n-1} > \lambda_n > \hat{\lambda}_n$, then λ_i are the exact eigenvalues of the matrix $\hat{\Lambda} + e_k \hat{\mathbf{v}}\hat{\mathbf{v}}^T$, where

$$\hat{v}_i = \operatorname{sign} v_i \sqrt{\frac{\prod_{j=1}^{n} (\lambda_j - \hat{\lambda}_i)}{\prod_{j=1, j \neq i}^{n} (\hat{\lambda}_j - \hat{\lambda}_i)}}.$$

Instead of computing $\mathbf{x}_i$ according to Fact 4, we compute $\hat{\mathbf{x}}_i = (\hat{\Lambda} - \lambda_i I)^{-1}\hat{\mathbf{v}}$. The eigenvector matrix of T is now computed as $U = \hat{U}\hat{X}$, where $\hat{X} = \begin{bmatrix} \mathbf{x}_1 & \cdots & \mathbf{x}_n \end{bmatrix}$, instead of $U = \hat{U}X$ as in Fact 1. See also Fact 8.

7. The algorithm for the divide and conquer method is the following:

```
Algorithm 6: Divide and conquer method
Input: real symmetric tridiagonal $n \times n$ matrix $T$ with $t_{i-1,i} > 0$ for all $i$
Output: eigenvalue matrix $\Lambda$ and eigenvector matrix $U$ of $T$
 function $(\Lambda, U) = \mathit{Divide\_and\_Conquer}(T)$
    if $n = 1$, then
       $U = 1$
       $\Lambda = T$
    else
       $k = floor(n/2)$
       form $\hat{T}_1$ and $\hat{T}_2$ = as in Eq. (55.6) in Fact 1
       $(\hat{\Lambda}_1, \hat{U}_1) = \mathit{Divide\_and\_Conquer}(\hat{T}_1)$
       $(\hat{\Lambda}_2, \hat{U}_2) = \mathit{Divide\_and\_Conquer}(\hat{T}_2)$
       form $\hat{\Lambda} + e_k\mathbf{v}\mathbf{v}^T$ as in Eq. (55.7) in Fact 1
       compute the eigenvalues $\lambda_i$ via Fact 3
       compute $\hat{\mathbf{v}}$ via Fact 6
       $\hat{\mathbf{x}}_i = (\hat{\Lambda} - \lambda_i I)^{-1}\hat{\mathbf{v}}$
       $U = \begin{bmatrix} \hat{U}_1 & \\ & \hat{U}_2 \end{bmatrix} \hat{X}$
    endif
```

8. The rationale for the approach of Fact 6 and Algorithm 6 is the following: The computations of $\hat{\mathbf{v}}$ and $\hat{\mathbf{x}}_i$ involve only subtractions of exact quantities, so there is no cancellation. Thus, all entries of each $\hat{\mathbf{x}}_i$ are computed with high relative accuracy so $\hat{\mathbf{x}}_i$ are mutually orthonormal to working precision. Also, the transition from the matrix $\hat{\Lambda} + e_k\mathbf{v}\mathbf{v}^T$ to the matrix $\hat{\Lambda} + e_k\hat{\mathbf{v}}\hat{\mathbf{v}}^T$ induces only perturbations that are bounded by $\epsilon\|T\|$. Thus, the EVD computed by Algorithm 6 satisfies the error bounds given in Fact 55.1.15, producing at the same time numerically orthogonal eigenvectors. For details, see [Dem97, pp. 224–226] and [GE95].
9. Although Algorithm 6 requires $O(n^3)$ operations (this is due to the computation of U in the last line), it is in practice usually faster than Algorithm 4 from Fact 55.3.2. This is due to deflations which are performed when solving the secular equation from Fact 3, resulting in matrix $\hat{X}$ having many zeros.
10. The operation count of Algorithm 6 can be reduced to $O(n^2 \log n)$ if the Fast Multipole Method, originally used in particle simulation, is used for solving the secular equation from Fact 3 and for multiplying $\hat{U}\hat{X}$ in the last line of Algorithm 6. For details, see [Dem97, pp. 227–228] and [GE95].

Examples:

1. Let T be the matrix from Example 55.2.1 pre- and postmultiplied by the matrix $D = \operatorname{diag}(1, -1, -1, 1)$:

$$T = \begin{bmatrix} 4.5013 & 3.0194 & 0 & 0 \\ 3.0194 & -0.3692 & 1.2804 & 0 \\ 0 & 1.2804 & 0.5243 & 0.9303 \\ 0 & 0 & 0.9303 & 2.6774 \end{bmatrix}.$$

The EVDs of the matrices $\hat{T}_1$ and $\hat{T}_2$ from Eq. (55.6) in Fact 1 are

$$\hat{T}_1 = \begin{bmatrix} 4.5013 & 3.0194 \\ 3.0194 & -1.6496 \end{bmatrix}, \quad \hat{U}_1 = \begin{bmatrix} 0.3784 & -0.9256 \\ -0.9256 & -0.3784 \end{bmatrix}, \quad \hat{\Lambda}_1 = \begin{bmatrix} -2.8841 & 0 \\ 0 & 5.7358 \end{bmatrix},$$
$$\hat{T}_2 = \begin{bmatrix} -0.7561 & 0.9303 \\ 0.9303 & 2.6774 \end{bmatrix}, \quad \hat{U}_2 = \begin{bmatrix} -0.9693 & -0.2458 \\ 0.2458 & -0.9693 \end{bmatrix}, \quad \hat{\Lambda}_2 = \begin{bmatrix} -0.9920 & 0 \\ 0 & 2.9132 \end{bmatrix},$$

so, in Eq. (55.7) in Fact 1, we have

$$\hat{\Lambda} = \operatorname{diag}(-2.8841, 5.7358, -0.9920, 2.9132),$$
$$\mathbf{v} = [-0.9256 \quad -0.3784 \quad -0.9693 \quad -0.2458]^T.$$

2. Algorithm 6 is implemented in the LAPACK subroutine DSTEDC. This routine can compute just the eigenvalues or both eigenvalues and eigenvectors. The routine requires workspace of approximately n^2 elements. The timings are given in Section 55.9.

55.5 Bisection and Inverse Iteration

The bisection method is convenient if only part of the spectrum is needed. If the eigenvectors are needed as well, they can be efficiently computed by the inverse iteration method (see Facts 55.1.7 and 55.1.8).

Facts:

The following facts can be found in [Dem97, pp. 228–213] and [Par80, pp. 65–75].

A is a real symmetric $n \times n$ matrix and T is a real symmetric tridiagonal $n \times n$ matrix.

1. (Sylvester's theorem) For a real nonsingular matrix X, the matrices A and X^TAX have the same inertia. (See also Section 9.3.)
2. Let $\alpha, \beta \in \mathbb{R}$ with $\alpha < \beta$. The number of eigenvalues of A in the interval $[\alpha, \beta)$ is equal to $\nu(A - \beta I) - \nu(A - \alpha I)$. By systematically choosing the intervals $[\alpha, \beta)$, the bisection method pinpoints each eigenvalue of A to any desired accuracy.
3. In the factorization $T - \mu I = LDL^T$, where $D = \operatorname{diag}(d_1, \ldots, d_n)$ and L is the unit lower bidiagonal matrix, the elements of D are computed by the recursion

$$d_1 = t_{11} - \mu, \quad d_i = (t_{ii} - \mu) - t_{i,i-1}^2 / d_{i-1}, \quad i = 2, \ldots n,$$

and the subdiagonal elements of L are given by $l_{i+1,i} = t_{i+1,i}/d_i$. By Fact 1 the matrices T and D have the same inertia; thus, the above recursion enables an efficient implementation of the bisection method for T.
4. The factorization from Fact 3 is essentially Gaussian elimination without pivoting. Nevertheless, if $d_i \neq 0$ for all i, the above recursion is very stable (see [Dem97, Lemma 5.4] for details).
5. Even when $d_{i-1} = 0$ for some i, if the IEEE arithmetic is used, the computation will continue and the inertia will be computed correctly. Namely, in that case, we would have $d_i = -\infty$, $l_{i+1,i} = 0$, and $d_{i+1} = t_{i+1.i+1} - \mu$. For details, see [Dem97, pp. 230–231] and the references therein.

6. Computing one eigenvalue of T by using the recursion from Fact 3 and bisection requires $O(n)$ operations. For a computed eigenvalue, the corresponding eigenvector is computed by inverse iteration given by Eq. (55.2). The convergence is very fast (Fact 55.1.7), so the cost of computing each eigenvector is also $O(n)$ operations. Therefore, the overall cost for computing all eigenvalues and eigenvectors is $O(n^2)$ operations.
7. Both bisection and inverse iteration are highly parallel since each eigenvalue and eigenvector can be computed independently.
8. If some of the eigenvalues are too close, the corresponding eigenvectors computed by inverse iteration may not be sufficiently orthogonal. In this case, it is necessary to orthogonalize these eigenvectors (for example, by the modified Gram–Schmidt procedure). If the number of close eigenvalues is too large, the overall operation count can increase to $O(n^3)$.
9. The EVD computed by bisection and inverse iteration satisfies the error bounds from Fact 55.1.15.

Examples:

1. The bisection method for tridiagonal matrices is implemented in the LAPACK subroutine DSTEBZ. This routine can compute all eigenvalues in a given interval or the eigenvalues from λ_l to λ_k, where $l < k$, and the eigenvalues are ordered from smallest to largest. Inverse iteration (with reorthogonalization) is implemented in the LAPACK subroutine DSTEIN. The timings for computing half of the largest eigenvalues and the corresponding eigenvectors are given in Section 55.9.

55.6 Multiple Relatively Robust Representations

The computation of the tridiagonal EVD which satisfies the error bounds of Fact 55.1.15 such that the eigenvectors are orthogonal to working precision, all in $O(n^2)$ operations, has been the "holy grail" of numerical linear algebra for a long time. The method of Multiple Relatively Robust Representations (MRRR) does the job, except in some exceptional cases. The key idea is to implement inverse iteration more carefully. The practical algorithm is quite elaborate and only main ideas are described here.

Facts:

The following facts can be found in [Dhi97], [DP04], and [DPV06].

$T = [t_{ij}]$ denotes a real symmetric tridiagonal matrix of order n. D, D_+, and D_- are diagonal matrices with the i-th diagonal entry denoted by d_i, $D_+(i)$, and $D_-(i)$, respectively. L and L_+ are unit lower bidiagonal matrices and U_- is a unit upper bidiagonal matrix, where we denote $(L)_{i+1,i}$ by l_i, $(L_+)_{i+1,i}$ by $L_+(i)$, and $(U_-)_{i,i+1}$ by $U_-(i)$.

1. Instead of working with the given T, the MRRR method works with the factorization $T = LDL^T$ (computed, for example, as in Fact 55.5.3 with $\mu = 0$). If T is positive definite, then all eigenvalues of LDL^T are determined to high relative accuracy in the sense that small relative changes in the elements of L and D cause only small relative changes in the eigenvalues. If T is indefinite, then the tiny eigenvalues of LDL^T are determined to high relative accuracy in the same sense. The bisection method based on Algorithms 7a and 7b computes the well-determined eigenvalues of LDL^T to high relative accuracy; that is, the computed eigenvalue $\hat{\lambda}$ satisfies $|\lambda - \hat{\lambda}| = O(n\epsilon|\hat{\lambda}|)$.

2. The MRRR method is based on the following three algorithms:

Algorithm 7a: Differential stationary qd transform

Input: factors L and D of T and the computed eigenvalue $\hat{\lambda}$

Output: matrices D_+ and L_+ such that $LDL^T - \hat{\lambda} I = L_+ D_+ L_+^T$ and vector $\mathbf{s}$

```
$s_1 = -\hat{\lambda}$
for $i = 1 : n-1$
    $D_+(i) = s_i + d_i$
    $L_+(i) = (d_i l_i)/D_+(i)$
    $s_{i+1} = L_+(i) l_i s_i - \hat{\lambda}$
endfor
$D_+(n) = s_n + d_n$
```

Algorithm 7b: Differential progressive qd transform

Input: factors L and D of T and the computed eigenvalue $\hat{\lambda}$

Output: matrices D_- and U_- such that $LDL^T - \hat{\lambda} I = U_- D_- U_-^T$ and vector $\mathbf{p}$

```
$p_n = d_n - \hat{\lambda}$
for $i = n-1 : -1 : 1$
    $D_-(i+1) = d_i l_i^2 + p_{i+1}$
    $t = d_i / D_-(i+1)$
    $U_-(i) = l_i t$
    $p_i = p_{i+1} t - \hat{\lambda}$
endfor
$D_-(1) = p_1$
```

Algorithm 7c: Eigenvector computation

Input: output of Algorithms 7a and 7b and the computed eigenvalue $\hat{\lambda}$

Output: index r and the eigenvector $\mathbf{u}$ such that $LDL^T \mathbf{u} = \hat{\lambda} \mathbf{u}$

```
for $i = 1 : n-1$
    $\gamma_i = s_i + \frac{d_i}{D_-(i+1)} p_{i+1}$
endfor
$\gamma_n = s_n + p_n + \hat{\lambda}$
find $r$ such that $|\gamma_r| = \min_i |\gamma_i|$
$u_r = 1$
for $i = r-1 : -1 : 1$
    $u_i = -L_+(i) u_{i+1}$
endfor
for $i = r : n-1$
    $u_{i+1} = -U_-(i) u_i$
endfor
$\mathbf{u} = \mathbf{u} / \|\mathbf{u}\|_2$
```

3. Algorithm 7a is accurate in the sense that small relative perturbations (of the order of few ϵ) in the elements l_i, d_i, and the computed elements $L_+(i)$ and $D_+(i)$ make $LDL^T - \hat{\lambda} I = L_+ D_+ L_+^T$ an exact equality. Similarly, Algorithm 7b is accurate in the sense that small relative perturbations in the elements l_i, d_i, and the computed elements $U_-(i)$ and $D_-(i)$ make $LDL^T - \hat{\lambda} I = U_- D_- U_-^T$ an exact equality.
4. The idea behind Algorithm 7c is the following: Index r is the index of the column

of the matrix $(LDL^T - \hat{\lambda}I)^{-1}$ with the largest norm. Since the matrix $LDL^T - \hat{\lambda}I$ is nearly singular, the eigenvector is computed in just one step of inverse iteration given by Eq. (55.2) starting from the vector $\gamma_r \mathbf{e}_r$. Further, $LDL^T - \hat{\lambda}I = N\Delta N^T$, where $N\Delta N^T$ is the the so-called twisted factorization obtained from L_+, D_+, U_-, and D_-:

$$\begin{aligned} \Delta &= \operatorname{diag}(D_+(1), \ldots, D_+(r-1), \gamma_r, D_-(r+1), \ldots, D_-(n)), \\ N_{ii} &= 1, \\ N_{i+1,i} &= L_+(i), \quad i = 1, \ldots, r-1, \\ N_{i,i+1} &= U_-(i), \quad i = r, \ldots, n-1. \end{aligned}$$

Since $\Delta \mathbf{e}_r = \gamma_r \mathbf{e}_r$ and $N\mathbf{e}_r = \mathbf{e}_r$, solving $N\Delta N^T \mathbf{u} = \gamma_r \mathbf{e}_r$ is equivalent to solving $N^T \mathbf{u} = \mathbf{e}_r$, which is exactly what is done by Algorithm 7c.

5. If an eigenvalue λ is well separated from other eigenvalues in the relative sense (the quantity $\min_{\mu \in \sigma(A), \mu \neq \lambda} |\lambda - \mu|/|\lambda|$ is large, say greater than 10^{-3}), then the computed vector $\hat{\mathbf{u}}$ satisfies $\|\sin \Theta(\mathbf{u}, \hat{\mathbf{u}})\|_2 = O(n\epsilon)$. If all eigenvalues are well separated from each other, then the computed EVD satisfies error bounds of Fact 55.1.15 and the computed eigenvectors are numerically orthogonal, that is, $|\hat{\mathbf{u}}_i^T \hat{\mathbf{u}}_j| = O(n\epsilon)$ for $i \neq j$.
6. If there is a cluster of poorly separated eigenvalues which is itself well separated from the rest of $\sigma(A)$, the MRRR method chooses a shift μ which is near one end of the cluster and computes a new factorization $LDL^T - \mu I = L_+ D_+ L_+^T$. The eigenvalues within the cluster are then recomputed by bisection as in Fact 1 and their corresponding eigenvectors are computed by Algorithms 7a, 7b, and 7c. When properly implemented, this procedure results in the computed EVD, which satisfies the error bounds of Fact 55.1.15 and the computed eigenvectors are numerically orthogonal.

Examples:

1. The MRRR method is implemented in the LAPACK subroutine DSTEGR. This routine can compute just the eigenvalues, or both eigenvalues and eigenvectors. The timings are given in Section 55.9.

55.7 Jacobi Method

The Jacobi method is the oldest method for EVD computations [Jac846]. The method does not require tridiagonalization. Instead, the method computes a sequence of orthogonally similar matrices which converge to Λ. In each step a simple plane rotation, which sets one off-diagonal element to zero, is performed.

Definitions:

A is a real symmetric matrix of order x and $A = U\Lambda U^T$ is its EVD.

The **Jacobi method** forms a sequence of matrices,

$$A_0 = A, \qquad A_{k+1} = G(i_k, j_k, c, s) A_k G(i_k, j_k, c, s)^T, \qquad k = 1, 2, \ldots,$$

where $G(i_k, j_k, c, s)$ is the plane rotation matrix defined in Section 51.5. The parameters c and s are chosen such that $[A_{k+1}]_{i_k j_k} = [A_{k+1}]_{j_k i_k} = 0$ and are computed as described in Fact 1.

The plane rotation with c and s as above is also called the **Jacobi rotation**.

The **off-norm** of A is defined as $\operatorname{off}(A) = (\sum_i \sum_{j \neq i} a_{ij}^2)^{1/2}$, that is, off-norm is the Frobenius norm of the matrix consisting of all off-diagonal elements of A.

The choice of **pivot elements** $[A_k]_{i_k j_k}$ is called the **pivoting strategy**.

The **optimal pivoting** strategy, originally used by Jacobi, chooses pivoting elements such that $|[A_k]_{i_k j_k}| = \max_{i<j} |[A_k]_{ij}|$.

The **row cyclic** pivoting strategy chooses pivot elements in the systematic row-wise order,

$$(1,2),(1,3),\ldots,(1,n),(2,3),(2,4),\ldots,(2,n),(3,4),\ldots,(n-1,n).$$

Similarly, the column-cyclic strategy chooses pivot elements column-wise.

One pass through all matrix elements is called **cycle** or **sweep**.

Facts:

Facts 1 to 8 can be found in [Wil65, pp. 265–282], [Par80, Chap. 9], [GV96, Chap. 8.4], and [Dem97, Chap. 5.3.5].

1. The Jacobi rotations parameters c and s are computed as follows: If $[A_k]_{i_k j_k} = 0$, then $c = 1$ and $s = 0$, otherwise

$$\tau = \frac{[A_k]_{i_k i_k} - [A_k]_{j_k j_k}}{2[A_k]_{i_k j_k}}, \qquad t = \frac{\operatorname{sign}(\tau)}{|\tau| + \sqrt{1+\tau^2}}, \qquad c = \frac{1}{\sqrt{1+t^2}}, \qquad s = c \cdot t.$$

2. After each rotation, the off-norm decreases, that is,

$$\operatorname{off}^2(A_{k+1}) = \operatorname{off}^2(A_k) - 2[A_k]_{i_k j_k}^2.$$

With the appropriate pivoting strategy, the method converges in the sense that

$$\operatorname{off}(A_k) \to 0, \qquad A_k \to \Lambda, \qquad \prod_{k=1}^{\infty} R_{(i_k,j_k)}^T \to U.$$

3. For the optimal pivoting strategy the square of the pivot element is greater than the average squared element, $[A_k]_{i_k j_k}^2 \geq \operatorname{off}^2(A)\frac{1}{n(n-1)}$. Thus,

$$\operatorname{off}^2(A_{k+1}) \leq \left(1 - \frac{2}{n(n-1)}\right) \operatorname{off}^2(A_k)$$

and the method converges.

4. For the row cyclic and the column cyclic pivoting strategies, the method converges. The convergence is ultimately quadratic in the sense that

$$\operatorname{off}(A_{k+n(n-1)/2}) \leq \ \gamma \operatorname{off}^2(A_k)$$

for some constant γ, provided $\operatorname{off}(A_k)$ is sufficiently small.

5. We have the following algorithm:

```
**Algorithm 8:** Jacobi method with row-cyclic pivoting strategy
Input: real symmetric $n \times n$ matrix $A$
Output: the eigenvalue matrix $\Lambda$ and the eigenvector matrix $U$
$U = I_n$
repeat    % one cycle
    for $i = 1 : n-1$
        for $j = i+1 : n$
            compute $c$ and $s$ according to Fact 1
            $\begin{bmatrix} A_{i,1:n} \\ A_{j,1:n} \end{bmatrix} = G(i,j,c,s) \begin{bmatrix} A_{i,1:n} \\ A_{j,1:n} \end{bmatrix}$
            $\begin{bmatrix} A_{1:n,i} & A_{1:n,j} \end{bmatrix} = \begin{bmatrix} A_{1:n,i} & A_{1:n,j} \end{bmatrix} G(i,j,c,s)^T$
            $\begin{bmatrix} U_{1:n,i} & U_{1:n,j} \end{bmatrix} = \begin{bmatrix} U_{1:n,i} & U_{1:n,j} \end{bmatrix} G(i,j,c,s)^T$
        endfor
    endfor
until  $\mathrm{off}(A) \leq tol$  for some user defined stopping criterion $tol$
$\Lambda = \mathrm{diag}(A)$
```

6. Detailed implementation of the Jacobi method can be found in [Rut66] and [WR71].
7. The EVD computed by the Jacobi method satisfies the error bounds from Fact 55.1.15.
8. The Jacobi method is suitable for parallel computation. There exist convergent parallel strategies that enable simultaneous execution of several rotations.
9. [GV96, p. 429] The Jacobi method is simple, but it is slower than the methods based on tridiagonalization. It is conjectured that standard implementations require $O(n^3 \log n)$ operations. More precisely, each cycle clearly requires $O(n^3)$ operations and it is conjectured that $\log n$ cycles are needed until convergence.
10. [DV92], [DV07] If A is positive definite, the method can be modified such that it reaches the speed of the methods based on tridiagonalization and at the same time computes the eigenvalues with high relative accuracy. See Chapter 59 for details.

Examples:

1. Let A be the matrix from Example 55.1.1. After executing two cycles of Algorithm 8, we have

$$A = \begin{bmatrix} 6.0054 & -0.0192 & 0.0031 & 0.0003 \\ -0.0192 & 3.0455 & -0.0005 & -0.0000 \\ 0.0031 & -0.0005 & 0.6024 & -0.0000 \\ 0.0003 & -0.0000 & 0.0000 & -2.3197 \end{bmatrix}.$$

55.8 Lanczos Method

If the matrix A is large and sparse and if only some eigenvalues and their eigenvectors are desired, sparse matrix methods are the methods of choice. For example, the power method can be useful to compute the eigenvalue with the largest modulus. The basic operation in the power method is matrix-vector multiplication, and this can be performed very fast if A is sparse. Moreover, A need not be stored in the computer — the input for the algorithm can be just a program which, given some vector $\mathbf{x}$, computes the product $A\mathbf{x}$. An "improved" version of the power method, which efficiently computes several eigenvalues (either largest in modulus or near some target value μ) and the corresponding eigenvectors, is the Lanczos method.

Definitions:

A is a real symmetric matrix of order n.

Given a nonzero vector $\mathbf{x}$ and an index $k < n$, the **Krylov matrix** is defined as $K_k = [\mathbf{x} \quad A\mathbf{x} \quad A^2\mathbf{x} \quad \cdots \quad A^{k-1}\mathbf{x}]$.

Facts:

The following facts can be found in [Par80, Chap. 13], [GV96, Chap. 9], [Dem97, Chap. 7], and [Ste01, Chap. 5.3].

1. The Lanczos method is based on the following observation. If $K_k = XR$ is the QR factorization of the matrix K_k (see Sections 5.5 and 51.5), then the $k \times k$ matrix $T = X^T AX$ is tridiagonal. The matrices X and T can be computed by using only matrix-vector products in just $O(kn)$ operations. Let $T = Q\Lambda Q^T$ be the EVD of T (computed by any of the methods from Sections 55.3 to 55.6). Then λ_i approximate well some of the largest and smallest eigenvalues of A. The columns of the matrix $U = XQ$ approximate the corresponding eigenvectors of A. We have the following algorithm:

```
Algorithm 9: Lanczos method
Input: real symmetric $n \times n$ matrix $A$, unit vector $\mathbf{x}$ and index $k < n$
Output: matrices $\Lambda$ and $U$
$X_{:,1} = \mathbf{x}$
for $i = 1 : k$
    $\mathbf{z} = A\,X_{:,i}$
    $t_{ii} = X_{:,i}^T\,\mathbf{z}$
    if $i = 1$, then
        $\mathbf{z} = \mathbf{z} - t_{ii}X_{:,i}$
    else
        $\mathbf{z} = \mathbf{z} - t_{ii}X_{:,i} - t_{i,i-1}X_{:,i-1}$
    endif
    $\mu = \|\mathbf{z}\|_2$
    if $\mu = 0$, then
        stop
    else
        $t_{i+1,i} = \mu$
        $t_{i,i+1} = \mu$
        $X_{:,i+1} = z/\mu$
    endif
endfor
compute the EVD of the tridiagonal matrix, $T(1:k, 1:k) = Q\Lambda Q^T$
$U = XQ$
```

2. As j increases, the largest (smallest) eigenvalues of the matrix $T_{1:j,1:j}$ converge toward some of the largest (smallest) eigenvalues of A (due to the Cauchy interlace property). The algorithm can be redesigned to compute only largest or smallest eigenvalues. Also, by using shift and invert strategy, the method can be used to compute eigenvalues near some specified value. In order to obtain better approximations, k should be greater than the number of required eigenvalues. On the other side, in order to obtain better accuracy and efficacy, k should be as small as possible (see Facts 3 and 4 below).

3. The eigenvalues of A are approximated from the matrix $T_{1:k,1:k}$; thus, the last element $\nu = t_{k+1,k}$ is not needed. However, this element provides key information about accuracy at no extra computational cost. The exact values of residuals are as follows: $\|AU - U\Lambda\|_2 = \nu$ and, in particular, $\|AU_{:,i} - \lambda_i U_{:,i}\|_2 = \nu|q_{ki}|$, $i = 1, \ldots, k$. Further, there are k eigenvalues $\tilde{\lambda}_1, \ldots, \tilde{\lambda}_k$ of A such that $|\lambda_i - \tilde{\lambda}_i| \leq \nu$. For the corresponding eigenvectors, we have $\sin 2\Theta(\mathbf{u}_i, \tilde{\mathbf{u}}_i) \leq 2\nu / \min_{j \neq i} |\lambda_i - \tilde{\lambda}_j|$. In practical implementations of Algorithm 9, ν is usually used to determine the index k.
4. Although theoretically very elegant, the Lanczos method has inherent numerical instability in the floating point arithmetic, and so it must be implemented carefully (see, e.g., [LSY98]). Since the Krylov vectors are, in fact, generated by the power method, they converge toward an eigenvector of A. Thus, as k increases, the Krylov vectors become more and more parallel. As a consequence, the recursion in Algorithm 9, which computes the orthogonal bases X for the subspace range K_k, becomes numerically unstable and the computed columns of X cease to be sufficiently orthogonal. This affects both the convergence and the accuracy of the algorithm. For example, it can happen that T has several eigenvalues that converge toward some simple eigenvalue of A (these are the so-called ghost eigenvalues).

   The loss of orthogonality is dealt with by using the full reorthogonalization procedure. In each step, the new $\mathbf{z}$ is orthogonalized against all previous columns of X. In Algorithm 9, the formula $\mathbf{z} = \mathbf{z} - t_{ii}X_{:,i} - t_{i,i-1}X_{:,i-1}$ is replaced by $\mathbf{z} = \mathbf{z} - \sum_{j=1}^{i-1}(\mathbf{z}^T X(:,j))X(:,j)$. To obtain better orthogonality, the latter formula is usually executed twice.

   The full reorthogonalization raises the operation count to $O(k^2 n)$. The selective reorthogonalization is the procedure in which the current $\mathbf{z}$ is orthogonalized against some selected columns of X. This is the way to attain sufficient numerical stability and not increase the operation count too much. The details of selective reorthogonalization procedures are very subtle and can be found in the references. (See also Chapter 57.)
5. The Lanczos method is usually used for sparse matrices. Sparse matrix A is stored in the sparse format in which only values and indices of nonzero elements are stored. The number of operations required to multiply some vector by A is also proportional to the number of nonzero elements. (See also Chapter 56.)

Examples:

1. Let A be the matrix from Example 55.1.1 and let $x = [1/2 \quad 1/2 \quad 1/2 \quad 1/2]^T$. For $k = 2$, the output of Algorithm 9 is

$$\Lambda = \begin{bmatrix} -2.0062 & \\ & 5.7626 \end{bmatrix}, \qquad U = \begin{bmatrix} -0.4032 & -0.8804 \\ 0.4842 & -0.2749 \\ 0.3563 & -0.3622 \\ 0.6899 & -0.1345 \end{bmatrix},$$

   with $\nu = 1.4965$ (c.f. Fact 3). For $k = 3$, the output is

$$\Lambda = \begin{bmatrix} -2.3107 & 0 & 0 \\ 0 & 2.8641 & 0 \\ 0 & 0 & 5.9988 \end{bmatrix}, \qquad U = \begin{bmatrix} 0.3829 & -0.0244 & 0.8982 \\ -0.2739 & -0.9274 & 0.0312 \\ -0.3535 & -0.1176 & 0.3524 \\ -0.8084 & 0.3541 & 0.2607 \end{bmatrix},$$

   with $\nu = 0.6878$.
2. The Lanczos method is implemented in the ARPACK routine `DSDRV`*, where * denotes the computation mode [LSY98, App. A]. The routines from ARPACK are implemented in the

MATLAB command `eigs`. Generation of a sparse symmetric 10,000 × 10,000 matrix with 10% nonzero elements with the MATLAB command `A=sprandsym(10000,0.1)` takes 6.5 seconds on a processor described in Fact 55.9.1. The computation of 100 largest eigenvalues and the corresponding eigenvectors with `[U,Lambda]=eigs(A,100,'LM',opts)` takes approximately 100 seconds. Here, index $k = 200$ is automatically chosen by the algorithm. (See also Chapter 94.)

55.9 Comparison of Methods

In this section, we give timings for the LAPACK implementations of the methods described in Sections 55.2 to 55.6. The timing for the Lanczos method is given in Example 55.8.3.

Definitions:

A measure of a processor's **efficacy** or **speed** is the number of floating-point operations per second (flops).

Facts:

A is an $n \times n$ real symmetric matrix and $A = U\Lambda U^T$ is its EVD. T is a tridiagonal $n \times n$ real symmetric matrix and $T = Q\Lambda Q^T$ is its EVD. $T = X^T AX$ is the reduction of A to a tridiagonal from Section 55.2.

1. Our tests were performed on the Intel64 Xeon Quad Core processor running at 2.33 GHz with 4 Gbytes of RAM and 4 Mbytes of cache memory. This processor performs up to 23 Gflops (23 billion operations per second). This performance is attained for the matrix multiplication with the BLAS 3 subroutine DGEMM.
2. Our test programs were compiled with the Intel `ifort` FORTRAN compiler (version 12.1.2) and linked with the Intel Math Kernel Library (version 10.3.8) in which LAPACK (version 3.3) and BLAS are implemented.
3. Timings for the methods are given in Table 55.1. The execution times for DSTEBZ (bisection) and DSTEIN (inverse iteration) are for computing one-half of the eigenvalues (the largest ones) and the corresponding eigenvectors, respectively. DSTEDC without eigenvectors, DSTEBZ, DSTEIN, and DSTEGR are implemented to use only one core.

TABLE 55.1 Execution times(s) for LAPACK routines for various matrix dimensions n.

Routine	Input	Output	Example	$n = 1000$	$n = 2000$	$n = 4000$
DSYTRD	A	T	2.3	0.24	3.11	32.6
DSYTRD/DORGTR		T, X		0.44	3.92	40.8
DSTEQR	T	Λ	3.2	0.09	0.33	1.26
		Λ, Q		0.62	5.03	37
DSYEV	A	Λ	3.4	0.44	2.91	15
		Λ, U		1.04	7.32	68
DSTEDC	T	Λ	4.2	0.07	0.24	0.95
		Λ, Q		0.21	0.24	0.94
DSTEBZ	T	Λ	5.1	0.43	1.66	6.45
DSTEIN		Q		0.1	0.43	4.01
DSTEGR	T	Λ	6.1	0.13	0.49	1.78
		Λ, Q		0.30	1.22	4.7

4. The performance attained for practical algorithms is lower than the peak performance from Fact 1. For example, by combining Facts 55.2.6 and 55.2.7 with Table 55.1, we see that the tridiagonalization routines DSYTRD and DORGTR attain the speed of 4 Gflops.
5. The computation times for the implicitly shifted QR routine, DSTEQR, grow approximately with n^2 when only eigenvalues are computed, and with n^3 when eigenvalues and eigenvectors are computed, as predicted in Facts 55.3.5 and 55.3.6.
6. The execution times for DSYEV are approximately equal to the sums of the timings for DSYTRD (tridiagonalization), DORGTR (computing X), and DSTEQR with the eigenvector option (computing the EVD of T).
7. The divide and conquer method, implemented in DSTEDC, is the fastest method for computing the EVD of a tridiagonal matrix.
8. DSTEBZ and DSTEIN (bisection and inverse iteration) are faster, especially for larger dimensions, than DSTEQR (tridiagonal QR iteration), but slower than DSTEDC (divide and conquer) and DSTEGR (multiple relatively robust representations).
9. Another algorithm to compute the EVD of T is to use DSTEQR to compute only the eigenvalues and then use DSTEIN (inverse iteration) to compute the eigenvectors. This is usually considerably faster than computing both eigenvalues and eigenvectors by DSTEQR.
10. The execution times for DSTEGR are proportional to $O(n^2)$.

Washington State University

56.1 The Generalized Eigenvalue Problem 56-1
56.2 Dense Matrix Techniques 56-3
56.3 Sparse Matrix Techniques............................. 56-10
References... 56-12

The definitions and basic properties of eigenvalues and eigenvectors are given in Section 4.4. A natural generalization is presented here in Section 56.1. Algorithms for computation of eigenvalues, eigenvectors, and their generalizations will be discussed in Sections 56.2 and 56.3.

If a large fraction of a matrix's entries are zeros, the matrix is called **sparse**. A matrix that is not sparse is called **dense**. Dense matrix techniques are methods that store the matrix in the conventional way, as an array, and operate on the array elements. Any matrix that is not too big to fit into a computer's main memory can be handled by dense matrix techniques, regardless of whether the matrix is dense or not. However, since the time to compute the eigenvalues of an $n \times n$ matrix by dense matrix techniques is proportional to n^3, the user may have to wait a while for the results if n is very large. Dense matrix techniques do not exploit the zeros in a matrix and tend to destroy them. With modern computers, dense matrix techniques can be applied to matrices of dimension up to 2000 or more. If a matrix is very large and sparse, and only a portion of the spectrum is needed, sparse matrix techniques (Section 56.3) are preferred.

The usual approach is to preprocess the matrix into Hessenberg form and then to effect a similarity transformation to triangular form: $T = S^{-1}AS$ by an iterative method. This yields the eigenvalues of A as the main-diagonal entries of T. For $k = 1, \ldots, n-1$, the first k columns of S span an invariant subspace. The eigenvectors of an upper-triangular matrix are easily computed by back substitution, and the eigenvectors of A can be deduced from the eigenvectors of T [GV13, Chap. 7.6], [Wat07, Chap. 4.8], [Wat10, Chap. 5.7]. If a matrix A is very large and sparse, only a partial similarity transformation is possible because a complete similarity transformation would require too much memory and take too long to compute.

56.1 The Generalized Eigenvalue Problem

Many matrix eigenvalue problems are most naturally viewed as generalized eigenvalue problems.

Definitions:

Given $A \in \mathbb{C}^{n\times n}$ and $B \in \mathbb{C}^{n\times n}$, the nonzero vector $\mathbf{v} \in \mathbb{C}^n$ is called an **eigenvector** of the pair

(A, B) if there are scalars μ, $\nu \in \mathbb{C}$, not both zero, such that

$$\nu A\mathbf{v} = \mu B\mathbf{v}.$$

Then, the scalar $\lambda = \mu/\nu$ is called the **eigenvalue** of (A, B) associated with the eigenvector $\mathbf{v}$. If $\nu = 0$, then the eigenvalue is ∞ by convention.

The expression $A - \lambda B$, with indeterminate λ, is called a **matrix pencil**. Whether we refer to the pencil $A - \lambda B$ or the pair (A, B), we are speaking of the same object. The pencil (or the pair (A, B)) is called **singular** if $A - \lambda B$ is singular for all $\lambda \in \mathbb{C}$. The pencil is **regular** if there exists a $\lambda \in \mathbb{C}$ such that $A - \lambda B$ is nonsingular. We will restrict our attention to regular pencils.

The **characteristic polynomial** of the pencil $A - \lambda B$ is $\det(\lambda B - A)$, and the **characteristic equation** is $\det(\lambda B - A) = 0$.

Two pairs (A, B) and (C, D) are **strictly equivalent** if there exist nonsingular matrices S_1 and S_2 such that $C - \lambda D = S_1(A - \lambda B)S_2$ for all $\lambda \in \mathbb{C}$. If S_1 and S_2 can be taken to be unitary, then the pairs are **strictly unitarily equivalent**.

A pair (A, B) is called **upper triangular** if both A and B are upper triangular.

Facts:

The following facts are discussed in [GV13, Chap. 7.7], [Wat07, Chap. 6.1], and [Wat10, Chap. 7.4].

1. When $B = I$, the generalized eigenvalue problem for the pair (A, B) reduces to the standard eigenvalue problem for the matrix A.
2. λ is an eigenvalue of (A, B) if and only if $A - \lambda B$ is singular.
3. λ is an eigenvalue of (A, B) if and only if $\ker(\lambda B - A) \neq \{0\}$.
4. The eigenvalues of (A, B) are exactly the solutions of the characteristic equation $\det(\lambda B - A) = 0$.
5. The characteristic polynomial $\det(\lambda B - A)$ is a polynomial in λ of degree $\leq n$.
6. The pair (A, B) (or the pencil $A - \lambda B$) is singular if and only if $\det(\lambda B - A) = 0$ for all λ.
7. If the pair (A, B) is regular, then $\det(\lambda B - A)$ is a nonzero polynomial of degree $k \leq n$. (A, B) has k finite eigenvalues.
8. The degree of $\det(\lambda B - A)$ is exactly n if and only if B is nonsingular.
9. If B is nonsingular, then the eigenvalues of (A, B) are exactly the eigenvalues of the matrices AB^{-1} and $B^{-1}A$.
10. If $\lambda \neq 0$, then λ is an eigenvalue of (A, B) if and only if λ^{-1} is an eigenvalue of (B, A).
11. Zero is an eigenvalue of (A, B) if and only if A is a singular matrix.
12. Infinity is an eigenvalue of (A, B) if and only if B is a singular matrix.
13. Two pairs that are strictly equivalent have the same eigenvalues.
14. If $C - \lambda D = S_1(A - \lambda B)S_2$, then $\mathbf{v}$ is an eigenvector of (A, B) if and only if $S_2^{-1}\mathbf{v}$ is an eigenvector of (C, D).
15. (Schur's Theorem) Every $A \in \mathbb{C}^{n\times n}$ is unitarily similar to an upper-triangular matrix S.
16. (Generalized Schur Theorem) Every pair (A, B) is strictly unitarily equivalent to an upper triangular pair (S, T).
17. The characteristic polynomial of an upper triangular pair (S, T) is $\displaystyle\prod_{k=1}^{n}(\lambda t_{kk} - s_{kk})$.

    The eigenvalues of (S, T) are $\lambda_k = s_{kk}/t_{kk}$, $k = 1, \ldots, n$. If $t_{kk} = 0$ and $s_{kk} \neq 0$, then $\lambda_k = \infty$. If $t_{kk} = 0$ and $s_{kk} = 0$ for some k, the pair (S, T) is singular.

Examples:

1. Let $A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix}$ and $B = \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix}$. Then the characteristic equation of the pair (A, B) is $\lambda^2 + \lambda - 2 = 0$, and the eigenvalues are 1 and -2.
2. Since the pencil
$$\begin{bmatrix} 2 & 5 \\ 0 & 7 \end{bmatrix} - \lambda \begin{bmatrix} 5 & 1 \\ 0 & 3 \end{bmatrix}$$
is upper triangular, its characteristic polynomial is $(5\lambda - 2)(3\lambda - 7)$, and its eigenvalues are $2/5$ and $7/3$.
3. The pencil
$$\begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix} - \lambda \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}$$
has characteristic equation $\lambda = 0$. It is a regular pencil with eigenvalues 0 and ∞.

56.2 Dense Matrix Techniques

The steps that are usually followed for solving the unsymmetric eigenvalue problem are preprocessing, eigenvalue computation with Francis's implicitly shifted QR algorithm, and eigenvector computation. The characteristic equation, which is important in theory, plays no role in practical eigenvalue computations.

The most widely used public domain software for this problem is from LAPACK [ABB99] and Chapter 93. Versions in FORTRAN and C are available. The most popular proprietary software is MATLAB, which uses computational routines from LAPACK. Several of LAPACK's computational routines will be mentioned in this section. LAPACK also has a number of driver routines that call the computational routines to perform the most common tasks, thereby making the user's job easier. A very easy way to use LAPACK routines is to use MATLAB.

This section presents algorithms for the reader's edification. However, the reader is strongly advised to use well-tested software written by experts whenever possible, rather than writing his or her own code. The actual software is very complex and addresses details that cannot be discussed here.

Definitions:

A matrix $A \in \mathbb{C}^{n \times n}$ is called **upper Hessenberg** if $a_{ij} = 0$ whenever $i > j + 1$. This means that every entry below the first subdiagonal of A is zero. An upper Hessenberg matrix is called **unreduced upper Hessenberg** if $a_{j+1,j} \neq 0$ for $j = 1, \ldots, n - 1$.

A matrix $A \in \mathbb{R}^{n \times n}$ is called **quasi-triangular** if it is block upper triangular with 1×1 and 2×2 blocks along the main diagonal.

Facts:

The following facts are proved in [Dem97], [GV13], [Kre05], [Wat07], or [Wat10].

1. Preprocessing is a two-step process involving balancing the matrix and transforming by unitary similarity to upper Hessenberg form.
2. The first step, which is optional, is to balance the matrix. The balancing operation begins by performing a permutation similarity transformation that exposes any obvious eigenvalues. The remaining submatrix is irreducible. It then performs a diagonal similarity transformation $D^{-1}AD$ that attempts to make the norms of the ith row

and ith column as nearly equal as possible, $i = 1, \ldots, n$. This has the effect of reducing the overall norm of the matrix and in diminishing the effects of roundoff errors [Osb60]. The scaling factors in D are taken to be powers of the base of floating point arithmetic (usually 2). No roundoff errors are caused by this transformation.

3. All modern balancing routines, including the code GEBAL in LAPACK, are derived from the code in Parlett and Reinsch [PR69]. See also [Kre05].

Algorithm 1: Balancing an Irreducible Matrix. An irreducible matrix $A \in \mathbb{C}^{n\times n}$ is input. On output, A has been overwritten by $D^{-1}AD$, where D is diagonal.

```
$b \leftarrow$ base of floating point arithmetic (usually 2)
$D \leftarrow I_n$
done $\leftarrow 0$
while done $= 0$
    done $\leftarrow 1$
    for $j = 1 : n$
        $c \leftarrow \sum_{i\neq j} |a_{ij}|, \quad r \leftarrow \sum_{k\neq j} |a_{jk}|$
        $s \leftarrow c + r, \quad f \leftarrow 1$
        while $b\,c < r$
            $c \leftarrow b\,c, \quad r \leftarrow r/b, \quad f \leftarrow b\,f$
        while $b\,r < c$
            $c \leftarrow c/b, \quad r \leftarrow b\,r, \quad f \leftarrow f/b$
        if $c + r < 0.95\,s$
            done $\leftarrow 0, \quad d_{jj} \leftarrow f\,d_{jj}$
            $A_{1:n,j} \leftarrow f\,A_{1:n,j}, \quad A_{j,1:n} \leftarrow (1/f)\,A_{j,1:n}$
end
```

4. In most cases, balancing will have little effect on the outcome of the computation, but sometimes it results in greatly improved accuracy [BDD00, Chap. 7.2].
5. The second preprocessing step is to transform the matrix to upper Hessenberg form. This is accomplished by a sequence of $n-2$ steps. On the jth step, zeros are introduced into the jth column.
6. For every $\mathbf{x} \in \mathbb{C}^n$ there is a unitary matrix U such that $U\mathbf{x} = \alpha\mathbf{e}_1$, for some scalar $\alpha \in \mathbb{C}$, where $\mathbf{e}_1$ is the vector having a 1 in the first position and zeros elsewhere. U can be chosen to be a rank-one modification of the identity matrix: $U = I + \mathbf{u}\mathbf{v}^*$. See Section 51.5 for a discussion of Householder and Givens matrices.
7.

Algorithm 2: Unitary Similarity Transformation to Upper Hessenberg Form. A general matrix $A \in \mathbb{C}^{n\times n}$ is input. On output, A has been overwritten by an upper Hessenberg matrix Q^*AQ. The unitary transforming matrix Q has also been generated.

```
$Q \leftarrow I_n$
for $j = 1 : n - 2$
    Let $\mathbf{x} = A_{j+1:n,j} \in \mathbb{C}^{n-j}$.
    Build unitary $U \in \mathbb{C}^{n-j\times n-j}$ such that $U^*\mathbf{x} = \gamma\mathbf{e}_1$.
    $A_{j+1:n,j:n} \leftarrow U^* A_{j+1:n,j:n}$
    $A_{1:n,j+1:n} \leftarrow A_{1:n,j+1:n}U$
    $Q_{1:n,j+1:n} \leftarrow Q_{1:n,j+1:n}U$
end
```

8. The cost of the reduction to Hessenberg form is proportional to n^3 for large n; that is, it is $O(n^3)$.
9. Once the matrix is in upper Hessenberg form, if any of the subdiagonal entries $a_{j+1,j}$ is zero, the matrix is block upper triangular with a $j \times j$ block and an $n-j \times n-j$ block, and the eigenvalue problem decouples to two independent problems of smaller size. Thus, we always work with unreduced upper Hessenberg matrices.
10. In practice we set an entry $a_{j+1,j}$ to zero whenever

$$|a_{j+1,j}| < \epsilon(|a_{jj}| + |a_{j+1,j+1}|),$$

where ϵ is the computer's unit roundoff.
11. If $T \in \mathbb{C}^{n\times n}$ is upper triangular and nonsingular, then T^{-1} is upper triangular. If $H \in \mathbb{C}^{n\times n}$ is upper Hessenberg, then TH, HT, and THT^{-1} are upper Hessenberg.
12. The standard method for computing the eigenvalues of a Hessenberg matrix is Francis's implicitly shifted QR algorithm [Fra61], [Wat11], an iterative method that produces a sequence of unitarily similar matrices that converges to upper triangular form.
13. The most basic (unshifted) version of the QR algorithm starts with $A_0 = A$, an unreduced upper Hessenberg matrix, and generates a sequence (A_m) as follows: Given A_{m-1}, a decomposition $A_{m-1} = Q_m R_m$, where Q_m is unitary and R_m is upper triangular, is computed. Then the factors are multiplied back together in reverse order to yield $A_m = R_m Q_m$. Equivalently, $A_m = Q_m^* A_{m-1} Q_m$.
14. Upper Hessenberg form is preserved by iterations of the QR algorithm.
15. The QR algorithm can also be applied to non-Hessenberg matrices, but the operations are much more economical in the Hessenberg case.
16. The basic QR algorithm converges slowly, so shifts of origin are used to accelerate convergence:

$$A_{m-1} - \mu_m I = Q_m R_m, \quad R_m Q_m + \mu_m I = Q_m^* A_{m-1} Q_m = A_m,$$

where $\mu_m \in \mathbb{C}$ is a shift chosen to approximate an eigenvalue.
17. Often it is convenient to take several steps at once:

Algorithm 3: Explicit QR iteration of degree k.

```
Choose $k$ shifts $\mu_1, \ldots \mu_k$.
Let $p(A) = (A - \mu_1 I)(A - \mu_2 I)\cdots(A - \mu_k I)$.
Compute a $QR$ decomposition $p(A) = QR$.
$A \leftarrow Q^* A Q$
```

18. A QR iteration of degree k is equivalent to k iterations of degree 1 with shifts $\mu_1, \ldots,$ μ_k applied in succession in any order [Wat07]. Upper Hessenberg form is preserved. In practice, k is never taken very big; typical values are 1, 2, 4, and 6.
19. One important application of multiple steps is to complex shifts applied to real matrices. Complex arithmetic is avoided by taking $k = 2$ and shifts related by $\mu_2 = \overline{\mu}_1$.
20. The usual choice of k shifts is the set of eigenvalues of the lower right hand $k \times k$ submatrix of the current iterate. With this choice of shifts at each iteration, the entry $a_{n-k+1,n-k}$ typically converges to zero quadratically [WE91], isolating a $k \times k$ submatrix after only a few iterations. However, convergence is not guaranteed, and failures do occasionally occur. No shifting strategy that guarantees convergence in all cases is known. For discussions of shifting strategies and convergence see [Wat07], [Wat10], or [WE91].

21. After each iteration, all of the subdiagonal entries should be checked to see if any of them can be set to zero. The objective is to break the big problem into many small problems in as few iterations as possible. Once a submatrix of size 1 × 1 has been isolated, an eigenvalue has been found. The eigenvalues of a 2 × 2 submatrix can be found by careful use of the quadratic formula. Complex conjugate eigenvalues of real matrices are extracted in pairs.
22. The explicit QR iteration shown above is expensive and never used in practice. Instead, the iteration is performed implicitly.

Algorithm 4: Francis Implicit QR iteration of degree k (chasing the bulge).

```
Choose $k$ shifts $\mu_1, \ldots \mu_k$.
$\mathbf{x} \leftarrow \mathbf{e}_1$   % first column of identity matrix
for $j = 1 : k$
    $\mathbf{x} \leftarrow (A - \mu_k I)\mathbf{x}$
end   % $\mathbf{x}$ is the first column of $p(A)$.
$\hat{\mathbf{x}} \leftarrow \mathbf{x}_{1:k+1}$   % $\mathbf{x}_{k+2:n} = 0$
Let $U \in \mathbb{C}^{k+1 \times k+1}$ be unitary with $U^* \mathbf{x} = \alpha \mathbf{e}_1$
$A_{1:k+1,1:n} \leftarrow U^* A_{1:k+1,1:n}$
$A_{1:n,1:k+1} \leftarrow A_{1:n,1:k+1} U$
Return $A$ to upper Hessenberg form as in Algorithm 2 (Fact 7).
```

23. The initial transformation in the implicit QR iteration disturbs the upper Hessenberg form of A, making a bulge in the upper left-hand corner. The size of the bulge is equal to k. In the case $k = 2$, the pattern of nonzeros is

$$\begin{bmatrix} * & * & * & * & * & * \\ * & * & * & * & * & * \\ * & * & * & * & * & * \\ * & * & * & * & * & * \\ & & & * & * & * \\ & & & & * & * \end{bmatrix}.$$

The subsequent reduction to Hessenberg form chases the bulge down through the matrix and off the bottom. The equivalence of the explicit and implicit QR iterations is demonstrated in [GV13, Chap. 7.5] and [Wat07, Chap. 4.5]. For this result it is crucial that the matrix is unreduced upper Hessenberg

24. For a fixed small value of k, the implicit QR iteration requires only $O(n^2)$ work. Typically only a small number of iterations, independent of n, are needed per eigenvalue found; the total number of iterations is $O(n)$. Thus, the implicit QR algorithm is considered to be an $O(n^3)$ process.
25. The main unsymmetric QR routine in LAPACK is HSEQR, which chases bulges of degree $k = 2$. For efficient cache use, many bulges are chased in tight succession, and the transforming matrices are aggregated [BBM02a]. The technique of aggressive early deflation [BBM02b] is used to decrease the total number of iterations. For processing small submatrices, HSEQR calls LAHQR, a standard implicitly shifted QR code with $k = 2$.
26. If eigenvectors are wanted, the aggregate similarity transformation matrix S, the product of all transformations from start to finish, must be accumulated. $T = S^{-1}AS$, where A is the original matrix and T is the final upper triangular matrix. In the real case, T will not quite be upper triangular. It is **quasi-triangular** with a 2 ×

2 block along the main diagonal for each complex conjugate pair of eigenvalues. This complicates the descriptions of the algorithms but does not cause any practical problems.

27. The eigenvectors of T are computed by back substitution [Wat10, Chap. 5.7]. For each eigenvector $\mathbf{x}$ of T, $S\mathbf{x}$ is an eigenvector of A. The total additional cost of the eigenvector computation is $O(n^3)$. In LAPACK these tasks are performed by the routines HSEQR and TREVC.
28. Invariant subspaces can also be computed. The eigenvalues of A are $\lambda_1 = t_{11}, \ldots, \lambda_n = t_{nn}$. If $\lambda_1, \ldots, \lambda_k$ are disjoint from $\lambda_{k+1}, \ldots, \lambda_n$, then because T is upper triangular, the first k columns of S span the invariant subspace associated with $\{\lambda_1, \ldots, \lambda_k\}$.
29. If an invariant subspace associated with k eigenvalues that are not at the top of T is wanted, then those k eigenvalues must be moved to the top by a sequence of swapping operations. Each operation is a unitary similarity transformation that reverses the positions of two adjacent main-diagonal entries of T. The transformations are applied to S as well. Once the desired eigenvalues have been moved to the top, the first k columns of the transformed S span the desired invariant subspace. For details see [BD93] and [GV13, Chap. 7.6]. In LAPACK these tasks are performed by the routines TREXC and TRSEN.
30. An important difference between the symmetric and unsymmetric eigenvalue problems is that in the unsymmetric case, the eigenvalues can be ill conditioned. That is, a small perturbation in the entries of A can cause a large change in the eigenvalues. Suppose λ is an eigenvalue of A of algebraic multiplicity 1, and let E be a perturbation that is small in the sense that $\|E\|_2 \ll \|A\|_2$. Then $A + E$ has an eigenvalue $\lambda + \delta$ near λ. A condition number for λ is the smallest number κ such that

   $$|\delta| \leq \kappa \|E\|_2$$

   for all small perturbations E. If $\mathbf{x}$ and $\mathbf{y}$ are eigenvectors of A and A^T, respectively, associated with λ, then [Wat10, Chap. 7.1]

   $$\kappa \approx \frac{\|\mathbf{x}\|_2 \; \|\mathbf{y}\|_2}{|\mathbf{y}^T\mathbf{x}|}.$$

   If $\kappa \gg 1$, λ is ill conditioned. If κ is not much bigger than 1, λ is well conditioned.
31. Condition numbers can also be defined for eigenvectors and invariant subspaces [GV13, Chap. 7.2], [Wat07, Chap. 2.7], [Wat10, Chap. 7.1]. Eigenvectors associated with a tight cluster of eigenvalues are always ill conditioned. A more meaningful object is the invariant subspace associated with all of the eigenvalues in the cluster. This space will usually be well conditioned, even though the eigenvectors are ill conditioned. The LAPACK routines TRSNA and TRSEN compute condition numbers for eigenvalues, eigenvectors, and invariant subspaces.
32. The invariant subspace associated with $\{\lambda_1, \ldots, \lambda_k\}$ will certainly be ill conditioned if any of the eigenvalues $\lambda_{k+1}, \ldots, \lambda_n$ are close to any of $\lambda_1, \ldots, \lambda_k$. A necessary (but not sufficient) condition for well conditioning is that $\lambda_1, \ldots, \lambda_k$ be well separated from $\lambda_{k+1}, \ldots, \lambda_n$. A related practical fact is that if two eigenvalues are very close together, it may not be possible to swap them stably by LAPACK's TREXC.
33. (Performance) A computer with an AMD Athlon dual-core processor running at 2.3 GHz with 2 GB main memory and 1 MB cache computed the complete eigensystem of a random 2000 × 2000 real matrix using MATLAB in 49 seconds. This included balancing, reduction to upper Hessenberg form, triangularization by the implicitly shifted QR algorithm, and back solving for the eigenvectors. All computed eigenpairs $(\lambda, \mathbf{v})$ satisfied $\|A\mathbf{v} - \lambda\mathbf{v}\|_1 < 10^{-15}\|A\|_1\|\mathbf{v}\|_1$.

34. (Performance, continued) A parallel version of the algorithm was used on 1024 cores of a parallel supercomputer to compute the Schur decomposition of a dense random matrix of dimension 10^5 in just under nine hours [GKK10].
35. (Generalized eigenvalue problem) The steps for solving the dense, unsymmetric, generalized eigenvalue problem $A\mathbf{v} = \lambda B\mathbf{v}$ are analogous to those for solving the standard problem. First (optionally) the pair (A, B) is balanced (by routine GGBAL in LAPACK). Then it is transformed by a strictly unitary equivalence to a condensed form in which A is upper Hessenberg and B is upper triangular. Then the QZ algorithm, a variant of Francis's algorithm, completes the reduction to triangular form. Details are given in [GV13, Chap. 7.7], [Wat07, Chap. 6], and [Wat10, Chap. 7.4]. In LAPACK the codes GGHRD and HGEQZ reduce the pair to Hessenberg-triangular form and perform the QZ iterations, respectively.
36. Once A has been reduced to triangular form, the eigenvalues are $\lambda_j = a_{jj}/b_{jj}$, $j = 1, \ldots, n$. The eigenvectors can be obtained by routines analogous to those used for the standard problem (LAPACK codes TGEVC and GGBAK), and condition numbers can be computed (LAPACK codes TGSNA and TGSEN).

Examples:

1. The matrix

$$A = \begin{bmatrix} -5.5849 \times 10^{-01} & -2.4075 \times 10^{+07} & -6.1644 \times 10^{+14} & 6.6275 \times 10^{+00} \\ -7.1724 \times 10^{-09} & -2.1248 \times 10^{+00} & -3.6183 \times 10^{+06} & 2.6435 \times 10^{-06} \\ -4.1508 \times 10^{-16} & -2.1647 \times 10^{-07} & 1.6229 \times 10^{-01} & -7.6315 \times 10^{-14} \\ 4.3648 \times 10^{-03} & 1.2614 \times 10^{+06} & -1.1986 \times 10^{+13} & -6.2002 \times 10^{-01} \end{bmatrix}$$

was balanced by Algorithm 1 (Fact 3) to produce

$$B = \begin{bmatrix} -0.5585 & -0.3587 & -1.0950 & 0.1036 \\ -0.4813 & -2.1248 & -0.4313 & 2.7719 \\ -0.2337 & -1.8158 & 0.1623 & -0.6713 \\ 0.2793 & 1.2029 & -1.3627 & -0.6200 \end{bmatrix}.$$

2. The matrix B of Example 1 was reduced to upper Hessenberg form by Algorithm 2 (Fact 7) to yield

$$H = \begin{bmatrix} -0.5585 & 0.7579 & 0.0908 & -0.8694 \\ 0.6036 & -3.2560 & -0.0825 & -1.8020 \\ 0 & 0.9777 & 1.2826 & -0.8298 \\ 0 & 0 & -1.5266 & -0.6091 \end{bmatrix}.$$

3. Algorithm 4 (Fact 22) was applied to the matrix H of Example 2 with $k = 1$ and shift $\mu_1 = h_{44} = -0.6091$ to produce

$$\begin{bmatrix} -3.1238 & -0.5257 & 1.0335 & 1.6798 \\ -1.3769 & 0.3051 & -1.5283 & 0.1296 \\ 0 & -1.4041 & 0.3261 & -1.0462 \\ 0 & 0 & -0.0473 & -0.6484 \end{bmatrix}.$$

The process was repeated twice again (with $\mu_1 = h_{44}$) to yield

$$\begin{bmatrix} -3.1219 & 0.7193 & 1.2718 & -1.4630 \\ 0.8637 & 1.8018 & 0.0868 & -0.3916 \\ 0 & 0.6770 & -1.2385 & 1.1642 \\ 0 & 0 & -0.0036 & -0.5824 \end{bmatrix}$$

and

$$\begin{bmatrix} -3.0939 & -0.6040 & 1.3771 & 1.2656 \\ -0.8305 & 1.8532 & -0.3517 & 0.5050 \\ 0 & 0.2000 & -1.3114 & -1.3478 \\ 0 & 0 & 0.00003 & -0.5888 \end{bmatrix}.$$

The (4,4) entry is an eigenvalue of A correct to four decimal places.

This matrix happens to have a real eigenvalue. If it had not, Algorithm 4 could have been used with $k = 2$ to extract the complex eigenvalues in pairs.

4. For an example of an ill-conditioned eigenvalue (Fact 30) consider a matrix

$$A = \begin{bmatrix} 1 & t \\ 0 & 1+\epsilon \end{bmatrix},$$

where t is large or ϵ is small or both. Since A is upper triangular, its eigenvalues are 1 and $1+\epsilon$. Eigenvectors of A and A^T associated with the eigenvalue 1 are

$$\mathbf{x} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad \text{and} \quad \mathbf{y} = \begin{bmatrix} 1 \\ -t/\epsilon \end{bmatrix},$$

respectively. Since $\|\mathbf{x}\|_2 = 1$, $\|\mathbf{y}\|_2 = \sqrt{1 + t^2/\epsilon^2}$, and $|\mathbf{y}^T\mathbf{x}| = 1$, the condition number of eigenvalue $\lambda = 1$ is $\kappa = \sqrt{1 + t^2/\epsilon^2} \approx t/\epsilon$. Thus if, for example, $t = 10^7$ and $\epsilon = 10^{-7}$, we have $\kappa \approx 10^{14}$.

5. This example illustrates Fact 31 on the ill conditioning of eigenvectors associated with a tight cluster of eigenvalues. Given a positive number ϵ that is as small as you please, the matrices

$$A_1 = \begin{bmatrix} 2+\epsilon & 0 & 0 \\ 0 & 2-\epsilon & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$A_2 = \begin{bmatrix} 2 & \epsilon & 0 \\ \epsilon & 2 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

both have eigenvalues 1, $2+\epsilon$, and $2-\epsilon$, and they are very close together: $\|A_1 - A_2\|_2 = \sqrt{2}\epsilon$. However, unit eigenvectors associated with clustered eigenvalues $2+\epsilon$ and $2-\epsilon$ for A_1 are

$$\mathbf{e}_1 = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix} \quad \text{and} \quad \mathbf{e}_2 = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix},$$

while unit eigenvectors for A_2 are

$$\frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix} \quad \text{and} \quad \frac{1}{\sqrt{2}} \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix}.$$

Thus, the tiny perturbation of order ϵ from A_1 to A_2 changes the eigenvectors completely; the eigenvectors are ill conditioned. In contrast, the two-dimensional invariant subspace associated with the cluster $2+\epsilon$, $2-\epsilon$ is $\mathit{Span}(\mathbf{e}_1, \mathbf{e}_2)$ for both A_1 and A_2, and it is well conditioned.

56.3 Sparse Matrix Techniques

If the matrix A is large and sparse, and just a few eigenvalues are needed, sparse matrix techniques are appropriate. Some examples of common tasks are (1) find the few eigenvalues of largest modulus, (2) find the few eigenvalues with largest real part, and (3) find the few eigenvalues nearest some target value τ. The corresponding eigenvectors might also be wanted. These tasks are normally accomplished by computing the low-dimensional invariant subspace associated with the desired eigenvalues. Then the information about the eigenvalues and eigenvectors is extracted from the invariant subspace.

The most widely used method for the sparse unsymmetric eigenvalue problem is the implicitly restarted Arnoldi method, as implemented in ARPACK [LSY98], which is discussed in Chapter 94. MATLAB's sparse eigenvalue command "eigs" calls ARPACK. An important variant is the Krylov-Schur algorithm of Stewart [Ste01].

Definitions:

Given a subspace $\mathcal{S}$ of $\mathbb{C}^n$, a vector $\mathbf{v} \in \mathcal{S}$ is called a **Ritz vector** of A from $\mathcal{S}$ if there is a $\theta \in \mathbb{C}$ such that $A\mathbf{v} - \theta\mathbf{v} \perp \mathcal{S}$. The scalar θ is the **Ritz value** associated with $\mathcal{S}$. The pair $(\theta, \mathbf{v})$ is a **Ritz pair**.

Facts:

1. [Wat10, Chap. 6.1] Let $\mathbf{v}_1, \ldots, \mathbf{v}_m$ be a basis for a subspace $\mathcal{S}$ of $\mathbb{C}^n$, and let $V = [\mathbf{v}_1 \ \cdots \mathbf{v}_m]$. Then $\mathcal{S}$ is invariant under A if and only if there is a $B \in \mathbb{C}^{m\times m}$ such that $AV = VB$.
2. [Wat10, Chap. 6.1] If $AV = VB$, then the eigenvalues of B are eigenvalues of A. If $\mathbf{x}$ is an eigenvector of B associated with eigenvalue μ, then $V\mathbf{x}$ is an eigenvector of A associated with μ.
3. [Wat10, Chap. 6.6] Let $\mathbf{v}_1, \ldots, \mathbf{v}_m$ be an orthonormal basis of $\mathcal{S}$, $V = [\mathbf{v}_1 \ \cdots \mathbf{v}_m]$, and $B = V^*AV$. Then the Ritz values of A associated with $\mathcal{S}$ are exactly the eigenvalues of B. If $(\theta, \mathbf{x})$ is an eigenpair of B, then $(\theta, V\mathbf{x})$ is a Ritz pair of A, and conversely.
4. If A is very large and sparse, it is essential to store A in a sparse data structure, in which only the nonzero entries of A are stored. One simple structure stores two integers n and nnz, which represent the dimension of the matrix and the number of nonzeros in the matrix, respectively. The matrix entries are stored in an array *ent* of length nnz, and the row and column indices are stored in two integer arrays of length nnz called *row* and *col*, respectively. For example, if the nonzero entry a_{ij} is stored in $ent(m)$, then this is indicated by setting $row(m) = i$ and $col(m) = j$. The space needed to store a matrix in this data structure is proportional to nnz.
5. Many operations that are routinely applied to dense matrices are impossible if the matrix is stored sparsely. Similarity transformations are out of the question because they quickly turn the zeros to nonzeros, transforming the sparse matrix to a full matrix.
6. One operation that is always possible is to multiply the matrix by a vector. This requires one pass through the data structure, and the work is proportional to nnz.

Algorithm 5: Sparse Matrix-Vector Multiply.
Multiply A by $\mathbf{x}$ and store the result in $\mathbf{y}$.

```
$\mathbf{y} \leftarrow 0$
for $m = 1 : nnz$
    [$\mathbf{y}(row(m)) \leftarrow \mathbf{y}(row(m)) + ent(m) * \mathbf{x}(col(m))$]
end
```

7. Because the matrix-vector multiply is so easy, many sparse matrix methods access

the matrix A in only this way. At each step, A is multiplied by one or several vectors, and this is the only way A is used.

8. The following standard methodology is widely used. A starting vector $\mathbf{v}_1$ is chosen, and the algorithm adds one vector per step, so that after $j-1$ steps it has produced j orthonormal vectors $\mathbf{v}_1, \ldots, \mathbf{v}_j$. Let $V_j = [\mathbf{v}_1, \ldots, \mathbf{v}_j] \in \mathbb{C}^{n \times j}$, and let $\mathcal{S}_j = \mathit{Span}(V_j) = \mathit{Span}(\mathbf{v}_1, \ldots, \mathbf{v}_j)$. The jth step uses information from $\mathcal{S}_j$ to produce $\mathbf{v}_{j+1}$. The Ritz values of A associated with $\mathcal{S}_j$ are the eigenvalues of the $j \times j$ matrix $B_j = V_j^* A V_j$. The Ritz pair $(\theta, \mathbf{w})$ for which θ has the largest modulus is an estimate of the largest eigenvalue of A, and $\mathbf{x} = V_j \mathbf{w}$ is an estimate of the associated eigenvector. The residual $\mathbf{r}_j = A\mathbf{x} - \mathbf{x}\theta$ gives an indication of the quality of the approximate eigenpair.
9. Several methods use the residual $\mathbf{r}_j$ to help decide on the next basis vector $\mathbf{v}_{j+1}$. These methods typically use $\mathbf{r}_j$ to determine another vector $\mathbf{s}_j$, which is then orthonormalized against $\mathbf{v}_1, \ldots, \mathbf{v}_j$ to produce $\mathbf{v}_{j+1}$. The choice $\mathbf{s}_j = \mathbf{r}_j$ leads to a method that is equivalent to the Arnoldi process. However, Arnoldi's process should not be implemented this way in practice; see Chapter 57. The choice $\mathbf{s}_j = (D - \theta I)^{-1}\mathbf{r}_j$, where D is the diagonal part of A, gives Davidson's method. The Jacobi-Davidson methods have more elaborate ways of choosing $\mathbf{s}_j$. See [BDD00, Chap. 7.12] for details.
10. Periodic purging is employed to keep the dimension of the active subspace from becoming too large. Given m vectors, the purging process keeps the most promising k-dimensional subspace of $\mathcal{S}_m = \mathit{Span}(V_m)$ and discards the rest. Again, let $B_m = V_m^* A V_m$, and let $B_m = U_m T_m U_m^*$ be a unitary similarity transformation to upper triangular form. The Ritz values lie on the main diagonal of T_m and can be placed in any order. Place the k most promising Ritz values at the top. Let $\tilde{V}_m = V_m U_m$, and let $\tilde{V}_k$ denote the $n \times k$ submatrix of $\tilde{V}_m$ consisting of the first k columns. The columns of $\tilde{V}_k$ are the vectors that are kept.
11. After each purge, the algorithm can be continued from step k. Once the basis has been expanded back to m vectors, another purge can be carried out. After a number of cycles of expansion and purging, the invariant subspace associated with the desired eigenvalues will have been found.
12. When purging is carried out in connection with the Arnoldi process, it is called an implicit restart, and there are some extra details. See Chapter 57, [Ste01], and [Wat07, Chap. 9.3].
13. The Implicitly Restarted Arnoldi process is well suited for computing the eigenvalues on the periphery of the spectrum of A. Thus, it is good for computing the eigenvalues of maximum modulus or those of maximum or minimum real part.
14. For computing interior eigenvalues, the shift-and-invert strategy is often helpful. Suppose the eigenvalues nearest some target value τ are sought. The matrix $(A - \tau I)^{-1}$ has the same eigenvectors as A, but the eigenvalues are different. If $\lambda_1, \ldots, \lambda_n$ are the eigenvalues of A, then $(\lambda_1 - \tau)^{-1} \ldots, (\lambda_n - \tau)^{-1}$ are the eigenvalues of $(A - \tau I)^{-1}$. The eigenvalues of $(A - \tau I)^{-1}$ of largest modulus correspond to the eigenvalues of A closest to τ. These can be computed by applying the implicitly restarted Arnoldi process to $(A - \tau I)^{-1}$. This is feasible whenever operations of the type $\mathbf{w} \leftarrow (A - \tau I)^{-1}\mathbf{x}$ can be performed efficiently. If a sparse decomposition $A - \tau I = PLU$ can be computed, as described in Chapters 51 and 53, then that decomposition can be used to perform the operation $\mathbf{w} \leftarrow (A - \tau I)^{-1}\mathbf{x}$ by back solves. If the LU factors take up too much space to fit into memory, this method cannot be used.
15. Another option for solving $(A - \tau I)\mathbf{w} = \mathbf{x}$ is to use an iterative method, as described in Chapter 54. However, this is very computationally intensive, as the systems must be solved to high accuracy if the eigenvalues are to be computed accurately.
16. The shift-and-invert strategy can also be applied to the generalized eigenvalue prob-

lem $A\mathbf{v} = \lambda B\mathbf{v}$. The implicitly restarted Arnoldi process is applied to the operator $(A - \tau B)^{-1}B$ to find eigenvalues near τ.

17. If the matrix is too large for the shift-and-invert strategy, Jacobi-Davidson methods can be considered [BDD00, Chap. 7.12]. These also require the iterative solution of linear systems. In this family of methods, inaccurate solution of the linear systems may slow convergence of the algorithm, but it will not cause the eigenvalues to be computed inaccurately.
18. Arnoldi-based and Jacobi-Davidson algorithms are described in [BDD00]. A brief overview is given in [Wat10, Chap. 6]. Balancing of sparse matrices is discussed in [BDD00, Chap. 7.2].

The implicitly restarted Arnoldi method (IRAM) [Sor92] is a variant of Arnoldi's method for computing a selected subset of eigenvalues and corresponding eigenvectors for large matrices. Implicit restarting is a synthesis of the implicitly shifted QR iteration and the Arnoldi process that effectively limits the dimension of the Krylov subspace required to obtain good approximations to desired eigenvalues. The space is repeatedly expanded and contracted with each new Krylov subspace generated by an updated starting vector obtained by implicit application of a matrix polynomial to the old starting vector. This process is designed to filter out undesirable components in the starting vector in a way that enables convergence to the desired invariant subspace. This method has been implemented and is freely available as ARPACK. The MATLAB® function `eigs` is based upon ARPACK. Use of this software is described in Chapter 94.

In this chapter, all matrices, vectors, and scalars are complex and the algorithms are phrased in terms of complex arithmetic. However, when the matrix (or matrix pair) happens to be real then the computations may be organized so that only real arithmetic is required. Multiplication of a vector $\mathbf{x}$ by a scalar λ is denoted by $\mathbf{x}\lambda$ so that the eigenvector–eigenvalue relation is $A\mathbf{x} = \mathbf{x}\lambda$. This convention provides for direct generalizations to the more general invariant subspace relations $AX = XH$, where X is an $n \times k$ matrix and H is a $k \times k$ matrix with $k < n$. More detailed discussion of all facts and definitions may be found in the overview article [Sor02].

57.1 Krylov Subspace Projection

The classic power method is the simplest way to compute the dominant eigenvalue and corresponding eigenvector of a large matrix. Krylov subspace projection provides a way to extract additional eigen-information from the power method iteration by considering all possible linear combinations of the sequence of vectors produced by the power method.

Definitions:

The best approximate eigenvectors and corresponding eigenvalues are extracted from the **Krylov subspace**

$$\mathcal{K}_k(A, \mathbf{v}) := \operatorname{span}\{\mathbf{v}, A\mathbf{v}, A^2\mathbf{v}, \ldots, A^{k-1}\mathbf{v}\}.$$

The approximate eigenpairs are constructed through a Galerkin condition. An approximate eigenvector $\mathbf{x} \in \mathcal{S}$ is called a **Ritz vector** with corresponding **Ritz value** θ if the **Galerkin condition**

$$\mathbf{w}^*(A\mathbf{x} - \mathbf{x}\theta) = 0, \quad \text{for all} \quad \mathbf{w} \in \mathcal{K}_k(A, \mathbf{v})$$

is satisfied.

Facts: [Sor92], [Sor02]

1. Every $\mathbf{w} \in \mathcal{K}_k$ is of the form $\mathbf{w} = \phi(A)\mathbf{v}_1$ for some polynomial ϕ of degree less than k and $\mathcal{K}_{j-1} \subset \mathcal{K}_j$ for $j = 2, 3, \ldots, k$.
2. If a sequence of orthogonal bases $V_k = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_k]$ has been constructed with $\mathcal{K}_k = \operatorname{range}(V_k)$ and $V_k^* V_k = I_k$, then a new basis vector $\mathbf{v}_{k+1}$ is obtained by the **projection formulas**

$$\begin{aligned} \mathbf{h}_k &= V_k^* A\mathbf{v}_k, \\ \mathbf{f}_k &= A\mathbf{v}_k - V_k\mathbf{h}_k, \\ \mathbf{v}_{k+1} &= \mathbf{f}_k / \|\mathbf{f}_k\|_2. \end{aligned}$$

   The vector $\mathbf{h}_k$ is constructed to achieve $V_k^*\mathbf{f}_k = 0$ so that $\mathbf{v}_{k+1}$ is a vector of unit length that is orthogonal to the columns of V_k.
3. The columns of $V_{k+1} = [V_k, \mathbf{v}_{k+1}]$ provide an orthonormal basis for $\mathcal{K}_{k+1}(A, \mathbf{v}_1)$.
4. The basis vectors are of the form $\mathbf{v}_j = \phi_{j-1}(A)\mathbf{v}_1$, where ϕ_{j-1} is a polynomial of degree $j-1$ for each $j = 1, 2, \ldots, k+1$.
5. This construction fails when $\mathbf{f}_k = 0$, but then

$$AV_k = V_k H_k,$$

   where $H_k = V_k^* A V_k = [\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_k]$ (with a slight abuse of notation). This "good breakdown" happens precisely when $\mathcal{K}_k$ is an invariant subspace of A. Hence, $\sigma(H_k) \subset \sigma(A)$.

57.2 The Arnoldi Factorization

The projection formulas given above result in the fundamental Arnoldi method for constructing an orthonormal basis for $\mathcal{K}_k$.

Definitions:

The relations between the matrix A, the basis matrix V_k, and the residual vector $\mathbf{f}_k$ may be concisely expressed as

$$AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^*,$$

where $V_k \in \mathbb{C}^{n \times k}$ has orthonormal columns, $V_k^* \mathbf{f}_k = 0$, and $H_k = V_k^* A V_k$ is a $k \times k$ upper Hessenberg matrix with nonnegative subdiagonal elements.

The above expression shall be called a **k-step Arnoldi factorization** of A.

When A is Hermitian, H_k will be real, symmetric, and tridiagonal and then the relation is called a **k-step Lanczos factorization** of A.

The columns of V_k are referred to as **Arnoldi vectors** or **Lanczos vectors**, respectively.

The Hessenberg matrix H_k is called **unreduced** if all subdiagonal elements are nonzero.

Facts: [Sor92], [Sor02]

1. The explicit steps needed to form a k-step Arnoldi factorization are shown in Algorithm 1.

Algorithm 1: k-step Arnoldi factorization. A square matrix A, a nonzero vector $\mathbf{v}$, and a positive integer $k \leq n$ are input.

Output is an $n \times k$ ortho-normal matrix V_k, an upper Hessenberg matrix H_k and a vector $\mathbf{f}_k$ such that $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^T$.

```
$\mathbf{v}_1 = \mathbf{v}/\|\mathbf{v}\|_2$;
$\mathbf{w} = A\mathbf{v}_1$;  $\alpha_1 = \mathbf{v}_1^* \mathbf{w}$;
$\mathbf{f}_1 \leftarrow \mathbf{w} - \mathbf{v}_1 \alpha_1$;
$V_1 \leftarrow [\mathbf{v}_1]$; $H_1 \leftarrow [\alpha_1]$;
for $j = 1, 2, 3, \ldots k-1$,
    $\beta_j = \|\mathbf{f}_j\|_2$; $\mathbf{v}_{j+1} \leftarrow \mathbf{f}_j/\beta_j$;
    $V_{j+1} \leftarrow [V_j, \mathbf{v}_{j+1}]$;
    $\hat{H}_j \leftarrow \begin{bmatrix} H_j \\ \beta_j \mathbf{e}_j^* \end{bmatrix}$;
    $\mathbf{w} \leftarrow A\mathbf{v}_{j+1}$;
    $\mathbf{h} \leftarrow V_{j+1}^* \mathbf{w}$;
    $\mathbf{f}_{j+1} \leftarrow \mathbf{w} - V_{j+1}\mathbf{h}$;
    $H_{j+1} \leftarrow [\hat{H}_j, \mathbf{h}]$;
end
```

2. Ritz pairs satisfying the Galerkin condition (see Section 57.1) are derived from the eigenpairs of the small projected matrix H_k. If $H_k \mathbf{y} = \mathbf{y}\theta$ with $\|\mathbf{y}\|_2 = 1$, then the vector $\mathbf{x} = V_k \mathbf{y}$ is a vector of unit norm that satisfies

$$\|A\mathbf{x} - \mathbf{x}\theta\|_2 = \|(AV_k - V_k H_k)\mathbf{y}\|_2 = |\beta_k \mathbf{e}_k^* \mathbf{y}|,$$

   where $\beta_k = \|\mathbf{f}_k\|_2$.

3. If $(\mathbf{x}, \theta)$ is a Ritz pair constructed as shown in Fact 2, then

$$\theta = \mathbf{y}^* H_k \mathbf{y} = (V_k \mathbf{y})^* A (V_k \mathbf{y}) = \mathbf{x}^* A \mathbf{x}$$

   is always a Rayleigh quotient (assuming $\|\mathbf{y}\|_2 = 1$).

4. The Rayleigh quotient residual $\mathbf{r}(\mathbf{x}) := A\mathbf{x} - \mathbf{x}\theta$ satisfies $\|\mathbf{r}(\mathbf{x})\|_2 = |\beta_k \mathbf{e}_k^* \mathbf{y}|$. When A is Hermitian, this relation provides computable rigorous bounds on the accuracy of the approximate eigenvalues [Par80]. When A is non-Hermitian, one needs additional sensitivity information. Nonnormality effects may corrupt the accuracy. In exact arithmetic, these Ritz pairs are eigenpairs of A whenever $\mathbf{f}_k = 0$. However, even with a very small residual these may be far from actual eigenvalues when A is highly nonnormal.

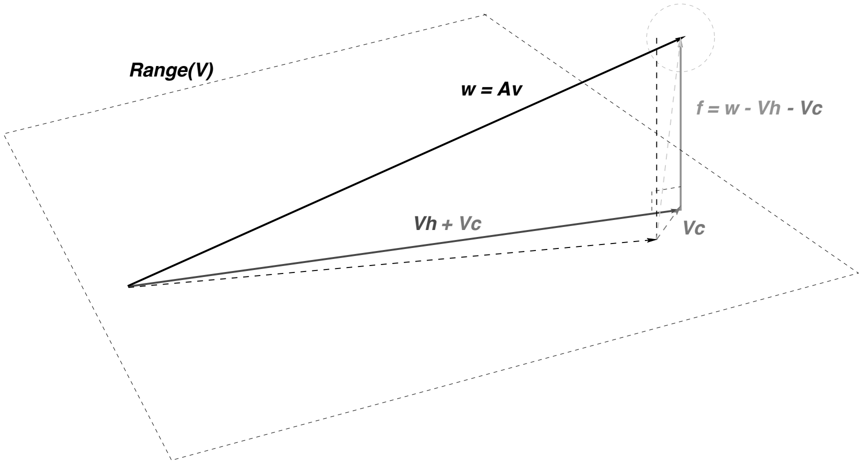

FIGURE 57.1 DGKS Correction.

5. The orthogonalization process is based upon the *classical Gram–Schmidt* (CGS) scheme. This process is notoriously unstable and will fail miserably in this application without modification. The iterative refinement technique proposed by Daniel, Gragg, Kaufman, and Stewart (DGKS) [DGK76] provides an excellent way to construct a vector $\mathbf{f}_{j+1}$ that is numerically orthogonal to V_{j+1}. It amounts to computing a correction
$$\mathbf{c} = V_{j+1}^*\mathbf{f}_{j+1}; \quad \mathbf{f}_{j+1} \leftarrow \mathbf{f}_{j+1} - V_{j+1}\mathbf{c}; \quad \mathbf{h} \leftarrow \mathbf{h} + \mathbf{c};$$
just after computing $\mathbf{f}_{j+1}$ if necessary, i.e., when $\mathbf{f}_{j+1}$ is not sufficiently orthogonal to the columns of V_{j+1}. This formulation is crucial to both accuracy and performance. It provides numerically orthogonal basis vectors and it may be implemented using the Level 2 BLAS operation _GEMV [DDH88]. This provides a significant performance advantage on virtually every platform from workstation to supercomputer.
6. The *modified Gram–Schmidt* (MGS) process will generally fail to produce orthogonal vectors and cannot be implemented with Level 2 BLAS in this setting. ARPACK relies on a restarting scheme wherein the goal is to reach a state of dependence in order to obtain $\mathbf{f}_k = 0$. MGS is completely inappropriate for this situation, but the CGS with DGKS correction performs beautifully.
7. Failure to maintain orthogonality leads to numerical difficulties in the Lanczos/Arnoldi process. Loss of orthogonality typically results in the presence of spurious copies of the approximate eigenvalue.

Examples:

1. Figure 57.1 illustrates how the DGKS mechanism works. When the vector $\mathbf{w} = A\mathbf{v}$ is nearly in the range(V), then the projection $V\mathbf{h}$ is possibly inaccurate, but vector $= \mathbf{w} - \mathbf{Vh}$ is not close to range(V) and can be safely orthogonalized to compute the correction $\mathbf{c}$ accurately. The corrected vector $\mathbf{f} \leftarrow \mathbf{f} - V\mathbf{c}$ will be numerically orthogonal to the columns of V in almost all cases. Additional corrections might be necessary in very unusual cases.

57.3 Restarting the Arnoldi Process

The number of Arnoldi steps required to calculate eigenvalues of interest to a specified accuracy cannot be pre-determined. Usually, eigen-information of interest does not appear until k gets very large. In Figure 57.2 the distribution in the complex plane of the Ritz values (shown in grey dots) is compared with the spectrum (shown as +s). The original matrix is a normally distributed random matrix of order 200 and the Ritz values are from a ($k = 50$)-step Arnoldi factorization. Eigenvalues at the extremes of the spectrum of A are clearly better approximated than the interior eigenvalues.

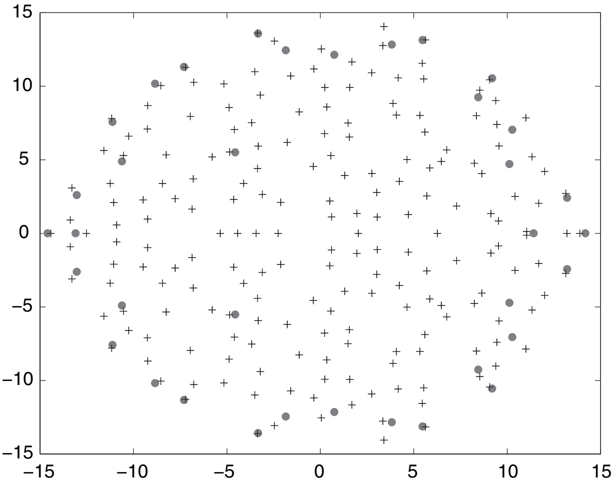

FIGURE 57.2 Typical distribution of Ritz values.

For large problems, it is intractable to compute and store a numerically orthogonal basis set V_k for large k. Storage requirements are $\mathcal{O}(n \cdot k)$ and arithmetic costs are $\mathcal{O}(n \cdot k^2)$ flops to compute the basis vectors plus $\mathcal{O}(k^3)$ flops to compute the eigensystem of H_k. Thus, restarting schemes have been developed that iteratively replace the starting vector $\mathbf{v}_1$ with an "improved" starting vector $\mathbf{v}_1^+$ and then compute a new Arnoldi factorization of fixed length k to limit the costs. Beyond this, there is an interest in forcing $\mathbf{f}_k = 0$ and, thus, producing an invariant subspace. However, this is useful only if the spectrum $\sigma(H_k)$ has the desired properties.

The structure of $\mathbf{f}_k$ suggests the restarting strategy. The goal will be to iteratively force $\mathbf{v}_1$ to be a linear combination of eigenvectors of interest.

Facts: [Sor92], [Sor02]

1. If $\mathbf{v} = \sum_{j=1}^{k} \mathbf{q}_j \gamma_j$ where $A\mathbf{q}_j = \mathbf{q}_j \lambda_j$ and
$$AV = VH + \mathbf{f}\mathbf{e}_k^T$$
is a k-step Arnoldi factorization with unreduced H, then $\mathbf{f} = 0$ and $\sigma(H) = \{\lambda_1, \lambda_2, \ldots, \lambda_k\}$.
2. Since $\mathbf{v}_1$ determines the subspace $\mathcal{K}_k$, this vector must be constructed to select the eigenvalues of interest. The starting vector must be forced to become a linear combination of eigenvectors that span the desired invariant subspace. There is a necessary and sufficient condition for $\mathbf{f}$ to vanish that involves Schur vectors and does not require diagonalizability.

57.4 Polynomial Restarting

Polynomial restarting strategies replace $\mathbf{v}_1$ by

$$\mathbf{v}_1 \leftarrow \psi(A)\mathbf{v}_1,$$

where ψ is a polynomial constructed to damp unwanted components from the starting vector. If $\mathbf{v}_1 = \sum_{j=1}^{n} \mathbf{q}_j \gamma_j$ where $A\mathbf{q}_j = \mathbf{q}_j \lambda_j$, then

$$\mathbf{v}_1^{+} = \psi(A)\mathbf{v}_1 = \sum_{j=1}^{n} \mathbf{q}_j \gamma_j \psi(\lambda_j),$$

where the polynomial ψ has also been normalized to give $\|\mathbf{v}_1\|_2 = 1$. Motivated by the structure of $\mathbf{f}_k$, the idea is to force the starting vector to be closer and closer to an invariant subspace by constructing ψ so that $|\psi(\lambda)|$ is as small as possible on a region containing the unwanted eigenvalues.

An iteration is defined by repeatedly restarting until the updated Arnoldi factorization eventually contains the desired eigenspace. An explicit scheme for restarting was proposed by Saad in [Saa92]. One of the more successful choices is to use Chebyshev polynomials in order to damp unwanted eigenvector components.

Definitions:

The polynomial ψ is sometimes called a **filter polynomial**, which may also be specified by its roots.

The roots of the filter polynomial may also be referred to as **shifts**. This terminology refers to their usage in an implicitly shifted QR-iteration.

One straightforward choice of shifts is to find the eigenvalues θ_j of the projected matrix H and sort these into two sets according to a given criterion: the wanted set $\mathcal{W} = \{\theta_j : j = 1, 2, \ldots, k\}$ and the unwanted set $\mathcal{U} = \{\theta_j : j = k+1, k+2, \ldots, k+p\}$. Then one specifies the polynomial ψ as the polynomial with these unwanted Ritz values as it roots. This choice of roots, called **exact shifts**, was suggested in [Sor92].

Facts: [Sor92], [Sor02]

1. Morgan [Mor96] found a remarkable property of this strategy. If exact shifts are used to define $\psi(\tau) = \prod_{j=k+1}^{k+p}(\tau - \theta_j)$ and if $\hat{\mathbf{q}}_j$ denotes a Ritz vector of unit length corresponding to θ_j, then the Krylov space generated by $\mathbf{v}_1^{+} = \psi(A)\mathbf{v}_1$ satisfies

$$\mathcal{K}_m(A, \mathbf{v}_1^{+}) = \mathit{Span}\{\hat{\mathbf{q}}_1, \hat{\mathbf{q}}_2, \ldots, \hat{\mathbf{q}}_k, A\hat{\mathbf{q}}_j, A^2\hat{\mathbf{q}}_j, \ldots, A^p\hat{\mathbf{q}}_j\},$$

   for any $j = 1, 2, \ldots, k$. Thus, polynomial restarting with exact shifts will generate a new subspace that contains all of the possible choices of updated staring vector consisting of linear combinations of the wanted Ritz vectors.
2. Exact shifts tend to perform remarkably well in practice and have been adopted as the shift selection of choice in ARPACK when no other information is available. However, there are many other possibilities such as the use of Leja points for certain containment regions or intervals [BCR96].

57.5 Implicit Restarting

There are a number of schemes used to implement polynomial restarting. We shall focus on an implicit restarting scheme.

Definitions:

A straightforward way to implement polynomial restarting is to explicitly construct the starting vector $\mathbf{v}_1^+ = \psi(A)\mathbf{v}_1$ by applying $\psi(A)$ through a sequence of matrix-vector products. This is called **explicit restarting**.

A more efficient and numerically stable alternative is **implicit restarting**. This technique applies a sequence of implicitly shifted QR steps to an m-step Arnoldi or Lanczos factorization to obtain a truncated form of the implicitly shifted QR-iteration.

On convergence, the IRAM iteration (see Algorithm 2) gives an orthonormal matrix V_k and an upper Hessenberg matrix H_k such that $AV_k \approx V_k H_k$.

If $H_k Q_k = Q_k R_k$ is a Shur decompositon of H_k, then we call $\hat{V}_k \equiv V_k Q_k$ a **Schur basis** for the Krylov subspace $\mathcal{K}_k(A, \mathbf{v}_1)$.

Note that if $AV_k = V_k H_k$ exactly, then $\hat{V}_k$ would form the leading k columns of a unitary matrix $\hat{V}$ and R_k would form the leading $k \times k$ block of an upper triangular matrix R, where $A\hat{V} = \hat{V}R$ is a complete Schur decomposition. We refer to this as a **partial Schur decomposition** of A.

Algorithm 2: IRAM iteration

Input is an $n \times k$ ortho-normal matrix V_k, an upper Hessenberg matrix H_k, and a vector $\mathbf{f}_k$ such that $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^T$.

Output is an $n \times k$ ortho-normal matrix V_k, an upper triangular matrix H_k such that $AV_k = V_k H_k$.

```
repeat until convergence,
    Beginning with the $k$-step factorization,
    apply $p$ additional steps of the Arnoldi process
    to compute an $m = k + p$ step Arnoldi factorization
        $AV_m = V_m H_m + \mathbf{f}_m \mathbf{e}_m^*$ .
    Compute $\sigma(H_m)$ and select $p$ shifts $\mu_1, \mu_2, ...\mu_p$;
    $Q = I_m$;
    for $j = 1, 2, ..., p$,
        Factor $[Q_j, R_j] = \mathrm{q}r(H_m - \mu_j I)$;
        $H_m \leftarrow Q_j^* H_m Q_j$;
        $Q \leftarrow Q Q_j$;
    end
    $\hat{\beta}_k = H_m(k+1, k)$;  $\sigma_k = Q(m, k)$;
    $\mathbf{f}_k \leftarrow \mathbf{v}_{k+1}\hat{\beta}_k + \mathbf{f}_m \sigma_k$;
    $V_k \leftarrow V_m Q(:, 1:k)$;  $H_k \leftarrow H_m(1:k, 1:k)$;
end
```

Facts: [Sor92], [Sor02]

1. Implicit restarting avoids numerical difficulties and storage problems normally associated with Arnoldi and Lanczos processes. The algorithm is capable of computing a few (k) eigenvalues with user specified features such as largest real part or largest magnitude using $2nk + \mathcal{O}(k^2)$ storage. The computed Schur basis vectors for the desired k-dimensional eigenspace are numerically orthogonal to working precision.
2. Desired eigen-information from a high-dimensional Krylov space is continually compressed into a fixed size k-dimensional subspace through an implicitly shifted QR mechanism. An Arnoldi factorization of length $m = k + p$,
$$AV_m = V_m H_m + \mathbf{f}_m \mathbf{e}_m^*,$$
is compressed to a factorization of length k that retains the eigen-information of interest. Then the factorization is expanded once more to m-steps and the compression process is repeated.

3. QR steps are used to apply p linear polynomial factors $A - \mu_j I$ implicitly to the starting vector $\mathbf{v}_1$. The first stage of this shift process results in
$$AV_m^+ = V_m^+ H_m^+ + \mathbf{f}_m \mathbf{e}_m^* Q,$$
where $V_m^+ = V_m Q$, $H_m^+ = Q^* H_m Q$, and $Q = Q_1 Q_2 \cdots Q_p$. Each Q_j is the orthogonal matrix associated with implicit application of the shift $\mu_j = \theta_{k+j}$. Since each of the matrices Q_j is Hessenberg, it turns out that the first $k-1$ entries of the vector $\mathbf{e}_m^* Q$ are zero (i.e., $\mathbf{e}_m^* Q = [\sigma \mathbf{e}_k^T, \hat{\mathbf{q}}^*]$). Hence, the leading k columns remain in an Arnoldi relation and provide an updated k-step Arnoldi factorization
$$AV_k^+ = V_k^+ H_k^+ + \mathbf{f}_k^+ \mathbf{e}_k^*,$$
with an updated residual of the form $\mathbf{f}_k^+ = V_m^+ \mathbf{e}_{k+1} \hat{\beta}_k + \mathbf{f}_m \sigma$. Using this as a starting point, it is possible to apply p additional steps of the Arnoldi process to return to the original m-step form.
4. Virtually any explicit polynomial restarting scheme can be applied with implicit restarting, but considerable success has been obtained with exact shifts. Exact shifts result in H_k^+ having the k wanted Ritz values as its spectrum. As convergence takes place, the subdiagonals of H_k tend to zero and the most desired eigenvalue approximations appear as eigenvalues of the leading $k \times k$ block of R as a partial Schur decomposition of A. The basis vectors V_k tend to numerically orthogonal Schur vectors.
5. The basic IRAM iteration is shown in Algorithm 2.

Examples:

1. The expansion and contraction process of the IRAM iteration is visualized in Figure 57.3.

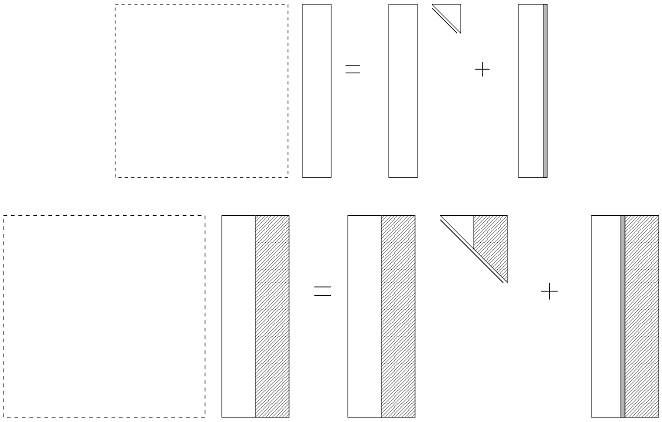

FIGURE 57.3 Visualization of IRAM.

57.6 Convergence of IRAM

IRAM converges linearly. An intuitive explanation follows. If $\mathbf{v}_1$ is expressed as a linear combination of eigenvectors $\{\mathbf{q}_j\}$ of A, then
$$\mathbf{v}_1 = \sum_{j=1}^{n} \mathbf{q}_j \gamma_j \Rightarrow \psi(A)\mathbf{v}_1 = \sum_{j=1}^{n} \mathbf{q}_j \psi(\lambda_j) \gamma_j.$$

Applying the same polynomial (i.e., using the same shifts) repeatedly for ℓ iterations will result in the j-th original expansion coefficient being attenuated by a factor

$$\left(\frac{\psi(\lambda_j)}{\psi(\lambda_1)}\right)^{\ell},$$

where the eigenvalues have been ordered according to decreasing values of $|\psi(\lambda_j)|$. The leading k eigenvalues become dominant in this expansion and the remaining eigenvalues become less and less significant as the iteration proceeds. Hence, the starting vector $\mathbf{v}_1$ is forced into an invariant subspace as desired. The adaptive choice of ψ provided with the exact shift mechanism further enhances the isolation of the wanted components in this expansion. Hence, the wanted eigenvalues are approximated ever better as the iteration proceeds. Making this heuristic argument precise has turned out to be quite difficult. Some fairly sophisticated analysis is required to understand convergence of these methods.

57.7 Convergence in Gap: Distance to a Subspace

To fully discuss convergence we need some notion of nearness of subspaces. When nonnormality is present or when eigenvalues are clustered, the distance between the computed subspace and the desired subspace is a better measure of success than distance between eigenvalues. The subspaces carry uniquely defined Ritz values with them, but these can be very sensitive to perturbations in the nonnormal setting.

Definitions:

A notion of distance that is useful in our setting is the **containment gap** between the subspaces $\mathcal{W}$ and $\mathcal{V}$:

$$\delta(\mathcal{W},\mathcal{V}) := \max_{\mathbf{w}\in\mathcal{W}} \ \min_{\mathbf{v}\in\mathcal{V}} \frac{\|\mathbf{w}-\mathbf{v}\|_2}{\|\mathbf{w}\|_2}.$$

Note: $\delta(\mathcal{W},\mathcal{V})$ is the sine of the largest canonical angle between $\mathcal{W}$ and the closest subspace of $\mathcal{V}$ with the same dimension as $\mathcal{W}$.

In keeping with the terminology developed in [BER04] and [BES05], $\mathcal{X}_g$ shall be the invariant subspace of A associated with the so called "good" eigenvalues (the desired eigenvalues) and $\mathcal{X}_b$ is the complementary subspace. $\mathbf{P}_g$ and $\mathbf{P}_b$ are the spectral projectors with respect to these spaces.

It is desirable to have **convergence in gap** for the Krylov method, meaning

$$\delta(\mathcal{K}_m(A,\mathbf{v}_1^{(\ell)}),\mathcal{X}_g) \to 0.$$

Fundamental quantities required to study convergence.

1. **Minimal polynomial for $\boldsymbol{\mathcal{X}_g}$:**

   $$a_g := \textit{minimal polynomial of } A \textit{ with respect to } \mathbf{P}_g\mathbf{v}_1,$$

   which is the monic polynomial of least degree s.t. $a_g(A)\mathbf{P}_g\mathbf{v}_1 = \mathbf{0}$.
2. **Nonnormality constant $\boldsymbol{\kappa(\Omega)}$:** The smallest positive number s.t.

   $$\|f(A)\,\Pi_{\mathcal{U}}\|_2 \le \kappa(\Omega) \max_{z\in\Omega}|f(z)|$$

   uniformly for all functions f analytic on Ω. This constant and its historical origins are discussed in detail in [BER04].
3. **$\boldsymbol{\varepsilon}$-pseudospectrum of $\boldsymbol{A}$:**

   $$\Lambda_\varepsilon(A) := \{z \in \mathbf{C} : \|(zI - A)^{-1}\|_2 \ge \varepsilon^{-1}\}.$$

Facts: [BER04], [BES05]

1. Two fundamental convergence questions:
   (a) What is the gap $\delta(\mathcal{U}_g, \mathcal{K}_k(A, \mathbf{v}_1))$ as k increases?
   (b) How does $\delta(\mathcal{U}_g, \mathcal{K}_m(A, \widehat{\mathbf{v}}_1))$ depend on $\widehat{\mathbf{v}}_1 = \Phi(A)\mathbf{v}_1$, and how can we optimize the asymptotic behavior?

   Key ingredients to convergence behavior are the nonnormality of A and the distribution of $\mathbf{v}_1$ w. r. t. $\mathcal{U}_g$. The goal of restarting is to attain the unrestarted iteration performance, but within *restricted subspace dimensions.*
2. *Convergence with no restarts:* In [BES05], it is shown that

   $$\delta(\mathcal{U}_g, \mathcal{K}_\ell(A, \mathbf{v}_1)) \leq C_o C_b \min_{p \in \mathcal{P}_{\ell-2m}} \max_{z \in \Omega_b} \left|1 - a_g(z) p(z)\right|,$$

   where the compact set $\Omega_g \subseteq \mathbf{C} \setminus \Omega_b$ contains all the good eigenvalues.

   $$C_o := \max_{\psi \in \mathcal{P}_{m-1}} \frac{\|\psi(A)\mathbf{P}_b \mathbf{v}_1\|_2}{\|\psi(A)\mathbf{P}_g \mathbf{v}_1\|_2}, \quad C_b := \kappa(\Omega_b).$$

3. Rate of convergence estimates are obtained from complex approximation theory. Construct conformal map $\mathcal{G}$ taking the exterior of Ω_b to the exterior of the unit disk with $\mathcal{G}(\infty) = \infty$ and $\mathcal{G}'(\infty) > 0$. Define $\rho := \left(\min_{j=1,\ldots,L} |\mathcal{G}(\lambda_j)|\right)^{-1}$. Then (Gaier, Walsh)

   $$\limsup_{k \to \infty} \min_{p \in \mathcal{P}_k} \max_{z \in \Omega_b} \left|\frac{1}{a_g(z)} - p(z)\right|^{1/k} = \rho.$$

   The image of $\{|z| = \rho^{-1}\}$ is a curve $\mathcal{C} := \mathcal{G}^{-1}(\{|z| = \rho^{-1}\})$ around Ω_b. This critical curve passes through a good eigenvalue "closest to" Ω_b. The curve contains at least one good eigenvalue, with all bad and no good eigenvalues in its interior.
4. Convergence with the exact shift strategy has not yet been fully analyzed. However, convergence rates have been established for restarts with asymptotically optimal points. These are the Fejér, Fekete, or Leja points for Ω_b. In [BES05], computational experiments are shown that indicate that exact shifts behave very much like optimal points for certain regions bounded by pseudo-spectral level curves or lemniscates.
5. Let Ψ_M interpolate $1/a_g(z)$ at the M restart shifts:

   $$\delta(\mathcal{U}_g, \mathcal{K}_\ell(A, \widehat{\mathbf{v}}_1)) \leq C_o C_g \max_{z \in \Omega_b} |1 - \Psi_M(z) a_g(z)| \leq C_o\, C_g\, C_r\, r^M$$

   for any $r > \rho$ (see [Gai87], [FR89]). Here, $\widehat{\mathbf{v}}_1 = \Phi(A)\mathbf{v}_1$, where Φ is the aggregate restart polynomial (its roots are all the implicit restart shifts that have been applied). The subspace dimension is $\ell = 2m$, the restart degree is m, and the aggregate degree is $M = \nu m$.

57.8 The Generalized Eigenproblem

In many applications, the generalized eigenproblem $A\mathbf{x} = M\mathbf{x}\lambda$ arises naturally. A typical setting is a finite element discretization of a continuous problem where the matrix M arises from inner products of basis functions. In this case, M is symmetric and positive (semi) definite, and for some algorithms this property is a necessary condition. Generally, algorithms are based upon transforming the generalized problem to a standard problem.

57.9 Krylov Methods with Spectral Transformations

Definitions:

A very successful scheme for converting the generalized problem to a standard problem that is amenable to a Krylov or a subspace iteration method is to use the **spectral transformation** suggested by Ericsson and Ruhe [ER80],

$$(A - \sigma M)^{-1} M x = \mathbf{x}\nu.$$

Facts: [Sor92], [Sor02]

1. An eigenvector $\mathbf{x}$ of the spectral transformation is also an eigenvector of the original problem $A\mathbf{x} = M\mathbf{x}\lambda$, with the corresponding eigenvalue given by $\lambda = \sigma + \frac{1}{\nu}$.
2. There is generally rapid convergence to eigenvalues near the shift σ because they are transformed to extremal well-separated eigenvalues. Perhaps an even more influential aspect of this transformation is that eigenvalues far from σ are damped (mapped near zero).
3. One strategy is to choose σ to be a point in the complex plane that is near eigenvalues of interest and then compute the eigenvalues ν of largest magnitude of the spectral transformation matrix. It is not necessary to have σ extremely close to an eigenvalue. This transformation, together with the implicit restarting technique, is usually adequate for computing a significant number of eigenvalues near σ.
4. Even when $M = I$, one generally must use the shift-invert spectral transformation to find interior eigenvalues. The extreme eigenvalues of the transformed operator A_σ are generally large and well separated from the rest of the spectrum. The eigenvalues ν of largest magnitude will transform back to eigenvalues λ of the original A that are in a disk about the point σ. This is illustrated in Figure 57.4, where the + symbols are the eigenvalues of A and the circled ones are the computed eigenvalues in the disk (dashed circle) centered at the point σ.

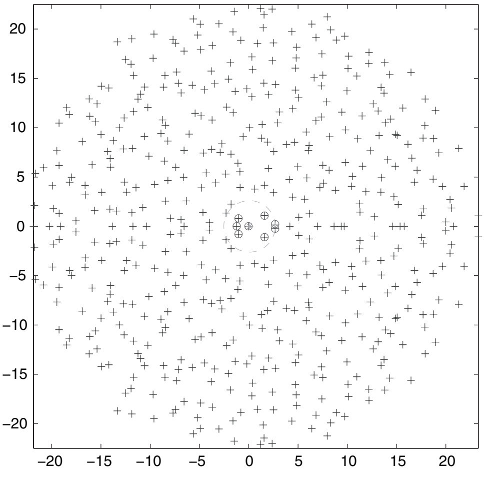

FIGURE 57.4 Eigenvalues from shift-invert.

5. With shift-invert, the Arnoldi process is applied to the matrix $A_\sigma := (A - \sigma M)^{-1} M$. Whenever a matrix-vector product $\mathbf{w} \leftarrow A_\sigma \mathbf{v}$ is required, the following steps are performed:
   (a) $\mathbf{z} = M\mathbf{v}$,

(b) Solve $(A - \sigma M)\mathbf{w} = \mathbf{z}$ for $\mathbf{w}$.

The matrix $A - \sigma M$ is factored initially with a sparse direct **LU**-decomposition or in a symmetric indefinite factorization and this single factorization is used repeatedly to apply the matrix operator A_σ as required.

6. The scheme is modified to preserve symmetry when A and M are both symmetric and M is positive (semi)definite. One can utilize a weighted M (semi)inner product in the Lanczos/Arnoldi process [ER80], [GLS94], [MS97]. This amounts to replacing the computation of $\mathbf{h} \leftarrow V_{j+1}^*\mathbf{w}$ and $\beta_j = \|\mathbf{f}_j\|_2$ with $\mathbf{h} \leftarrow V_{j+1}^* M\mathbf{w}$ and $\beta_j = \sqrt{\mathbf{f}_j^* M \mathbf{f}_j}$, respectively, in the Arnoldi process described in Algorithm 1.
7. The matrix operator A_σ is self-adjoint with respect to this (semi)inner product, i.e., $\langle A_\sigma \mathbf{x}, \mathbf{y}\rangle = \langle \mathbf{x}, A_\sigma \mathbf{y}\rangle$ for all vectors $\mathbf{x}, \mathbf{y}$, where $\langle \mathbf{w}, \mathbf{v}\rangle := \sqrt{\mathbf{w}^* M \mathbf{v}}$. This implies that the projected Hessenberg matrix H is actually symmetric and tridiagonal and the standard three-term Lanczos recurrence is recovered with this inner product.
8. There is a subtle aspect to this approach when M is singular. The most pathological case, when $\text{null}(A) \cap \text{null}(M) \neq \{0\}$, is not treated here. However, when M is singular there may be infinite eigenvalues of the pair (A, M) and the presence of these can introduce large perturbations to the computed Ritz values and vectors. To avoid these difficulties, a purging operation has been suggested by Ericsson and Ruhe [ER80]. If $\mathbf{x} = V\mathbf{y}$ with $H\mathbf{y} = \mathbf{y}\theta$, then

$$A_\sigma \mathbf{x} = VH\mathbf{y} + \mathbf{f}\mathbf{e}_k^T\mathbf{y} = \mathbf{x}\theta + \mathbf{f}\mathbf{e}_k^T\mathbf{y}.$$

   Replacing the $\mathbf{x}$ with the improved eigenvector approximation $\mathbf{x} \leftarrow (\mathbf{x} + \frac{1}{\theta}\mathbf{f}\mathbf{e}_k^T\mathbf{y})$ and renormalizing has the effect of purging undesirable components without requiring any additional matrix vector products with A_σ.
9. The residual error of the purged vector $\mathbf{x}$ with respect to the original problem is

$$\|A\mathbf{x} - M\mathbf{x}\lambda\|_2 = \|M\mathbf{f}\|_2 \frac{|\mathbf{e}_k^T\mathbf{y}|}{|\theta|^2},$$

   where $\lambda = \sigma + 1/\theta$. Since $|\theta|$ is usually quite large under the spectral transformation, this new residual is generally considerably smaller than the original.

58.1 Singular Value Decomposition

Definitions:

Given a complex matrix A having m rows and n columns, if σ is a nonnegative scalar and $\mathbf{u}$ and $\mathbf{v}$ are nonzero m- and n-vectors, respectively, such that

$$A\mathbf{v} = \sigma\mathbf{u} \quad \text{and} \quad A^*\mathbf{u} = \sigma\mathbf{v},$$

then σ is a **singular value** of A and $\mathbf{u}$ and $\mathbf{v}$ are corresponding **left** and **right singular vectors,** respectively. (For generality it is assumed that the matrices here are complex, although given these results, the analogs for real matrices are obvious.)

If, for a given positive singular value, there are exactly t linearly independent corresponding right singular vectors and t linearly independent corresponding left singular vectors, the singular value has **multiplicity** t and the space spanned by the right (left) singular vectors is the corresponding **right (left) singular space.**

Given a complex matrix A having m rows and n columns, the matrix product $U\Sigma V^*$ is a **singular value decomposition** for a given matrix A if

- $U$and V, respectively, have orthonormal columns.
- Σ has nonnegative elements on its principal diagonal and zeros elsewhere.
- $A = U\Sigma V^*$.

Let p and q be the number of rows and columns of Σ. U is $m \times p$, $p \leq m$, and V is $n \times q$ with $q \leq n$.

There are three **standard forms** of the SVD. All have the ith diagonal value of Σ denoted σ_i and are ordered as follows: $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_k$, and r is the index such that $\sigma_r > 0$ and either $k = r$ or $\sigma_{r+1} = 0$.

1. $p = m$ and $q = n$. The matrix Σ is $m \times n$ and has the same dimensions as A (see Figures 58.1 and 58.2).
2. $p = q = min\{m, n\}$.The matrix Σ is square (see Figures 58.3 and 58.4).
3. If $p = q = r$, the matrix Σ is square. This form is called a **reduced SVD** and denoted is by $\hat{U}\hat{\Sigma}\hat{V}^*$ (see Figures 58.5 and 58.6).

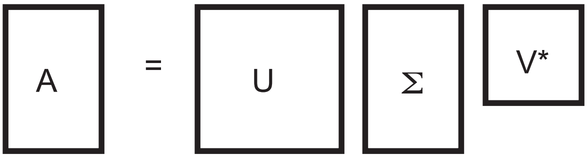

FIGURE 58.1 The first form of the singular value decomposition where $m \geq n$.

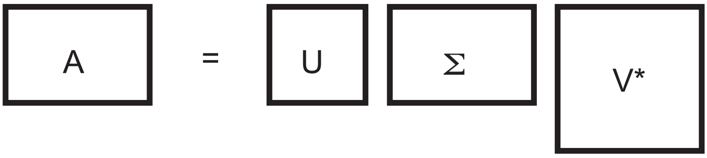

FIGURE 58.2 The first form of the singular value decomposition where $m < n$.

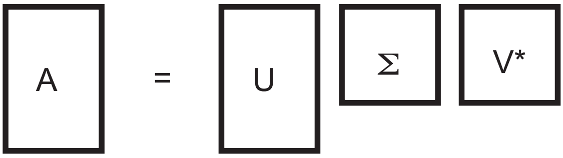

FIGURE 58.3 The second form of the singular value decomposition where $m \geq n$.

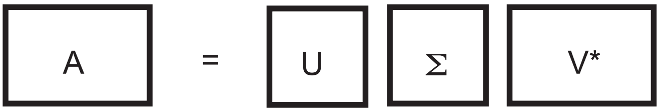

FIGURE 58.4 The second form of the singular value decomposition where $m < n$.

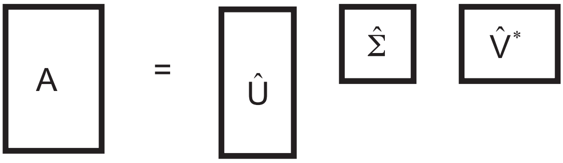

FIGURE 58.5 The third form of the singular value decomposition where $r \leq n \leq m$.

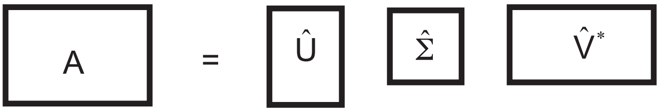

FIGURE 58.6 The third form of the singular value decomposition where $r \leq m < n$.

Facts:

The results can be found in [GV96, pp. 70–79]. Additionally, see Section 5.6 for introductory material and examples of SVDs, Chapter 24 for additional information on singular value decomposition, Chapter 21 for information on perturbations of singular values and vectors, and Section 52.9 for information about numerical rank.

1. If $U\Sigma V^*$ is a singular value decomposition for a given matrix A, then the diagonal elements $\{\sigma_i\}$ of Σ are singular values of A. The columns $\{\mathbf{u}_i\}_{i=1}^{p}$ of U and $\{\mathbf{v}_i\}_{i=1}^{q}$ of V are left and right singular vectors of A, respectively.
2. If $m \geq n$, the first standard form of the SVD can be found as follows:
    (a) Let $A^*A = V\Lambda V^*$ be an eigenvalue decomposition for the Hermitian, positive semidefinite $n \times n$ matrix A^*A such that Λ is diagonal (with the diagonal entries in nonincreasing order) and V is unitary.
    (b) Let the $m \times n$ matrix Σ have zero off-diagonal elements and for $i = 1, \ldots, n$ let σ_i, the ith diagonal element of Σ, equal $\sqrt[+]{\lambda_i}$, the positive square root of the ith diagonal element of Λ.
    (c) For $i = 1, \ldots, n$, let the $m \times m$ matrix U have ith column, $\mathbf{u}_i$, equal to $1/\sigma_i A\mathbf{v}_i$ if $\sigma_i \neq 0$. If $\sigma_i = 0$, let $\mathbf{u}_i$ be of unit length and orthogonal to all $\mathbf{u}_j$ for $j \neq i$, then $U\Sigma V^*$ is a singular decomposition of A.
3. If $m < n$ the matrix A^* has a singular value decomposition $U\Sigma V^*$ and $V\Sigma^T U^*$ is a singular value decomposition for A. The diagonal elements of Σ are the square roots of the eigenvalues of AA^*. The eigenvalues of A^*A are those of AA^* plus $n-m$ zeros. The notation Σ^T rather than Σ^* is used because in this case the two are identical and the transpose is more suggestive. All elements of Σ are real so that taking complex conjugates has no effect.
4. The value of r, the number of nonzero singular values, is the rank of A.
5. If A is real, then U and V (in addition to Σ) can be chosen real in any of the forms of the SVD.
6. The range of A is exactly the subspace of $\mathbb{C}^m$ spanned by the r columns of U that correspond to the positive singular values.
7. In the first form, the null space of A is that subspace of $\mathbb{C}^n$ spanned by the $n - r$ columns of V that correspond to zero singular values.
8. In reducing from the first form to the third (reduced) form, a basis for the null space of A has been discarded if columns of Vhave been deleted. A basis for the space orthogonal to the range of A (i.e., the null space of A^*) has been discarded if columns of U have been deleted.
9. In the first standard form of the SVD, U and V are unitary.
10. The second form can be obtained from the first form simply by deleting columns $n+1, \ldots, m$ of U and the corresponding rows of S, if $m > n$, or by deleting columns $m+1, \ldots, n$ of V and the corresponding columns of S, if $m < n$. If $m \neq n$, then only one of U and V is square and either $UU^* = I_m$ or $VV^* = I_n$ fails to hold. Both $U^*U = I_p$ and $V^*V = I_p$.
11. The reduced (third) form can be obtained from the second form by taking only the $r \times r$ principle submatrix of Σ, and only the first r columns of U and V. If A is rank deficient (i.e., $r < \min\{m, n\}$), then neither U nor V is square and neither U^*U nor V^*V is an identity matrix.
12. If $p < m$, let $\tilde{U}$ be an $m \times (m-p)$ matrix of columns that are mutually orthonormal to one another as well as to the columns of $U$and define the $m \times m$ unitary matrix

    $$\widehat{U} = \begin{bmatrix} U & \tilde{U} \end{bmatrix}.$$

    If $q < n$, let $\tilde{V}$ be an $n \times (n-q)$ matrix of columns that are mutually orthonormal to one another as well as to the columns of $V$and define the $n \times n$ unitary matrix

    $$\widehat{V} = \begin{bmatrix} V & \tilde{V} \end{bmatrix}.$$

    Let $\widehat{\Sigma}$ be the $m \times n$ matrix

    $$\widehat{\Sigma} = \begin{bmatrix} \Sigma & 0 \\ 0 & 0 \end{bmatrix}.$$

Then

$$A = \wideparen{U}\wideparen{\Sigma}\wideparen{V}^*, \ A\wideparen{V} = \wideparen{U}\wideparen{\Sigma}^*, \ A^* = \wideparen{V}\wideparen{\Sigma}^T\wideparen{U}^*, \ \text{and} \ A^*\wideparen{U} = \wideparen{V}\wideparen{\Sigma}^T.$$

13. Let $U\Sigma V^*$be a singular value decomposition for A, an $m \times n$ matrix of rank r. Then:
    (a) There are exactly r positive elements of Σ and they are the square roots of the r positive eigenvalues of A^*A (and also AA^*) with the corresponding multiplicities.
    (b) The columns of V are eigenvectors of A^*A; more precisely, $\mathbf{v}_j$ is a normalized eigenvector of A^*A corresponding to the eigenvalue σ_j^2, and $\mathbf{u}_j$ satisfies $\sigma_j \mathbf{u}_j = A\mathbf{v}_j$.
    (c) Alternatively, the columns of U are eigenvectors of AA^*; more precisely, $\mathbf{u}_j$ is a normalized eigenvector of AA^* corresponding to the eigenvalue σ_j^2, and $\mathbf{v}_j$ satisfies $\sigma_j v_j = A^*\mathbf{u}_j$.
14. The singular value decomposition $U\Sigma V^*$ is not unique. If $U\Sigma V^*$ is a singular value decomposition, so is $(-U)\Sigma(-V^*)$. The singular values may be arranged in any order if the columns of singular vectors in U and V are reordered correspondingly.
15. If the singular values are in nonincreasing order, then the only option for the construction of Σ is the choice for its dimensions p and q and these must satisfy $r \leq p \leq m$ and $r \leq q \leq n$.
16. If A is square and if the singular values are ordered in a nonincreasing fashion, the matrix Σ is unique.
17. Corresponding to a simple (i.e., nonrepeated) singular value σ_j, the left and right singular vectors, $\mathbf{u}_j$ and $\mathbf{v}_j$, are unique up to scalar multiples of modulus one. That is, if $\mathbf{u}_j$ and $\mathbf{v}_j$ are singular vectors, then for any real value of θ so are $e^{i\theta}\mathbf{u}_j$ and $e^{i\theta}\mathbf{v}_j$, but no other vectors are singular vectors corresponding to σ_j.
18. Corresponding to a repeated singular value, the associated left singular vectors $\mathbf{u}_j$ and right singular vectors $\mathbf{v}_j$ may be selected in any fashion such that they span the proper subspace. Thus, if $\mathbf{u}_{j_1}, \dots, \mathbf{u}_{j_r}$ and $\mathbf{v}_{j_1}, \dots, \mathbf{v}_{j_r}$ are the left and right singular vectors corresponding to a singular value σ_j of multiplicity s, then so are $\mathbf{u}'_{j_1}, \dots, \mathbf{u}'{}_{j_r}$ and $\mathbf{v}'{}_{j_1}, \dots, \mathbf{v}'{}_{j_r}$ if and only if there exists an $s \times s$ unitary matrix Q such that $[\mathbf{u}'_{j_1}, \dots, \mathbf{u}'{}_{j_r}] = [\mathbf{u}_{j_1}, \dots, \mathbf{u}_{j_r}]\, Q$ and $[\mathbf{v}'_{j_1}, \dots, \mathbf{v}'_{j_r}] = [\mathbf{v}_{j_1}, \dots, \mathbf{v}_{j_r}]\, Q$.

Examples:

For examples illustrating SVD, see Section 5.6.

58.2 Algorithms for the Singular Value Decomposition

Generally, algorithms for computing singular values are analogs of algorithms for computing eigenvalues of symmetric matrices. See Chapter 55 and Chapter 59 for additional information. The idea is always to find square roots of eigenvalues of A^TA without actually computing A^TA. As before, we assume the matrix A whose singular values or singular vectors we seek is $m \times n$. All algorithms assume $m \geq n$; if $m < n$, the algorithms may be applied to A^T. To avoid undue complication, all algorithms will be presented as if the matrix is real. Nevertheless, each algorithm has an extension for complex matrices. Algorithm 1 is presented in three parts. It is analogous to the QR algorithm for symmetric matrices. The developments for it can be found in [GK65], [GK68], [BG69], and [GR70]. Algorithm 1a is a Householder reduction of a matrix to bidiagonal form. Algorithm 1c is a step to be used iteratively in Algorithm 1b. Algorithm 2 computes the singular values and singular vectors of a bidiagonal matrix to high relative accuracy [DK90], [Dem97]. Algorithm 3 gives a "square-root-free" method to compute the singular values of a bidiagonal matrix to high relative accuracy — it is the method of choice when only singular values are desired [Rut54], [Rut90], [FP94], [PM00]. Algorithm 4 computes the singular values of an $n \times n$ bidiagonal matrix by the bisection method, which allows k singular values to be computed in O(kn) time. By specifying the input tolerance *tol* appropriately, Algorithm 4 can also compute the singular values to high relative accuracy. Algorithm 5 computes the SVD of a bidiagonal by the divide and conquer method [GE95]. The most recent method, based on the method of multiple relatively robust representations (not presented here), is the fastest and allows computation of k singular values as well as the corresponding singular vectors of a bidiagonal matrix in $O(kn)$ time [DP04a], [DP04b], [GL03], [WLV05]. All of the above-mentioned methods first reduce the matrix to bidiagonal form. The following algorithms iterate directly on the input matrix. Algorithms 6 and 7 are analogous to the Jacobi method for symmetric matrices. Algorithm 6 — also known as the "one-sided Jacobi method for SVD" — can be found in [Hes58] and Algorithm 7 can be found in [Kog55] and [FH60]. Algorithm 7 begins with an orthogonal reduction of the $m \times n$ input matrix so that all the nonzeros lie in the upper $n \times n$ portion. (Although this algorithm was named biorthogonalization in [FH60], it is not the biorthogonalization found in certain iterative methods for solving linear equations.) Many of the algorithms require a tolerance ε to control termination. It is suggested that ε be set to a small multiple of the unit round off precision ε_o.

```
Algorithm 1a: Householder reduction to bidiagonal form:
Input: $m, n, A$ where $A$ is $m \times n$.
Output: $B, U, V$ so that $B$ is upper bidiagonal, $U$ and $V$ are products of Householder matrices, and $A = UBV^T$.

  1. $B \leftarrow A$. (This step can be omitted if $A$ is to be overwritten with $B$.)
  2. $U = I_{m \times n}$.
  3. $V = I_{n \times n}$.
  4. For $k = 1, \ldots, n$
     a. Determine Householder matrix $Q_k$ with the property that:
        • Left multiplication by $Q_k$ leaves components $1, \ldots, k-1$ unaltered, and
        • $Q_k \begin{bmatrix} 0 \\ \vdots \\ 0 \\ b_{k-1,k} \\ b_{k,k} \\ b_{k+1,k} \\ \vdots \\ b_{m,k} \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ b_{k-1,k} \\ s \\ 0 \\ \vdots \\ 0 \end{bmatrix}$, where $s = \pm\sqrt{\sum_{i=k}^{m} b_{i,k}^2}$.
     b. $B \leftarrow Q_k B$.
     c. $U \leftarrow U Q_k$.
     d. If $k \leq n-2$, determine Householder matrix $P_{k+1}$ with the property that:
        • Right multiplication by $P_{k+1}$ leaves components $1, \ldots, k$ unaltered, and
        • $[0 \cdots 0 \quad b_{k,k} \quad b_{k,k+1} \quad b_{k,k+2} \cdots b_{k,n}]\, P_{k+1} = [0 \cdots 0 \quad b_{k,k} \quad s \quad 0 \cdots 0]$,
          where $s = \pm\sqrt{\sum_{j=k+1}^{n} b_{k,j}^2}$.
     e. $B \leftarrow BP_{k+1}$.
     f. $V \leftarrow P_{k+1} V$.
```

```
Algorithm 1b: Golub–Reinsch SVD:
Input: $m, n, A$ where $A$ is $m \times n$.
Output: $\Sigma, U, V$ so that $\Sigma$ is diagonal, $U$ and $V$ have orthonormal columns, $U$ is
$m \times n$, $V$ is $n \times n$, and $A = U\Sigma V^T$.
    1. Apply Algorithm 1a to obtain $B, U, V$ so that $B$ is upper bidiagonal, $U$ and $V$ are
       products of Householder matrices, and $A = UBV^T$.
    2. Repeat:
       a. If for any $i = 1, \ldots, n-1$, $|b_{i,i+1}| \leq \varepsilon\left(|b_{i,i}| + |b_{i+1,i+1}|\right)$, set $b_{i,i+1} = 0$.
       b. Determine the smallest $p$ and the largest $q$ so that $B$ can be blocked as

          $$B = \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \begin{matrix} p \\ n-p-q \\ q \end{matrix}$$

          where $B_{3,3}$ is diagonal and $B_{2,2}$ has no zero superdiagonal entry.
       c. If $q = n$, set $\Sigma =$ the diagonal portion of $B$ STOP.
       d. If for $i = p+1, \ldots, n-q-1$, $b_{i,i} = 0$, then
                Apply Givens rotations so that $b_{i,i+1} = 0$ and $B_{2,2}$ is still
                upper bidiagonal. (For details, see [GV96, p. 454].)
          else
                Apply Algorithm 1c to $n, B, U, V, p, q$.
```

```
Algorithm 1c: Golub–Kahan SVD step:
Input: $n, B, Q, P, p, q$ where $B$ is $n \times n$ and upper bidiagonal, $Q$ and $P$ have orthogonal columns, and $A = QBP^T$.
Output: $B, Q, P$ so that $B$ is upper bidiagonal, $A = QBP^T$, $Q$ and $P$ have orthogonal columns, and the output $B$ has smaller off-diagonal elements than the input $B$. In storage, $B, Q$, and $P$ are overwritten.
    1. Let $B_{2,2}$ be the diagonal block of $B$ with row and column indices $p+1, \ldots, n-q$.
    2. Set $C =$ lower, right $2 \times 2$ submatrix of $B_{2,2}^T B_{2,2}$.
    3. Obtain eigenvalues $\lambda_1, \lambda_2$ of $C$. Set $\mu =$ whichever of $\lambda_1, \lambda_2$ that is closer to $c_{2,2}$.
    4. $k = p+1, \alpha = b_{k,k}^2 - \mu, \beta = b_{k,k} b_{k,k+1}$.
    5. For $k = p+1, \ldots, n-q-1$
       a. Determine $c = \cos(\theta)$ and $s = \sin(\theta)$ with the property that:

          $$[\alpha \quad \beta] \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2 + \beta^2} & 0 \end{bmatrix}.$$

       b. $B \leftarrow BR_{k,k+1}(c, s)$ where $R_{k,k+1}(c, s)$ is the Givens rotation matrix that acts
          on columns $k$ and $k+1$ during right multiplication.
       c. $P \leftarrow PR_{k,k+1}(c, s)$.
       d. $\alpha = b_{k,k}, \beta = b_{k+1,k}$.
       e. Determine $c = \cos(\theta)$ and $s = \sin(\theta)$ with the property that:

          $$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2 + \beta^2} \\ 0 \end{bmatrix}.$$

       f. $B \leftarrow R_{k,k+1}(c, -s)B$, where $R_{k,k+1}(c, -s)$ is the Givens rotation matrix that
          acts on rows $k$ and $k+1$ during left multiplication.
       g. $Q \leftarrow QR_{k,k+1}(c, s)$.
       h. if $k \leq n-q-1 \alpha = b_{k,k+1}, \beta = b_{k,k+2}$.
```

Algorithm 2a: High Relative Accuracy Bidiagonal SVD:

```
Input: $n, B$ where $B$ is an $n \times n$ upper bidiagonal matrix.
Output: $\Sigma$ is an $n \times n$ diagonal matrix, $U$ and $V$ are orthogonal $n \times n$ matrices,
and $B = U\Sigma V^T$.

  1. Compute $\underline{\sigma}$ to be a reliable underestimate of $\sigma_{\min}(B)$ (for details, see [DK90]).
  2. Compute $\overline{\sigma} = \max_i(b_{i,i}, b_{i,i+1})$.
  3. Repeat:
     a. For all $i = 1, \ldots, n-1$, set $b_{i,i+1} = 0$ if a relative convergence criterion is met
        (see [DK90] for details).
     b. Determine the smallest $p$ and largest $q$ so that $B$ can be blocked as

        $$B = \begin{array}{c} \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \end{array} \begin{array}{c} p \\ n-p-q \\ q \end{array}$$

        where $B_{3,3}$ is diagonal and $B_{2,2}$ has no zero superdiagonal entry.
     c. If $q = n$, set $\Sigma =$ the diagonal portion of $B$. STOP.
     d. If for $i = p+1, \ldots, n-q-1$, $b_{i,i} = 0$, then
            Apply Givens rotations so that $b_{i,i+1} = 0$ and $B_{2,2}$ is still
            upper bidiagonal. (For details, see [GV96, p. 454].)
        else
            Apply Algorithm 2b with $n, B, U, V, p, q, \overline{\sigma}$, $\underline{\sigma}$ as inputs.
```

Algorithm 2b: Demmel–Kahan SVD step:

```
Input: $n, B, Q, P, p, q, \overline{\sigma}, \underline{\sigma}$ where $B$ is $n \times n$ and upper bidiagonal, $Q$ and $P$ have
orthogonal columns such that $A = QBP^T, \overline{\sigma} \approx ||B||$ and $\underline{\sigma}$ is an underestimate of
$\sigma_{\min}(B)$.
Output: $B, Q, P$ so that $B$ is upper bidiagonal, $A = QBP^T, Q$ and $P$ have orthogonal
columns, and the output $B$ has smaller off-diagonal elements than the
input $B$. In storage, $B, Q$, and $P$ are overwritten.

  1. Let $B_{2,2}$ be the diagonal block of $B$ with row and column indices $p+1, \ldots, n-q$.
  2. If $tol^*\underline{\sigma} \leq \varepsilon_0\overline{\sigma}$, then
     a. $c' = c = 1$.
     b. For $k = p+1, n-q-1$
        • $\alpha = cb_{k,k}; \beta = b_{k,k+1}$.
        • Determine $c$ and $s$ with the property that:

          $$[\alpha \quad \beta] \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = [r \quad 0], \text{ where } r = \sqrt{\alpha^2 + \beta^2}.$$

        • If $k \neq p+1, b_{k-1,k} = s'r$.
        • $P \leftarrow PR_{k,k+1}(c, s)$, where $R_{k,k+1}(c, s)$ is the Givens rotation matrix that acts
          on columns $k$ and $k+1$ during right multiplication.
        • $\alpha = c'r, \beta = sb_{k+1,k+1}$.
```

Algorithm 2b: Demmel–Kahan SVD step: (Continued)

```
        • Determine $c'$ and $s'$ with the property that:
              $$\begin{bmatrix} c' & -s' \\ s' & c' \end{bmatrix}\begin{bmatrix} \alpha \\ \beta \end{bmatrix} = \begin{bmatrix} \sqrt{\alpha^2+\beta^2} \\ 0 \end{bmatrix}.$$
        • $Q \leftarrow QR_{k,k+1}(c,-s)$, where $R_{k,k+1}(c,-s)$ is the Givens rotation matrix that
          acts on rows $k$ and $k+1$ during left multiplication.
        • $b_{k,k} = \sqrt{\alpha^2+\beta^2}$.
    c. $b_{n-q-1,n-q} = (b_{n-q,n-q}c)s'; b_{n-q,n-q} = (b_{n-q,n-q}c)c'$.
    Else
    d. Apply Algorithm 1c to $n, B, Q, P, p, q$.
```

Algorithm 3a: High Relative Accuracy Bidiagonal Singular Values:
Input: n, B where B is an $n \times n$ upper bidiagonal matrix.
Output: Σ is an $n \times n$ diagonal matrix containing the singular values of B.

```
1. Square the diagonal and off-diagonal elements of B to form the arrays $\mathbf{s}$ and $\mathbf{e}$,
   respectively, i.e., for $i = 1, \ldots, n-1$, $s_i = b_{i,i}^2$, $e_i = b_{i,i+1}^2$, end for $s_n = b_{n,n}^2$.
2. Repeat:
    a. For all $i = 1, \ldots, n-1$, set $e_i = 0$ if a relative convergence criterion is met (see
       [PM00] for details).
    b. Determine the smallest $p$ and largest $q$ so that $B$ can be blocked as
          $$B = \begin{bmatrix} B_{1,1} & 0 & 0 \\ 0 & B_{2,2} & 0 \\ 0 & 0 & B_{3,3} \end{bmatrix} \begin{matrix} p \\ n-p-q \\ q \end{matrix}$$
       where $B_{3,3}$ is diagonal and $B_{2,2}$ has no zero superdiagonal entry.
    c. If $q = n$, set $\Sigma = \sqrt{\text{diag}(\mathbf{s})}$. STOP.
    d. If for $i = p+1, \ldots, n-q-1$, $s_i = 0$ then
            Apply Givens rotations so that $e_i = 0$ and $B_{2,2}$ is still
            upper bidiagonal. (For details, see [GV96, p. 454].)
       else
            Apply Algorithm 3b with inputs $n, \mathbf{s}, \mathbf{e}$.
```

Algorithm 3b: Differential quotient-difference (dqds) step:
Input: $n, \mathbf{s}, \mathbf{e}$ where $\mathbf{s}$ and $\mathbf{e}$ are the squares of the diagonal and superdiagonal entries, respectively, of an $n \times n$ upper bidiagonal matrix.
Output: $\mathbf{s}$ and $\mathbf{e}$ are overwritten on output.

```
1. Choose $\mu$ by using a suitable shift strategy. The shift $\mu$ should be smaller than
   $\sigma_{\min}(B)^2$. See [FP94, PM00] for details.
2. $d = s_1 - \mu$.
```

(continued)

Algorithm 3b: Differential quotient-difference (dqds) step: (Continued)

```
1. For $k = 1, \ldots, n-1$
    a. $s_k = d + e_k$.
    b. $t = s_{k+1}/s_k$.
    c. $e_k = e_k t$.
    d. $d = dt - \mu$.
    e. If $d < 0$, go to step 1.
2. $s_n = d$.
```

Algorithm 4a: Bidiagonal Singular Values by Bisection:
Input: n, B, α, β, tol where $n \times n$ is a bidiagonal matrix, $[\alpha, \beta)$ is the input interval, and *tol* is the tolerance for the desired accuracy of the singular values.
Output: **w** is the output array containing the singular values of B that lie in $[\alpha, \beta)$.

```
1. $n_\alpha = Negcount(n, B, \alpha)$.
2. $n_\beta = Negcount(n, B, \beta)$.
3. If $n_\alpha = n_\beta$, there are no singular values in $[\alpha, \beta)$. STOP.
4. Put $[\alpha, n_\alpha, \beta, n_\beta]$ onto Worklist.
5. While Worklist is not empty do
    a. Remove $[low, n_{low}, up, n_{up}]$ from Worklist.
    b. $mid = (low + up)/2$.
    c. If $(up - low < tol)$, then
        • For $i = n_{low} + 1, n_{up}, w(i - n_a) = mid$;
       Else
        • $n_{mid} = Negcount(n, B, mid)$.
        • If $n_{mid} > n_{low}$ then
              Put $[low, n_{low}, mid, n_{mid}]$ onto Worklist.
        • If $n_{up} > n_{mid}$ then
              Put $[mid, n_{mid}, up, n_{up}]$ onto Worklist.
```

Algorithm 4b: *Negcount* (n, B, μ):
Input: The $n \times n$ bidiagonal matrix B and a number μ.
Output: *Negcount*, i.e., the number of singular values smaller than μ is returned.

```
1. $t = -\mu$.
2. For $k = 1, \ldots, n-1$
          $d = b_{k,k}^2 + t$.
          If $(d < 0)$ then $Negcount = Negcount + 1$
          $t = t * (b_{k,k+1}^2/d) - \mu$.
   End for
3. $d = b_{n,n}^2 + t$.
4. If $(d < 0)$, then $Negcount = Negcount + 1$.
```

```
Algorithm 5: DC_SVD($n, B, \Sigma, U, V$): Divide and Conquer Bidiagonal SVD:
Input: $n, B$ where $B$ is an $(n+1) \times n$ lower bidiagonal matrix.
Output: $\Sigma$ is an $n \times n$ diagonal matrix, $U$ is an $(n+1) \times (n+1)$ orthogonal matrix,
$V$ is an orthogonal $n \times n$ matrix, so that $B = U\Sigma V^T$.
  1. If $n < n_0$, then apply Algorithm 1b with inputs $n+1, n, B$ to get outputs $\Sigma, U, V$.
     Else
         Let $B = \begin{pmatrix} B_1 & \alpha_k \mathbf{e}_k & 0 \\ 0 & \beta_k \mathbf{e}_1 & B_2 \end{pmatrix}$, where $k = n/2$.
     a. Call DC_SVD($k-1, B_1, \Sigma_1, U_1, W_1$).
     b. Call DC_SVD($n-k, B_2, \Sigma_2, U_2, W_2$).
     c. Partition $U_i = (Q_i \quad \mathbf{q}_i)$, for $i = 1, 2$, where $\mathbf{q}_i$ is a column vector.
     d. Extract $l_1 = Q_1^T \mathbf{e}_k, \lambda_1 = \mathbf{q}_1^T \mathbf{e}_k, l_2 = Q_2^T \mathbf{e}_1, \lambda_2 = \mathbf{q}_2^T \mathbf{e}_1$.
     e. Partition $B$ as
        $B = \begin{pmatrix} c_0\mathbf{q}_1 & Q_1 & 0 & -s_0\mathbf{q}_1 \\ s_0\mathbf{q}_2 & 0 & Q_2 & c_0\mathbf{q}_2 \end{pmatrix} \begin{pmatrix} r_0 & 0 & 0 \\ \alpha_k l_1 & \Sigma_1 & 0 \\ \beta_k l_2 & 0 & \Sigma_2 \\ 0 & 0 & 0 \end{pmatrix} \begin{pmatrix} 0 & W_1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & W_2 \end{pmatrix}^T = (Q \quad q) \begin{pmatrix} M \\ 0 \end{pmatrix} W^T$
        where $r_0 = \sqrt{(\alpha_k \lambda_1)^2 + (\beta_k \lambda_2)^2}, c_0 = \alpha_k \lambda_1 / r_0, s_0 = \beta_k \lambda_2 / r_0$.
     f. Compute the singular values of $M$ by solving the secular equation
            $f(w) = 1 + \sum_{k=1}^{n} \frac{z_k^2}{d_k^2 - w^2} = 0,$
        and denote the computed singular values by $\hat{w}_1, \hat{w}_2, \ldots, \hat{w}_n$.
     g. For $i = 1, \ldots, n$, compute
            $\hat{z}_i = \sqrt{(\hat{w}_n^2 - d_i^2) \prod_{k=1}^{i-1} \frac{(\hat{w}_k^2 - d_i^2)}{(d_k^2 - d_i^2)} \prod_{k=1}^{n-1} \frac{(\hat{w}_k^2 - d_i^2)}{(d_{k+1}^2 - d_i^2)}}.$
     h. For $i = 1, \ldots, n$, compute the singular vectors
            $\mathbf{u}_i = \left( \frac{\hat{z}_1}{d_1^2 - \hat{w}_i^2}, \cdots, \frac{\hat{z}_n}{d_n^2 - \hat{w}_i^2} \right) \Bigg/ \sqrt{\sum_{k=1}^{n} \frac{\hat{z}_k^2}{(d_k^2 - \hat{w}_i^2)^2}},$
            $\mathbf{v}_i = \left( -1, \frac{d_2 \hat{z}_2}{d_2^2 - \hat{w}_i^2}, \cdots, \frac{d_n \hat{z}_n}{d_n^2 - \hat{w}_i^2} \right) \Bigg/ \sqrt{1 + \sum_{k=2}^{n} \frac{(d_k \hat{z}_k)^2}{(d_k^2 - \hat{w}_i^2)^2}}$
        and let $U = [\mathbf{u}_1, \ldots, \mathbf{u}_n], V = [\mathbf{v}_1, \ldots, \mathbf{v}_n]$.
     i. Return $\Sigma = \begin{pmatrix} \mathrm{diag}(\hat{w}_1, \hat{w}_2, \ldots, \hat{w}_n) \\ 0 \end{pmatrix}, U \leftarrow (QU \quad q), V \leftarrow WV$.
```

Algorithm 6: Biorthogonalization SVD:
Input: m, n, A where A is $m \times n$.
Output: Σ, U, V so that Σ is diagonal, U and V have orthonormal columns, U is $m \times n$, V is $n \times n$, and $A = U\Sigma V^T$.

```
1. $U \leftarrow A$. (This step can be omitted if $A$ is to be overwritten with $U$.)
2. $V = I_{n \times n}$.
3. Set $N^2 = \left( \sum_{i=1}^{n} \sum_{j=1}^{n} u_{i,j}^2 \right)$, $s = 0$, and first = true.
4. Repeat until $s^{1/2} \le \varepsilon^2 N^2$ and first = false.
   a. Set $s = 0$ and first = false.
   b. For $i = 1, \ldots, n-1$.
      i. For $j = i+1, \ldots, n$
         • $s \leftarrow s + \left( \sum_{k=1}^{m} u_{k,i} u_{k,j} \right)^2$.
         • Determine $d_1, d_2$, $c = \cos(\theta)$, and $s = \sin(\varphi)$ such that:
           $$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} \sum_{k=1}^{m} u_{k,i}^2 & \sum_{k=1}^{m} u_{k,i} u_{k,i} \\ \sum_{k=1}^{m} u_{k,i} u_{k,i} & \sum_{k=1}^{m} u_{k,j}^2 \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = \begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}.$$
         • $U \leftarrow U R_{i,j}(c,s)$ where $R_{i,j}(c,s)$ is the Givens rotation matrix that acts on
           columns $i$ and $j$ during right multiplication.
         • $V \leftarrow V R_{i,j}(c,s)$.
5. For $i = 1, \ldots, n$:
   a. $\sigma_i = \sqrt{\sum_{k=1}^{m} u_{k,i}^2}$.
   b. $U \leftarrow U\Sigma^{-1}$.
```

Algorithm 7: Jacobi Rotation SVD:
Input: m, n, A where A is $m \times n$.
Output: Σ, U, V so that Σ is diagonal, U and V have orthonormal columns, U is $m \times n$, V is $n \times n$, and $A = U\Sigma V^T$.

```
1. $B \leftarrow A$. (This step can be omitted if $A$ is to be overwritten with $B$.)
2. $U = I_{m \times n}$.
3. $V = I_{n \times n}$.
4. If $m > n$, compute the QR factorization of $B$ using Householder matrices so that
   $B \leftarrow QA$, where $B$ is upper triangular, and let $U \leftarrow UQ$. (See Algorithm 6 for
   details.)
5. Set $N^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} b_{i,j}^2$, $s = 0$, and first = true.
6. Repeat until $s \le \varepsilon^2 N^2$ and first = false.
   a. Set $s = 0$ and first = false.
   b. For $i = 1, \ldots, n-1$
```

(continued)

```
Algorithm 7: Jacobi Rotation SVD: (Continued)

        i. For $j = i + 1, \ldots, n$ :
          • $s = s + b_{i,j}^2 + b_{j,i}^2$.
          • Determine $d_1, d_2, c = \cos(\theta)$ and $s = \sin(\varphi)$ with the property that $d_1$
            and $d_2$ are positive and
            $$\begin{bmatrix} c & -s \\ s & c \end{bmatrix} \begin{bmatrix} b_{i,i} & b_{i,j} \\ b_{j,i} & b_{j,j} \end{bmatrix} \begin{bmatrix} \hat{c} & \hat{s} \\ -\hat{s} & \hat{c} \end{bmatrix} = \begin{bmatrix} d_1 & 0 \\ 0 & d_2 \end{bmatrix}.$$
          • $B \leftarrow R_{i,j}(c, s) B R_{i,j}(\hat{c}, -\hat{s})$ where $R_{i,j}(c, s)$ is the Givens rotation ma-
            trix that acts on rows $i$ and $j$ during left multiplication and $R_{i,j}(\hat{c}, -\hat{s})$
            is the Givens rotation matrix that acts on columns $i$ and $j$ during right
            multiplication.
          • $U \leftarrow U R_{i,j}(c, s)$.
          • $V \leftarrow V R_{i,j}(\hat{c}, \hat{s})$.
    7. Set $\Sigma$ to the diagonal portion of $B$.
```

Zlatko Drmač
University of Zagreb

To compute the eigenvalues and singular values to high relative accuracy means to have a guaranteed number of accurate digits in all computed approximate values. If $\tilde{\lambda}$ is the computed approximation of an eigenvalue λ of a given matrix A, then the desirable high relative accuracy means that $|\lambda - \tilde{\lambda}| \leq \varepsilon \; |\lambda|$, where $0 \leq \varepsilon \ll 1$ independent of the ratio $|\lambda|/\|A\|_2$. This is not always possible. The proper course of action is to first determine classes of matrices and classes of perturbations under which the eigenvalues (singular values) undergo only small relative changes. This means that the development of highly accurate algorithms is determined by the framework established by the perturbation theory.

Input to the perturbation theory is a perturbation matrix whose size is usually measured in a matrix norm. This may not be always adequate in numerical solutions of real world problems. If numerical information stored in the matrix represents a physical system, then choosing different physical units can give differently scaled rows and columns of the matrix, but representing the same physical system. Different scalings may be present because matrix entries represent quantities of different physical nature. It is possible that the smallest matrix entries are determined as accurately as the biggest ones. Choosing the most appropriate scaling from the application's point of view can be a difficult task. It is then desirable that simple changes of reference units do not cause instabilities in numerical algorithms because changing the description (scaling the data matrix) does not change the underlying physical system. This issue is often overlooked or ignored in numerical computations and it can be the cause of incorrectly computed and misinterpreted results with serious consequences.

This chapter describes algorithms for computation of the singular values and the eigenvalues of symmetric and some special classes of nonsymmetric matrices to high relative accuracy. Accurate computation of eigenvectors and singular vectors is not considered. Singular values are discussed in Sections 59.1 to 59.3; Section 59.3 also provides algorithms for accurate computation of eigenvalues of certain structured nonsymmetric matrices. Algorithms for computation of singular values are also given in Section 58.2.

Algorithms for computing the eigenvalues of symmetric matrices are given in Chapter 55. Sections 59.4 to 59.5 discuss numerical issues concerning the accuracy of the computed approximate eigenvalues, divided into the cases positive definite and symmetric indefinite (a negative definite matrix A is handled by applying methods for positive definite matrices to $-A$).

For symmetric H (which may contain initial uncertainty), perturbation theory determines whether or not it is numerically feasible to compute even the smallest eigenvalues with high relative accuracy. State of the art perturbation theory, which is a necessary prerequisite for algorithmic development, is given in Chapter 21. The insights from the perturbation theory are then capitalized in the development of numerical algorithms capable of achieving optimal theoretical accuracy. Unlike in the case of standard accuracy, positive definite and indefinite matrices are analyzed separately.

All matrices are assumed to be over the real field $\mathbb{R}$. Additional relevant preparatory results can be found in Chapter 9 and Chapter 24.

59.1 Accurate SVD and One-Sided Jacobi SVD Algorithm

Numerical computation of the SVD inevitably means computation with errors. How many digits in the computed singular values are provably accurate is answered by perturbation theory adapted to a particular algorithm. For dense matrices with no additional structure, the Jacobi SVD algorithm is proven to be more accurate than any other method that first bidiagonalizes the matrix. The simplest form is the one-sided Jacobi SVD introduced by Hestenes [Hes58]. It represents an implicit form of the classical Jacobi algorithm [Jac46] for symmetric matrices, with properly adjusted stopping criterion. Basic properties of classical Jacobi algorithm are listed in Section 55.7. Detailed analysis and implementation details can be found in [DV92], [Drm94], [Mat96], and [Drm97].

Definitions:

Two vectors $\mathbf{x}, \mathbf{y} \in \mathbb{R}^m$ are **numerically orthogonal** if $|\mathbf{x}^T\mathbf{y}| \leq \varepsilon \|\mathbf{x}\|_2 \|\mathbf{y}\|_2$, where $\varepsilon \geq 0$ is at most round-off unit $\boldsymbol{\epsilon}$ times a moderate function of m.

The square matrix $\tilde{U}$ is a **numerically orthogonal matrix** if each pair of its columns is numerically orthogonal.

A numerical algorithm that computes approximations $\tilde{U} \approx U$, $\tilde{V} \approx V$ and $\tilde{\Sigma} \approx \Sigma$ of the SVD $A = U\Sigma V^T$ of A is **backward stable** if $\tilde{U}$, $\tilde{V}$ are numerically orthogonal and $\tilde{U}\tilde{\Sigma}\tilde{V}^T = A + \delta A$, with **backward error** δA small compared to A.

Facts:

1. There is no loss of generality in considering real tall matrices, i.e., $m \geq n$. In case $m < n$, consider A^T with the SVD $A^T = V\Sigma^T U^T$.
2. Let $\tilde{U} \approx U$, $\tilde{V} \approx V$, $\tilde{\Sigma} \approx \Sigma$ be the approximations of the SVD of $A = U\Sigma V^T$, computed by a backward stable algorithm as $A + \delta A = \tilde{U}\tilde{\Sigma}\tilde{V}^T$. Since the orthogonality of $\tilde{U}$ and $\tilde{V}$ cannot be guaranteed, the product $\tilde{U}\tilde{\Sigma}\tilde{V}^T$ in general does not represent an SVD. However, there exist orthogonal $\hat{U}$ close to $\tilde{U}$ and an orthogonal $\hat{V}$, close to $\tilde{V}$, such that $(I + E_1)(A + \delta A)(I + E_2) = \hat{U}\tilde{\Sigma}\hat{V}^T$, where E_1, E_2, which represent departure from orthogonality of $\tilde{U}$, $\tilde{V}$, are small in norm.
3. Different algorithms produce differently structured δA. Consider the singular values $\sigma_1 \geq \cdots \geq \sigma_n$ and $\tilde{\sigma}_1 \geq \cdots \geq \tilde{\sigma}_n$ of A and $A + \delta A$, respectively.
   (a) If $\|\delta A\|_2 \leq \varepsilon \|A\|_2$ and without any additional structure of δA (δA small in norm), then the best error bound in the singular values is $\max\limits_{1\leq i\leq n} |\sigma_i - \tilde{\sigma}_i| \leq \|\delta A\|_2$, i.e.,
$$\max_{1\leq i\leq n} \frac{|\sigma_i - \tilde{\sigma}_i|}{\sigma_i} \leq \kappa_2(A)\, \varepsilon.$$

   (b) [DV92] Let, for all i, the ith column $\delta \mathbf{a}_i$ of δA satisfy $\|\delta \mathbf{a}_i\|_2 \leq \varepsilon \|\mathbf{a}_i\|_2$, where $\mathbf{a}_i$ is the ith column of A. (δA is column-wise small perturbation.) Then $A + \delta A = (B + \delta B)D$, where $A = BD$, $D = \mathrm{diag}(\|\mathbf{a}_1\|_2, \ldots, \|\mathbf{a}_n\|_2)$, and $\|\delta B\|_F \leq \sqrt{n}\varepsilon$. Let A have full column rank and let p be the rank of δA.
   Then $\max\limits_{1 \leq i \leq n} \dfrac{|\sigma_i - \tilde{\sigma}_i|}{\sigma_i} \leq \|\delta B B^\dagger\|_2 \leq \sqrt{p}\varepsilon \|B^\dagger\|_2$.

   (c) [vdS69] $\|B^\dagger\|_2 \leq \kappa_2(B) \leq \sqrt{n} \min\limits_{S=\mathrm{diag}} \kappa_2(AS) \leq \sqrt{n}\kappa_2(A)$. This implies that a numerical algorithm with column-wise small backward error δA computes more accurate singular values than an algorithm with backward error that is only small in norm.

4. In the process of computation of the SVD of A, an algorithm can produce intermediate matrix with singular values highly sensitive even to the smallest entry-wise rounding errors.
5. The matrix A may have initial uncertainty on input and, in fact, $A = A_0 + \delta A_0$, where A_0 is the true unknown data matrix and δA_0 the initial error already present in A. If δA generated by the algorithm is comparable with δA_0, the computed SVD is as accurate as warranted by the data.
6. [Hes58] If $H = A^T A$, then the classical Jacobi algorithm can be applied to H implicitly. The one-sided (or implicit) Jacobi SVD method starts with general $m \times n$ matrix $A^{(0)} = A$ and it generates the sequence $A^{(k+1)} = A^{(k)} V^{(k)}$, where the matrix $V^{(k)}$ is the plane rotation as in the classical symmetric Jacobi method for the matrix $H^{(k)} = (A^{(k)})^T A^{(k)}$. Only $H^{(k)}[\{i_k, j_k\}]$ is needed to determine $V^{(k)}$, where (i_k, j_k) is the pivot pair determined by pivot strategy.
7. In the one-sided Jacobi SVD algorithm applied to $A \in \mathbb{R}^{m \times n}$, $m \geq n$, $A^{(k)}$ tends to $U\Sigma$, with diagonal $\Sigma = \mathrm{diag}(\sigma_1, \ldots, \sigma_n)$ carrying the singular values. If A has full column rank, then the columns of U are the n corresponding left singular vectors. If $\mathrm{rank}(A) < n$, then for each $\sigma_i = 0$ the ith column of U is zero. The m-$\mathrm{rank}(A)$ left singular vectors from the orthogonal complement of $\mathrm{range}(A)$ cannot be computed using one-sided Jacobi SVD. (For arbitrary A, see Section 59.2.) The accumulated product $V^{(0)} V^{(1)} \cdots$ converges to orthogonal matrix V of right singular vectors.
8. Simple implementation of Jacobi rotation in the one-sided Jacobi SVD algorithm (one-sided Jacobi rotation) is given in Algorithm 1. At any step, $A^{(k+1)}$ overwrites $A^{(k)}$. Further, $d_1, \ldots, d_n$ contain the squared Euclidean norms of the columns of current $A^{(k)}$, and ξ_{ij} is the Euclidean inner product of the pivot columns $A_{1:m,i}$ and $A_{1:m,j}$.

```
**Algorithm 1:** One-sided Jacobi rotation
ROTATE $(A_{1:m,i}, A_{1:m,j}, d_i, d_j, \xi_{ij}, [V_{1:m,i}, V_{1:m,j}])$
    $\vartheta = \dfrac{d_j - d_i}{2 \cdot \xi_{ij}}$; $t = \dfrac{\mathrm{sign}(\vartheta)}{|\vartheta| + \sqrt{1 + \vartheta^2}}$ ; $c = \dfrac{1}{\sqrt{1 + t^2}}$ ; $s = t \cdot c$ ;
    $[A_{1:m,i}\ A_{1:m,j}] = [A_{1:m,i}\ A_{1:m,j}] \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$;
    $d_i = d_i - t \cdot \xi_{ij}$ ; $d_j = d_j + t \cdot \xi_{ij}$ ;
    if $V$ is wanted, then
        $[V_{1:n,i}\ V_{1:n,j}] = [V_{1:n,i}\ V_{1:n,j}] \begin{bmatrix} c & s \\ -s & c \end{bmatrix}$
    end if
```

In case of cancellation in computation of the smaller of d_i, d_j, the value is refreshed by explicit computation of the squared norm of the corresponding column.

9. [Rij89], [DV92] Numerical convergence of the one-sided Jacobi SVD algorithm (Algorithm 2) is declared at step k if $\max_{i \neq j} \frac{|(A^{(k)}_{1:m,i})^T A^{(k)}_{1:m,j}|}{\|A^{(k)}_{1:m,i}\|_2 \|A^{(k)}_{1:m,j}\|_2} \leq \zeta \approx m\boldsymbol{\epsilon}$. This stopping criterion guarantees that computed approximation $\tilde{A}^{(k)}$ of $A^{(k)}$ can be written as $\tilde{U}\tilde{\Sigma}$, where the columns of $\tilde{U}$ are numerically orthogonal, and $\tilde{\Sigma}$ is diagonal.

```
Algorithm 2: One-sided Jacobi SVD (de Rijk's row-cyclic pivoting)
 $(U, \Sigma, [V]) = \mathrm{SVD0}(A)$
  $\zeta = m\epsilon$ ; $\hat{p} = n(n-1)/2$ ; $s = 0$ ; convergence = false ;
  if $V$ is wanted, then initialize $V = I_n$ end if
  for $i = 1$ to $n$ do $d_i = A^T_{1:m,i} A_{1:m,i}$ end for;
  repeat
    $s = s + 1$ ; $p = 0$;
    for $i = 1$ to $n - 1$ do
        find index $i_0$ such that $d_{i_0} = \max_{i \leq \ell \leq n} d_\ell$; swap$(d_i, d_{i_0})$ ;
        swap$(A_{1:m,i}, A_{1:m,i_0})$; swap$(V_{1:m,i}, V_{1:m,i_0})$ ;
        for $j = i + 1$ to $n$ do
            $\xi = A^T_{1:m,i} A_{1:m,j}$;
            if $|\xi| > \zeta\sqrt{d_i d_j}$ then % apply Jacobi rotation
                call ROTATE$(A_{1:m,i}, A_{1:m,j}, d_i, d_j, \xi, [V_{1:m,i}, V_{1:m,j}])$ ;
            else $p = p + 1$ end if
        end for
    end for
    if $p = \hat{p}$, then convergence = true end if
  until convergence or $(s > 30)$
  if convergence then % numerical orthogonality reached
      for $i = 1$ to $n$ do $\Sigma_{ii} = \sqrt{d_i}$ ; $U_{1:m,i} = A_{1:m,i}\Sigma^{-1}_{ii}$ end for
  else
      Error: Numerical convergence did not occur after 30 sweeps.
  end if
```

10. [DV92], [Mat96], [Drm97] Let $\tilde{A}^{(k)}$, $k = 0, 1, 2, \ldots$ be the matrices computed by Algorithm 2 in floating point arithmetic. Write each $\tilde{A}^{(k)}$ as $\tilde{A}^{(k)} = B^{(k)} D^{(k)}$, with diagonals $D^{(k)}$ and $B^{(k)}$ with columns of unit Euclidean norms. Then
    (a) $\tilde{A}^{(k+1)} = (\tilde{A}^{(k)} + \delta\tilde{A}^{(k)})\breve{V}^{(k)}$, where $\breve{V}^{(k)}$ is the exact plane rotation transforming pivot columns, and $\delta\tilde{A}^{(k)}$ is zero except in the i_kth and the j_kth columns.
    (b) $\tilde{A}^{(k)} + \delta\tilde{A}^{(k)} = (B^{(k)} + \delta B^{(k)})D^{(k)}$, with $\|\delta B^{(k)}\|_F < c_k\boldsymbol{\epsilon}$, where c_k is a small factor (e.g., $c_k < 20$) that depends on the implementation of the rotation.
    (c) The above holds as long as the Euclidean norms of the i_kth and the j_kth columns of $\tilde{A}^{(k)}$ do not underflow or overflow. It holds even if the computed angle is so small that the computed value of $\tan\phi_k$ underflows (gradually or flushed to zero). This, however, requires special implementation of the Jacobi rotation.
    (d) If all matrices $\tilde{A}^{(j)}$, $j = 0, \ldots, k-1$ are nonsingular, then for all $i = 1, \ldots, n$,

$$\max\left\{0, \prod_{j=0}^{k-1}(1 - \eta_j)\right\} \leq \frac{\sigma_i(\tilde{A}^{(k)})}{\sigma_i(A)} \leq \prod_{j=0}^{k-1}(1 + \eta_j),$$

where $\eta_j = \|\delta\tilde{A}^{(j)}(\tilde{A}^{(j)})^\dagger)\|_2 \leq c_j\boldsymbol{\epsilon}\|(B^{(j)})^\dagger\|_2$, and $\sigma_i(\cdot)$ stands for the ith largest singular value of a matrix. The accuracy of Algorithm 2 is determined by $\beta \equiv \max_{k\geq 0}\|(B^{(k)})^\dagger\|_2$. It is observed in practice that β never exceeds $\|B^\dagger\|_2$ too much.

(e) If A initially contains column-wise small uncertainty and if $\beta/\|B^\dagger\|_2$ is moderate, then Algorithm 2 computes as accurate approximations of the singular values as warranted by the data.

Examples:

1. Using orthogonal factorizations in finite precision arithmetic does not guarantee high relative accuracy in SVD computation. Bidiagonalization, as a preprocessing step in state-of-the-art SVD algorithms, is an example. We use MATLAB with roundoff $\boldsymbol{\epsilon} = \texttt{eps} \approx 2.22\cdot 10^{-16}$. Let $\xi = 10/\boldsymbol{\epsilon}$. Then floating point bidiagonalization of

$$A = \begin{pmatrix} 1 & 1 & \boxed{1} \\ 0 & 1 & \xi \\ 0 & -1 & \xi \end{pmatrix} \text{ yields } \tilde{A}^{(1)} = \begin{pmatrix} 1 & \alpha & 0 \\ 0 & \beta & \beta \\ 0 & \boxed{\beta} & \beta \end{pmatrix}, \quad \tilde{A}^{(2)} = \begin{pmatrix} 1 & \alpha & 0 \\ 0 & \gamma & \gamma \\ 0 & 0 & 0 \end{pmatrix},$$

$\alpha \approx$ 1.4142135e+0, $\beta \approx$ 3.1845258e+16, $\gamma \approx$ 4.5035996e+16. The matrices $\tilde{A}^{(1)}$ and $\tilde{A}^{(2)}$ are computed using Givens plane rotations at the positions indicated by $\boxed{\cdot}$. The computed matrix $\tilde{A}^{(1)}$ entry-wise approximates with high relative accuracy the matrix $A^{(1)}$ from the exact computation (elimination of A_{13}). However, A and $A^{(1)}$ are nonsingular and $\tilde{A}^{(1)}$ is singular. The smallest singular value of A is lost — $\tilde{A}^{(1)}$ carries no information about σ_3. Transformation from $\tilde{A}^{(1)}$ to $\tilde{A}^{(2)}$ is again perfectly entry-wise accurate. But, even exact SVD of the bidiagonal $\tilde{A}^{(2)}$ cannot restore the information lost in the process of bidiagonalization. (See Fact 4 above.)

On the other hand, let $\hat{A}^{(1)}$ denote the matrix obtained from A by perturbing A_{13} to zero. This changes the third column $\mathbf{a}_3$ of A by $\|\delta\mathbf{a}_3\|_2 \leq (\boldsymbol{\epsilon}/14)\|\mathbf{a}_3\|_2$ and causes, at most, $\boldsymbol{\epsilon}/5$ relative perturbation in the singular values. (See Fact 3 above. Here, $A = BD$ with $\kappa(B) < 2$.) If we apply Givens rotation from the left to annihilate the $(3,2)$ entry in $\hat{A}^{(1)}$, the introduced perturbation is column-wise small. Also, the largest singular value decouples; the computed matrix is $\hat{A}^{(2)} = \begin{bmatrix} 1 & 1 \\ 0 & \alpha \end{bmatrix} \bigoplus [\tilde{\sigma}_1]$.

59.2 Preconditioned Jacobi SVD Algorithm

The accuracy properties and the run-time efficiency of the one-sided Jacobi SVD algorithm can be enhanced using appropriate preprocessing and preconditioning. More details can be found in [Drm94], [Drm99], [DV08a], and [DV08b].

Definitions:

QR factorization with column pivoting of $A \in \mathbb{R}^{m\times n}$ is the factorization $A\Pi = Q\begin{bmatrix} R \\ 0 \end{bmatrix}$, where Π is a permutation matrix, Q is orthogonal, and R is $n\times n$ upper triangular.

The QR factorization with **Businger–Golub pivoting** chooses Π to guarantee that $r_{kk}^2 \geq \sum_{i=k}^{j} r_{ij}^2$ for all $j = k,\ldots,n$ and $k = 1,\ldots,n$.

The QR factorization with **Powell–Reid's complete (row and column) pivoting** computes the QR factorization using row and column permutations, $\Pi_r A\Pi_c = Q\begin{bmatrix} R \\ 0 \end{bmatrix}$, where Π_c is as in Businger–Golub pivoting and Π_r enhances numerical stability in case of A with differently scaled rows.

QR factorization with pivoting of A is **rank revealing** if small singular values of A are revealed by correspondingly small diagonal entries of R.

Facts:

1. [Drm94], [Hig96]. Let the QR factorization $A = Q\begin{bmatrix} R \\ 0 \end{bmatrix}$ of $A \in \mathbb{R}^{m\times n}$, $m \geq n$, be computed using the Givens or the Householder algorithm in the IEEE floating point arithmetic with rounding relative error $\boldsymbol{\epsilon} < 10^{-7}$. Let the computed approximations of Q and R be $\tilde{Q}$ and $\tilde{R}$, respectively. Then there exist an orthogonal matrix $\hat{Q}$ and a backward perturbation δA such that

$$A + \delta A = \hat{Q}\begin{bmatrix} \tilde{R} \\ 0 \end{bmatrix}, \quad \|\tilde{Q}_{1:m,i} - \hat{Q}_{1:m,i}\|_2 \leq \varepsilon_{qr}, \quad \|\delta A_{1:m,i}\|_2 \leq \varepsilon_{qr}\|A_{1:m,i}\|_2$$

holds for all $i = 1, \ldots, n$, with $\varepsilon_{qr} \leq O(mn)\boldsymbol{\epsilon}$. This remains true if the factorization is computed with pivoting. It suffices to assume that the matrix A is already prepermuted on input, and that the factorization itself is performed without pivoting.
2. [DB08] Software implementations of the Businger–Golub pivoted QR factorization in packages such as LAPACK (Chapter 93) and Matlab (Chapter 88) may suffer from a subtle numerical instability resulting in loss of diagonally dominant structure in the computed upper triangular factor R. The problem is resolved in LAPACK 3.1.0.
3. [Drm94], [Mat96], [Drm99] Let $A = BD$, where D is diagonal and B has unit columns in Euclidean norm.
   (a) If $\|B^\dagger\|_2$ is moderate, then the computed $\tilde{R}$ allows approximation of the singular values of A to high relative accuracy. If $\tilde{R}$ is computed with Businger–Golub pivoting, then Algorithm 2 applied to $\tilde{R}^T$ converges swiftly and computes the singular values of A with relative accuracy determined by $\|B^\dagger\|_2$.
   (b) Let A have full column rank and let its QR factorization be computed by Businger–Golub column pivoting. Write $R = ST$, where S is the diagonal matrix and T has unit rows in Euclidean norm. Then $\|T^{-1}\|_2 \leq n\|B^\dagger\|_2$.
4. [DV08a] The following algorithm carefully combines the properties of the one–sided Jacobi SVD and the properties of the QR factorization (Facts 1, 2, and 3):

```
Algorithm 3: Preconditioned Jacobi SVD
($(U, \Sigma, [V]) = \mathrm{SVD1}(A)$)
    Input: $A \in \mathbb{R}^{m\times n}$, $m \geq n$.
1:    $(P_r A)P_c = Q_1 \begin{bmatrix} R_1 \\ 0 \end{bmatrix}$; % $R_1 \in \mathbb{R}^{\rho\times n}$, rank revealing QRF.
2:    $R_1^T = Q_2 \begin{bmatrix} R_2 \\ 0 \end{bmatrix}$; % $R_2 \in \mathbb{R}^{\rho\times\rho}$.
3:    $(U_2, \Sigma_2, V_2) = \mathrm{SVD0}(R_2^T)$ ;% one-sided Jacobi SVD on $R_2^T$.
    Output: $U = P_r^T Q_1 \begin{bmatrix} U_2 & 0 \\ 0 & I_{m-\rho} \end{bmatrix}$; $\Sigma = \begin{bmatrix} \Sigma_2 & 0 \\ 0 & 0 \end{bmatrix}$; $V = P_c Q_2 \begin{bmatrix} V_2 & 0 \\ 0 & I_{n-\rho} \end{bmatrix}$.
```

5. [Drm99], [DV08a], [DV08b]
   (a) Let A and the computed matrix $\tilde{R}_1 \approx R_1$ in Algorithm 3 be of full column rank. Let $\tilde{R}_2$ be computed approximation of R_2 in Step 2. Then, there exist perturbations

δA, $\delta\tilde{R}_1$, and there exist orthogonal matrices $\hat{Q}_1$, $\hat{Q}_2$ such that

$$(I+\delta A A^\dagger)A(I+\tilde{R}_1^{-1}\delta\tilde{R}_1)=\hat{Q}_1\begin{bmatrix}\tilde{R}_2^T\\ 0\end{bmatrix}\hat{Q}_2^T.$$

Thus, the first two steps of Algorithm 3 preserve the singular values if $\|B^\dagger\|_2$ is moderate.

(b) Let the one-sided Jacobi SVD algorithm with row cyclic pivot strategy be applied to $\tilde{R}_2^T$. Let the stopping criterion be satisfied at the matrix $(\tilde{R}_2^T)^{(k)}$ during the sth sweep. Write $(\tilde{R}_2^T)^{(k)}=\tilde{U}_2\tilde{\Sigma}$, where $\tilde{\Sigma}$ is diagonal and $\tilde{U}_2$ is numerically orthogonal. Then there exist an orthogonal matrix $\hat{V}_2$ and a backward error $\delta\tilde{R}_2$ such that $\tilde{U}_2\tilde{\Sigma}=(\tilde{R}_2+\delta\tilde{R}_2)^T\hat{V}_2$, $\|\delta(\tilde{R}_2)_{1:\rho,i}\|_2\le\varepsilon_J\|(\tilde{R}_2)_{1:\rho,i}\|_2$, $i=1,\ldots,\rho$, with $\varepsilon_J\le(1+6\boldsymbol{\epsilon})^{s(2n-3)}-1$. If $\hat{U}_2$ is the closest orthogonal matrix to $\tilde{U}_2$, then $\tilde{R}_2^T=\hat{V}_2\tilde{\Sigma}\hat{U}_2^T(I+E)$, where the dominant part of $\|E\|_2$ is $\|\delta\tilde{R}_2\tilde{R}_2^{-1}\|_2$. Similar holds for any serial or parallel convergent pivot strategy.

(c) Assembling the above yields

$$(I+\delta A A^\dagger)A(I+\tilde{R}_1^{-1}\delta\tilde{R}_1)=\hat{Q}_1\begin{bmatrix}\hat{V}_2 & 0\\ 0 & I\end{bmatrix}\begin{bmatrix}\tilde{\Sigma}\\ 0\end{bmatrix}\hat{U}_2^T\hat{Q}_2^T(I+\hat{Q}_2E\hat{Q}_2^T).$$

The upper bound on the maximal relative error $\|\Sigma^{-1}(\Sigma-\tilde{\Sigma})\|_2$ is dominated by $\|\delta A A^\dagger\|_2+\|\tilde{R}_1^{-1}\delta\tilde{R}_1\|_2+\|\delta\tilde{R}_2\tilde{R}_2^{-1}\|_2$.

(d) Let A have the structure $A=BD$, where full-column rank B has equilibrated columns and D is arbitrary diagonal scaling. The only relevant condition number for relative accuracy of Algorithm 3 is $\|B^\dagger\|_2$.

6. [DV08a], [DV08b] Algorithm 3 outperforms Algorithm 2 in both speed and accuracy.
7. [Drm99], [Drm00b], [Hig00], [DV08a] It is possible that $\kappa_2(B)$ is large, but A is structured as $A=D_1CD_2$ with diagonal scalings D_1, D_2 (diagonal entries in nonincreasing order) and well-conditioned C. In that case, desirable backward error for the first QR factorization (Step 1) is $P_rD_1(C+\delta C)D_2P_c$ with satisfactory bound on $\|\delta C\|_2$. This is nearly achieved if the QR factorization is computed with Powell–Reid's complete pivoting or its simplification, which replaces row pivoting with initial sorting. Although theoretical understanding of this fact is not complete, initial row sorting (descending in $\|\cdot\|_\infty$ norm) is highly recommended.

Examples:

1. The key step of the preconditioning is in transposing the computed triangular factors. If A is a 100×100 Hilbert matrix, written as $A=BD$ (cf. Fact 3,), then $\kappa_2(B)>10^{19}$. If in Step 2 of Algorithm 3, we write R_1^T as $R_1^T=B_1D_1$, where D_1 is diagonal and B_1 has unit columns in Euclidean norm, then $\kappa_2(B_1)<50$.
2. Take $\gamma=10^{-20}$, $\delta=10^{-40}$ and consider the matrix

$$A=\begin{bmatrix}1 & \gamma & \gamma\\ -\gamma & \gamma & \gamma^2\\ 0 & \delta & 0\end{bmatrix}=\begin{bmatrix}1&0&0\\0&\gamma&0\\0&0&\delta\end{bmatrix}\begin{bmatrix}1&\gamma&1\\-1&1&1\\0&1&0\end{bmatrix}\begin{bmatrix}1&0&0\\0&1&0\\0&0&\gamma\end{bmatrix},$$

with singular values nearly $\sigma_1\approx1$, $\sigma_2\approx\gamma$, $\sigma_3\approx2\gamma\delta$, cf. [DGE99]. A cannot be written as $A=BD$ with diagonal D and well-conditioned B. Algorithm 2 computes no accurate digit of σ_3, while Algorithm 3 approximates all singular values to nearly full accuracy. (See Fact 6.) The computed R_1^T in Step 2 is

$$\tilde{R}_1^T = \begin{bmatrix} -1.000000000000000e+0 & 0 & 0 \\ -1.000000000000000e-20 & -1.000000000000000e-20 & 0 \\ -1.000000000000000e-20 & -1.000000000000000e-40 & -2.000000000000000e-60 \end{bmatrix}.$$

Note that neither the columns of A nor the columns of $\tilde{R}_1$ reveal the singular value of order 10^{-60}. On the other hand, the Euclidean norms of the column of $\tilde{R}_1^T$ nicely approximate the singular values of A. (See Facts 3 and 4.) If the order of the rows of A is changed, $\tilde{R}_1$ is computed with zero third row.

59.3 Accurate SVD from a Rank Revealing Decomposition: Structured Matrices

In some cases, the matrix A is given implicitly as the product of two or three matrices or it can be factored into such a product using more general nonorthogonal transformations. For instance, some specially structured matrices allow Gaussian eliminations with complete pivoting $P_1AP_2 = LDU$ to compute entry-wise accurate $\tilde{L} \approx L$, $\tilde{D} \approx D$, $\tilde{U} \approx U$. Moreover, it is possible that the triple $\tilde{L}, \tilde{D}, \tilde{U}$ implicitly defines the SVD of A to high relative accuracy, and that direct application of any SVD algorithm directly to A does not return accurate SVD. An excellent in-depth survey of high accuracy in linear algebra is given in [DDHK08]. For more information on matrices and bipartite graphs, see Chapter 41. For more information on sign pattern matrices, see Chapter 42. For more information on totally nonnegative (TN) matrices, see Chapter 29.

Definitions:

The singular values of A are said to be **perfectly well determined to high relative accuracy** if the following holds: No matter what the entries of the matrix are, changing an arbitrary nonzero entry $a_{k\ell}$ to $\theta a_{k\ell}$, with arbitrary $\theta \neq 0$, will cause perturbation $\sigma_i \rightsquigarrow \tilde{\sigma}_i \in [\theta_l \sigma_i, \theta_u \sigma_i]$, $\theta_l = \min\{|\theta|, 1/|\theta|\}$, $\theta_u = \max\{|\theta|, 1/|\theta|\}$, $i = 1, \ldots, n$.

The **sparsity pattern** Struct(A) of A is defined as the set of indices (k, ℓ) of the entries of A permitted to be nonzero.

The **bipartite graph** $\mathcal{G}(\mathcal{S})$ of the sparsity pattern $\mathcal{S}$ is the graph with vertices partitioned into row vertices $r_1, \ldots, r_m$ and column vertices $c_1, \ldots, c_n$, where r_k and r_l are connected if and only if $(k, l) \in \mathcal{S}$.

If $\mathcal{G}(\mathcal{S})$ is acyclic, matrices with sparsity pattern $\mathcal{S}$ are **biacyclic**.

The **sign** pattern sgn(A) prescribes locations and signs of nonzero entries of A.

A sign pattern S is **total signed compound** (TSC) if every square submatrix of every matrix A such that sgn$(A) = S$ is either **sign nonsingular** (nonsingular and determinant expansion is the sum of monomials of like sign) or **sign singular** (determinant expansion degenerates to sum of monomials, which are all zero); cf. Section 42.2.

$A \in \mathbb{R}^{m \times n}$ is **diagonally scaled totally unimodular (DSTU)** if there exist diagonal D_1, D_2 and **totally unimodular** Z (all minors of Z are from $\{-1, 0, 1\}$) such that $A = D_1 Z D_2$.

A decomposition $A = XDY^T$ with diagonal matrix D is called an **RRD** if X and Y are full-column rank, well-conditioned matrices. (RRD is an abbreviation for "rank revealing decomposition," but that term is defined slightly differently in Section 52.9, where X, Y are required to be orthogonal and D is replaced by an upper triangular matrix.)

For an $n \times n$ matrix $A = [a_{ij}]$ define A_D as the matrix with zero diagonal and $(A_D)_{ij} = a_{ij}$ for $i \neq j$. Further, let $v_i = a_{ii} - \sum_{j \neq i} |a_{ij}|$, $i = 1, \ldots, n$. The vector $v = (v_1, \ldots, v_n)$ is the

vector of diagonally dominant parts of A. The representation of A by the pair (A_D, v) is called **representation by the diagonally dominant parts**.

Facts:

1. [DG93] The singular values of A are perfectly well determined to high relative accuracy if and only if the bipartite graph $\mathcal{G}(\mathcal{S})$ is acyclic (forest of trees). Sparsity pattern $\mathcal{S}$ with acyclic $\mathcal{G}(\mathcal{S})$ allows at most $m+n-1$ nonzero entries. A bisection algorithm computes all singular values of biacyclic matrices to high relative accuracy.
2. [DK90], [FP94] Bidiagonal matrices are a special case of acyclic sparsity pattern. Let $n \times n$ bidiagonal matrix B be perturbed by $b_{ii} \rightsquigarrow b_{ii}\varepsilon_{2i-1}$, $b_{i,i+1} \rightsquigarrow b_{i,i+1}\varepsilon_{2i}$ for all admissible i's, and let $\varepsilon = \prod_{i=1}^{2n-1} \max(|\varepsilon_i|, 1/|\varepsilon_i|)$, where all $\varepsilon_i \neq 0$. If $\tilde{\sigma}_1 \geq \cdots \geq \tilde{\sigma}_n$ are the singular values of the perturbed matrix, then for all i, $\sigma_i/\varepsilon \leq \tilde{\sigma}_i \leq \varepsilon\sigma_i$. The singular values of bidiagonal matrices are efficiently computed to high relative accuracy by the zero shift QR algorithm and the differential qd algorithm.
3. [DGE99] Let $\mathcal{S}_\pm$ be a sparsity-and-sign pattern. Let each matrix A with pattern $\mathcal{S}_\pm$ have the property that small relative changes of its (nonzero) entries cause only small relative perturbations of its singular values. This is equivalent with $\mathcal{S}_\pm$ being total signed compound (TSC).
4. [Drm98a], [DGE99] Let A be given by an RRD $A = XDY^T$. Without loss of generality assume that X and Y have equilibrated (e.g., unit in Euclidean norm) columns. Algorithm 4 computes the SVD of A to high relative accuracy.

Algorithm 4: RRD Jacobi SVD

```
$(U, \Sigma, V) = \mathrm{SVD2}(X, D, Y)$
    Input: $X \in \mathbb{R}^{m\times p}$, $Y \in \mathbb{R}^{n\times p}$ full column rank, $D \in \mathbb{R}^{p\times p}$ diagonal.
1:      $\Upsilon = YD$; $\Upsilon P = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ % rank revealing QR factorization.
2:      $Z = XPR^T$ ; % explicit standard matrix multiplication.
3:      $(U_z, \Sigma_z, V_z) = \mathrm{SVD1}(Z)$ % one-sided Jacobi SVD on Z.
    Output: $U = U_z$; $\Sigma = \begin{bmatrix} \Sigma_z & 0 \\ 0 & 0 \end{bmatrix}$; $V = Q \begin{bmatrix} V_z & 0 \\ 0 & I_{n-p} \end{bmatrix}$. $XDY^T = U\Sigma V^T$.
```

5. [GE96], [Drm98a], [DGE99], [DM04]
   (a) In Step 2 of Algorithm 4, the matrix R^T has the structure $R^T = LS$, where S is diagonal scaling, L has unit columns, and $\|L^{-1}\|_2$ is bounded by a function of p independent of input data. The upper bound on $\kappa_2(L)$ depends on pivoting P in Step 1 and it can be $O(p^{1+(1/4)\log_2 p})$. For the Businger–Golub, pivoting the upper bound is $O(2^p)$, but in practice one can expect an $O(p)$ bound.

   (b) The product $Z = (XP)R^T$ must not be computed by fast (e.g., Strassen) algorithm if all singular values are wanted to high relative accuracy. The reason is that fast matrix multiplication algorithms can produce larger component-wise perturbations than the standard $O(n^3)$ algorithm.

   (c) The computed $\tilde{U}$, $\tilde{\Sigma}$, $\tilde{V}$ satisfy the following: There exist orthogonal $\hat{U} \approx \tilde{U}$, orthogonal $\hat{V} \approx \tilde{V}$, and E_1, E_2 such that $\hat{U}\tilde{\Sigma}\hat{V}^T = (I+E_1)A(I+E_2)$, $\|E_1\|_2 \leq O(\epsilon)\kappa_2(X)$, $\|E_2\|_2 \leq O(\epsilon)\kappa_2(L)\kappa_2(Y)$. The relative errors in the computed singular values are bounded by $O(\epsilon)\kappa_2(L)\max\{\kappa_2(X), \kappa_2(Y)\}$. Here, $O(\epsilon)$ denotes machine precision ϵ multiplied by a moderate polynomial in m, n, p.
6. [DGE99] Classes of matrices with accurate LDU factorization and, thus, accurate

SVD computation by Algorithm 4, or other algorithms tailored for special classes of matrices (e.g., QR and qd algorithms for bidiagonal matrices), include:

   (a) *Acyclic matrices:* Accurate LDU factorization with pivoting uses the correspondence between the monomials in determinant expansion and perfect matchings in $\mathcal{G}(\mathcal{S})$.

   (b) *Total signed compound (TSC) matrices:* LDU factorization with complete pivoting $P_r A P_c = LDU$ of an TSC matrix A can be computed in a forward stable way. Cancellations in Gaussian eliminations can be avoided by computing some elements as quotients of minors. All entries of L, D, U are computed to high relative accuracy. The behavior of $\kappa(L)$ and $\kappa(U)$ is not fully analyzed, but they behave well in practice.

   (c) *Diagonally scaled totally unimodular (DSTU) matrices:* This class includes acyclic and certain finite element (e.g., mass-spring systems) matrices. Gaussian elimination with complete pivoting is modified by replacing dangerous cancellations by exactly predicted exact zeros. All entries of L, D, U are computed to high relative accuracy, and $\kappa(L)$, $\kappa(U)$ are at most $O(mn)$ and $O(n^2)$, respectively.

7. [Dem99] In some cases, new classes of matrices and accurate SVD computation are derived from relations with previously solved problems or by suitable matrix representations. The following cases are analyzed and solved with $O(n^3)$ complexity:

   (a) *Cauchy matrices:* $C = C(x, y)$, $c_{ij} = 1/(x_i - y_j)$, and the parameters x_is, y_is are the initial data (cf. Section 22.5). The algorithm extends to Cauchy-like matrices $C' = D_1 C D_2$, where C is a Cauchy matrix and D_1, D_2 are diagonal scalings. The required LDU factorization is computed with $\frac{4}{3}n^3$ operations and given as input to Algorithm 4. It should be noted that this does not imply that Cauchy matrices determine their singular values perfectly well. The statement is: For a Cauchy matrix C, given by a set of parameters x_i's, y_i's stored as floating point numbers in computer memory, all singular values of C can be computed in a forward stable way. Thus, for example, singular values of a notoriously ill-conditioned Hilbert matrix can be computed to high relative accuracy.

   (b) *Vandermonde matrices:* $V = [v_{ij}]$, $v_{ij} = x_i^{j-1}$ (cf. Section 22.4). An accurate algorithm exploits the fact that postmultiplication of V by the discrete Fourier transform matrix gives a Cauchy-like matrix. The finite precision arithmetic requires a guard digit and extra precision to tabulate certain constants.

   (c) *Unit displacement rank matrix X:* Solution of matrix equation $AX + XB = d_1 d_2^T$, where A, B are diagonal, or normal matrices with known accurate spectral decompositions. The class of unit displacement rank matrices generalizes the Cauchy-like matrices (A and B diagonal) and Vandermonde matrices (A diagonal and B circular shift).

8. [K02], [DK04] Weakly diagonally dominant M-matrices given with $a_{ij} \leq 0$ for $i \neq j$ and with the row-sums $s_i = \sum_{j=1}^{n} a_{ij} \geq 0$, $i = 1, \ldots, n$ known with small relative errors, allow accurate LDU factorization with complete pivoting.

9. [Koe05], [Koe07] Totally nonnegative (TN) matrix A can be expressed as the product of nonnegative bidiagonal matrices. If A is given implicitly by this bidiagonal representation, then all its singular values (and eigenvalues, too) can be computed from the bidiagonals to high relative accuracy. Accurate bidiagonal representation for given TN matrix A is possible for totally positive cases (all minors positive), provided certain pivotal minors can be computed accurately.

10. [KD07] Eigenvalues of certain sign regular matrices (for each k, all k-th order nonzero minors of sign $(-1)^{k(k-1)/2}$) can be computed from accurately computed singular

values, provided the matrices are given implicitly, in a factored form as a product of bidiagonals and the reverse identity. The bidiagonal representation is transformed without subtractions to a bidiagonal matrix whose singular values $\sigma_1 \geq \cdots \geq \sigma_n$ are the moduli of the wanted eigenvalues $\lambda_i = (-1)^{i-1}\sigma_i$.

11. [K02], [DK06a] The singular values of the matrix V with entries $v_{ij} = P_i(x_j)$, where the P_i's are orthonormal polynomials and the x_j's are the nodes, can be computed to high relative accuracy.
12. [Ye08], [DK11] If real diagonally dominant matrix $A = [a_{ij}]$ with $a_{ii} \geq 0$, $i = 1, \ldots, n$, is given in the representation by the diagonally dominant parts (A_D, v), then the LDU factorization with complete diagonal pivoting provides an accurate RRD, and Algorithm 4 computes the SVD to high relative accuracy.
13. [HB11] Con–eigenvalues and con–eigenvectors of Hermitian positive definite Cauchy matrix $C = [c_{ij}] \in \mathbb{C}^{n\times n}$ ($Cv = \lambda\overline{v}$, where $v \neq \mathbf{0}$ and $\overline{v}$ denotes complex conjugation) can be computed from the eigenvalues and eigenvectors of $\overline{C}C$, where $\overline{C} = [\overline{c}_{ij}]$. If C has a RRD $C = XD^2X^*$ (Fact 7), then the problem reduces to accurate SVD of $A = DX^TXD$ using a preconditioned Jacobi SVD algorithm. This high accuracy con–eigenvalue (eigenvector) computation enables optimal rational approximation of given rational function with n poles in the unit disc.
14. [Drm00a] Accurate SVD of the RRD XDY^T extends to the triple product XSY^T, where S is not necessarily diagonal, but it can be accurately factored by Gaussian eliminations with pivoting.

Examples:

1. An illustration of the power of the algorithms described in this section is the example of a 100×100 Hilbert matrix described in [Dem99]. Its singular values range over 150 orders of magnitude and are computed using the package Mathematica with 200-decimal digit software floating point arithmetic. The computed singular values are rounded to 16 digits and used as reference values. The singular values computed in IEEE double precision floating point ($\boldsymbol{\epsilon} \approx 10^{-16}$) by the algorithms described in this section agree with the reference values with relative error less than $34 \cdot \boldsymbol{\epsilon}$.
2. In [HB11], using double precision IEEE floating point computation with 500 random Cauchy matrices $C_{ij} = \alpha_i\overline{\alpha_j}/(1-\gamma_i\overline{\gamma}_j)$ of order $n = 120$, the maximal relative error in all con–eigenvalues and all con–eigenvectors was below $5.4 \cdot 10^{-12}$. The reference values are obtained using Mathematica with 300-decimal digit eigenvalue solver.
3. [DGE99] Examples of sign patterns of TSC matrices:

$$\begin{bmatrix} + & + & 0 & 0 & 0 \\ + & - & + & 0 & 0 \\ 0 & + & + & + & 0 \\ 0 & 0 & + & - & + \\ 0 & 0 & 0 & + & + \end{bmatrix}, \quad \begin{bmatrix} + & + & + & + & + \\ + & - & 0 & 0 & 0 \\ + & 0 & - & 0 & 0 \\ + & 0 & 0 & - & 0 \\ + & 0 & 0 & 0 & - \end{bmatrix}.$$

TSC matrices must be sparse because an $m \times n$ TSC matrix can have at most $\frac{3}{2}(m+n) - 2$ nonzero entries.

59.4 Positive Definite Matrices

Definitions:

The **Cholesky factorization with pivoting** of symmetric positive definite $n \times n$ matrix H computes the Cholesky factorization $P^THP = LL^T$, where the permutation matrix P is such that $\ell_{ii}^2 \geq \sum_{k=i}^{j} \ell_{jk}^2$, $1 \leq i \leq j \leq n$.

The **component-wise relative distance** between H and its component-wise relative perturbation $\tilde{H}$ is $\mathrm{reldist}(H,\tilde{H}) = \max_{i,j} \frac{|h_{ij} - \tilde{h}_{ij}|}{|h_{ij}|}$, where $0/0 = 0$.

A **diagonally scaled representation** of symmetric matrix H with positive diagonal entries is a factored representation $H = DAD$ with $D = \mathrm{diag}(\sqrt{h_{11}}, \ldots, \sqrt{h_{nn}})$, $a_{ij} = \frac{h_{ij}}{\sqrt{h_{ii}h_{jj}}}$.

Facts:

1. [Dem89], [Dem92] Let $H = DAD$ be a diagonally scaled representation of positive definite H, and let $\lambda_{\min}(A)$ denote the minimal eigenvalue of A.
   (a) If δH is a symmetric perturbation such that $H + \delta H$ is not positive definite, then
   $$\max_{1\le i,j\le n} \frac{|\delta h_{ij}|}{\sqrt{h_{ii}h_{jj}}} \ge \frac{\lambda_{\min}(A)}{n} = \frac{1}{n\|A^{-1}\|_2}.$$
   (b) If $\delta H = -\lambda_{\min}(A)D^2$, then $\max_{i,j} \frac{|\delta h_{ij}|}{\sqrt{h_{ii}h_{jj}}} = \lambda_{\min}(A)$, $\mathrm{reldist}(H, H+\delta H) = \lambda_{\min}(A)$, and $H + \delta H$ is singular.
2. [Dem89] Let $H = DAD$ be an $n \times n$ symmetric matrix with positive diagonal entries, stored in the machine memory. Let H be the input matrix in the Cholesky factorization algorithm. Then the following holds:
   (a) If the Cholesky algorithm successfully completes all operations and computes lower triangular matrix $\tilde{L}$, then there exists symmetric backward perturbation δH such that $\tilde{L}\tilde{L}^T = H + \delta H$ and $|\delta h_{ij}| \le \eta_C \sqrt{h_{ii}h_{jj}}$, $\eta_C \le O(n\boldsymbol{\epsilon})$.
   (b) If $\lambda_{\min}(A) > n\eta_C$, then the Cholesky algorithm will succeed and compute $\tilde{L}$.
   (c) If $\lambda_{\min}(A) < \boldsymbol{\epsilon}$, then there exists simulation of rounding errors in which the Cholesky algorithm fails to complete all operations.
   (d) If $\lambda_{\min}(A) \le -n\eta_C$, then it is certain that the Cholesky algorithm will fail.
3. [DV92] If $H = DAD \in \mathrm{PD}_n$ is perturbed to a positive definite $\tilde{H} = H + \delta H$, then
   (a) $\max_{1\le i\le n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \le \|L^{-1}\delta H L^{-T}\|_2 \le \frac{\|D^{-1}\delta H D^{-1}\|_2}{\lambda_{\min}(A)} = \|A^{-1}\|_2 \|D^{-1}\delta H D^{-1}\|_2.$
   (b) Let $\delta H = \eta D^2$, with any $\eta \in (0, \lambda_{\min}(A))$. Then for some index i it holds that
   $$\frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \ge \sqrt[n]{1 + \frac{\eta}{\lambda_{\min}(A)}}.$$
4. [DV92], [VS93] Let $H = DAD$ be positive definite and $c > 0$ constant such that for all $\varepsilon \in (0, 1/c)$ and for all symmetric component-wise relative perturbations δH with $|\delta h_{ij}| \le \varepsilon |h_{ij}|$, $1 \le i,j \le n$, the ordered eigenvalues λ_i and $\tilde{\lambda}_i$ of H and $H + \delta H$ satisfy $\max_{1\le i\le n} \frac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \le c\,\varepsilon$. Then $\|A^{-1}\|_2 < (1 + c)/2$. The same holds for more general perturbations, e.g., δH with $|\delta h_{ij}| \le \varepsilon\sqrt{h_{ii}h_{jj}}$.
5. [vdS69] It holds that $\|A^{-1}\|_2 \le \kappa_2(A) \le n \min_{D=\mathrm{diag}} \kappa_2(DHD) \le n\kappa_2(H)$.
6. For a general dense positive definite $H = DAD$ stored in the machine memory, eigenvalue computation with high relative accuracy is numerically feasible if and only if $\lambda_{\min}(A)$ is not smaller than the machine round-off unit. It is possible that matrix H is theoretically positive definite and that errors in computing its entries as functions of some parameters cause the stored matrix to be indefinite. Failure of the Cholesky algorithm is a warning that the matrix is entry-wise close to a symmetric matrix that is not positive definite.

7. [VH89] If $P^THP = LL^T$ is the Cholesky factorization with pivoting of positive definite H, then the SVD $L = U\Sigma V^T$ of L is computed very efficiently by the one-sided Jacobi SVD algorithm, and H is diagonalized as $H = (PU)\Sigma^2(PU)^T$.

```
Algorithm 5: Positive definite Jacobi EVD
(λ, U) = EIG₊(H)
    Input: $H \in \mathrm{PD}_n$ ;
1:  $P^THP = LL^T$ ; % Cholesky factorization with pivoting.
2:  if $L$ computed successfully, then
3:      $(U, \Sigma) = \mathrm{SVD0}(L)$ % One-sided Jacobi SVD on L. V is not computed.
4:      $\lambda_i = \Sigma_{ii}^2$ , $U_{1:n,i} = PU_{1:n,i}$, $i = 1, \ldots, n$ ;
5:      Output: $\lambda = (\lambda_1, \ldots, \lambda_n)$ ; $U$
6:  else
7:      Error: $H$ is not numerically positive definite
8:  end if
```

8. [DV92], [Mat96], [Drm98b]. Let $\tilde{\lambda}_1 \geq \cdots \geq \tilde{\lambda}_n$ be the approximations of the eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$ of $H = DAD$, computed by Algorithm 5. Then
   (a) The computed approximate eigenvalues of H are the exact eigenvalues of a nearby symmetric positive definite matrix $H + \delta H$, where $\max\limits_{1\leq i,j\leq n} \dfrac{|\delta h_{ij}|}{\sqrt{h_{ii}h_{jj}}} \leq \varepsilon$, and ε is bounded by $O(n)$ times the round-off unit $\boldsymbol{\epsilon}$.

   (b) $\max\limits_{1\leq i\leq n} \dfrac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq n\varepsilon\|A^{-1}\|_2$. The dominant part in the forward relative error is committed during the Cholesky factorization. The one-sided Jacobi SVD contributes to this error with, at most, $O(n)\boldsymbol{\epsilon}\sqrt{\|A^{-1}\|_2} + O(n^2)\boldsymbol{\epsilon}$.

9. Numerical properties of Algorithm 5, given in Fact 8, are better appreciated if compared with algorithms that first reduce H to tridiagonal matrix T and then diagonalize T. For such triadiagonalization-based procedures, the following hold:
   (a) The computed approximate eigenvalues of H are the exact eigenvalues of a nearby symmetric matrix $H + \delta H$, where $\|\delta H\|_2 \leq \varepsilon\|H\|_2$ and ε is bounded by a low degree polynomial in n times the round-off unit $\boldsymbol{\epsilon}$.

   (b) The computed eigenvalue approximations $\tilde{\lambda}_i \approx \lambda_i$ satisfy the *absolute error* bound $|\lambda_i - \tilde{\lambda}_i| \leq \varepsilon\|H\|_2$, that is, $\max\limits_{1\leq i\leq n} \dfrac{|\lambda_i - \tilde{\lambda}_i|}{\lambda_i} \leq \varepsilon\kappa_2(H)$.

10. [Arg75], [Vav96], [DGE99], [BHV08] In some applications it might be possible to work with a positive definite matrix implicitly as $H = C^TC$, where only a full column rank C is explicitly formed. Then the spectral computation with H is replaced with the SVD of C. The Cholesky factor L of H is computed implicitly from the QR factorization of C. This implicit formulation has many numerical advantages and it should be the preferred way of computation with positive definite matrices. An example is natural factor formulation of stiffness matrices in finite element computations, where, e.g., *(i)* $H = BSB^T$ with $B = [b_{ij}]$, $b_{ij} \in \{0, 1\}$, and block diagonal S carrying the element stiffness matrices; *(ii)* $H = A^TJ^TDJA$, where $A = [a_{ij}]$ with $a_{ij} \in \{-1, 0, 1\}$ encodes combinatorial connectivity of the finite element mesh, J is block diagonal, and D is diagonal.

TABLE 59.1

	$\texttt{eig}(H)$	$\texttt{eig}(P^T HP)$, $P \simeq (2,1,3)$	$\texttt{eig}(\texttt{inv}(\texttt{inv}(H)))$

$\tilde{\lambda}_3$	−3.966787845610502e + 023	9.818181818181818e − 001	9.818181818181817e − 001
	$\texttt{eig}(H + \Delta H)$	$\texttt{eig}(P^T HP)$, $P \simeq (3,2,1)$	$\texttt{eig}(H + \delta H)$
$\tilde{\lambda}_1$	1.000000000000000e + 040	1.000000000000000e + 040	1.000000000000000e + 040
$\tilde{\lambda}_2$	−8.100009764062724e + 019	9.900000000000000e + 019	1.208844819952007e + 024
$\tilde{\lambda}_3$	−3.966787845610502e + 023	9.818181818181819e − 001	9.899993299416013e − 001

11. [Drm98a], [Drm98b] Generalized eigenvalues of $HM - \lambda I$ and $H - \lambda M$ can be computed to high relative accuracy if $H = D_H A_H D_H$, $M = D_M A_M D_M$ with diagonal D_H, D_M and moderate $\|A_H^{-1}\|_2$, $\|A_M^{-1}\|_2$.

Examples:

1. In this numerical experiment we use MATLAB 6.5, Release 13 (on a Pentium 4 machine under MS Windows$^{\text{R}}$ 2000), and the function $\texttt{eig}(\cdot)$ for eigenvalue computation. Let

$$H = \begin{bmatrix} 10^{40} & 10^{29} & 10^{19} \\ 10^{29} & 10^{20} & 10^{9} \\ 10^{19} & 10^{9} & 1 \end{bmatrix}.$$

   The sensitivity of the eigenvalues of H and the accuracy of numerical algorithms can be illustrated by applications of the algorithms to various functions and perturbations of H. Let $P^T HP$ be obtained from H by permutation similarity with permutation matrix P. Let $H + \Delta H$ be obtained from H by changing H_{22} into $-H_{22} = -10^{20}$, and let $H + \delta H$ be obtained from H by multiplying H_{13} and H_{31} by $1 + \epsilon$, where $\epsilon \approx 2.22 \cdot 10^{-16}$ is the round-off unit in MATLAB. For the sake of experiment, the eigenvalues of numerically computed $(H^{-1})^{-1}$ are also examined. The values returned by `eig()` are shown in Table 59.1. All six approximations of the spectrum of H are with small absolute error, $\max\limits_{1 \le i \le 3} \dfrac{|\lambda_i - \tilde{\lambda}_i|}{\|H\|_2} \le O(\epsilon)$. Some results might be different if a different version of MATLAB, operating system, or hardware is used.
2. Let H be the matrix from Example 1. H is positive definite, $\kappa_2(H) > 10^{40}$, and its $H = DAD$ representation with $D = \text{diag}(10^{20}, 10^{10}, 1)$ gives $\kappa_2(A) < 1.4$, $\|A^{-1}\|_2 < 1.2$. The Cholesky factor L of H is successfully computed in MATLAB by the $\texttt{chol}(\cdot)$ function. The matrix $L^T L$, which is implicitly diagonalized in Algorithm 5, reads

$$\hat{H} = L^T L = \begin{bmatrix} 1.000000000e+40 & 9.949874371e+18 & 9.908673886e-02 \\ 9.949874371e+18 & 9.900000000e+19 & 8.962732759e-02 \\ 9.908673886e-02 & 8.962732759e-02 & 9.818181818e-01 \end{bmatrix}.$$

   The diagonal of $\hat{H}$ approximates the eigenvalues of H with all shown digits correct. To see that, write $\hat{H}$ as $\hat{H} = \hat{D}\hat{A}\hat{D}$, where $\hat{D} = \text{diag}(\sqrt{\hat{H}_{11}}, \sqrt{\hat{H}_{22}}, \sqrt{\hat{H}_{33}})$ and

$$\hat{A} = \begin{bmatrix} 1.000000000e+00 & 1.000000000e-11 & 1.000000000e-21 \\ 1.000000000e-11 & 1.000000000e+00 & 9.090909091e-12 \\ 1.000000000e-21 & 9.090909091e-12 & 1.000000000e+00 \end{bmatrix}$$

with $\|\hat{A} - I_3\| < 1.4 \cdot 10^{-11}$, $\|\hat{A}^{-1}\|_2 \approx 1$. Algorithm 5 computes the eigenvalues of H, as $\lambda_1 \approx 1.0e + 40, \lambda_2 \approx 9.900000000000002e + 19, \lambda_3 \approx 9.818181818181817\mathrm{e} - 01$.

3. Smallest eigenvalues can be irreparably damaged simply by computing and storing matrix entries. This rather convincing example is discussed in [DGE99]. The stiffness matrix of a mass spring system with 3 masses,

$$K = \begin{bmatrix} k_1 + k_2 & -k_2 & 0 \\ -k_2 & k_2 + k_3 & -k_3 \\ 0 & -k_3 & k_3 \end{bmatrix}, \quad k_1,\ k_2,\ k_3 \text{ spring constants,}$$

is computed with $k_1 = k_3 = 1$ and $k_2 = \boldsymbol{\epsilon}/2$, where $\boldsymbol{\epsilon}$ is the round-off unit. Then the true and the computed assembled matrix are, respectively,

$$K = \begin{bmatrix} 1 + \boldsymbol{\epsilon}/2 & -\boldsymbol{\epsilon}/2 & 0 \\ -\boldsymbol{\epsilon}/2 & 1 + \boldsymbol{\epsilon}/2 & -1 \\ 0 & -1 & 1 \end{bmatrix}, \quad \tilde{K} = \begin{bmatrix} 1 & -\boldsymbol{\epsilon}/2 & 0 \\ -\boldsymbol{\epsilon}/2 & 1 & -1 \\ 0 & -1 & 1 \end{bmatrix}.$$

$\tilde{K}$ is the component-wise relative perturbation of K with $\mathrm{reldist}(K, \tilde{K}) = \boldsymbol{\epsilon}/(2+\boldsymbol{\epsilon}) < \boldsymbol{\epsilon}/2$. K is positive definite with minimal eigenvalue near $\boldsymbol{\epsilon}/4$, $\tilde{K}$ is indefinite with minimal eigenvalue near $-\boldsymbol{\epsilon}^2/8$. MATLAB'S function `chol`$(\cdot)$ fails to compute the Cholesky factorization of $\tilde{K}$ and reports that the matrix is not positive definite.

On the other hand, writing $K = A^T A$ with

$$A = \begin{bmatrix} \sqrt{k_1} & 0 & 0 \\ -\sqrt{k_2} & \sqrt{k_2} & 0 \\ 0 & -\sqrt{k_3} & \sqrt{k_3} \end{bmatrix} = \begin{bmatrix} \sqrt{k_1} & 0 & 0 \\ 0 & \sqrt{k_2} & 0 \\ 0 & 0 & \sqrt{k_3} \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ -1 & 1 & 0 \\ 0 & -1 & 1 \end{bmatrix}$$

clearly separates physical parameters and the geometry of the connections. Since A is bidiagonal, for any choice of k_1, k_2, k_3, the eigenvalues of K can be computed as squared singular values of A to nearly the same number of accurate digits to which the spring constants are given.

59.5 Accurate Eigenvalues of Symmetric Indefinite Matrices

Relevant relative perturbation theory for floating point computation with symmetric indefinite matrices is presented in [BD90], [DV92], [VS93], [DMM00], and [Ves00]. Full review of perturbation theory is given in Chapter 21.

Definitions:

Bunch–Parlett factorization of symmetric H is the factorization $P^T H P = LBL^T$, where P is a permutation matrix, B is a block-diagonal matrix with diagonal blocks of size 1×1 or 2×2, and L is a full column rank unit lower triangular matrix, where the diagonal blocks in L that correspond to 2×2 blocks in B are 2×2 identity matrices.

A **symmetric rank revealing decomposition (SRRD)** of H is a decomposition $H = XDX^T$, where D is diagonal and X is a full column rank well-conditioned matrix.

Let $\mathcal{J}$ denote a nonsingular symmetric matrix. Matrix B is **$\mathcal{J}$-orthogonal** if $F^T \mathcal{J} F = \mathcal{J}$. (Warning: this is a nonstandard usage of F, since in this book F usually denotes a field, and nonstandard usage of $\mathcal{J}$, which usually denotes a tridiagonal Jacobi matrix.)

The **hyperbolic SVD** decomposition of the matrix pair $(G, \mathcal{J})$ is a decomposition of G, $G = W\Sigma F^{-1}$, where W is orthogonal, Σ is diagonal, and F is $\mathcal{J}$-orthogonal.

Facts:

1. If $H = U\Sigma V^T$ is the SVD of an $n \times n$ symmetric H, where $\Sigma = \oplus_{i=1}^{m} \sigma_{j_i} I_{n_i}$, then the matrix $V^T U$ is block-diagonal with m symmetric and orthogonal blocks of sizes $n_i \times n_i$, $i = 1, \ldots, m$ along its diagonal. The n_i eigenvalues of the ith block are from $\{-1, 1\}$ and they give the signs of n_i eigenvalues of H with absolute value σ_{j_i}.
2. If $H = G\mathcal{J}G^T$ is a factorization with full column rank $G \in \mathbb{R}^{n\times r}$ and $\mathcal{J} = \operatorname{diag}(\pm 1)$, then the eigenvalue problems $Hx = \lambda x$ and $(G^T G)y = \lambda \mathcal{J} y$ are equivalent. If F is the $\mathcal{J}$orthogonal eigenvector matrix of the pencil $G^T G - \lambda\mathcal{J}$ ($F^T \mathcal{J} F = \mathcal{J}$, $F^T(G^T G)F = \Sigma^2 = \operatorname{diag}(\sigma_1^2, \ldots, \sigma_r^2)$), then the matrix $\Sigma^2\mathcal{J} = \operatorname{diag}(\lambda_1, \ldots, \lambda_r)$ contains the nonzero eigenvalues of H with the columns of $(GF)\Sigma^{-1}$ as corresponding eigenvectors.
3. [Ves00] Let H have factorization $H = G\mathcal{J}G^T$ as in Fact 2. Suppose that H is perturbed implicitly by changing $G \rightsquigarrow G + \delta G$, thus $\tilde{H} = (G + \delta G)\mathcal{J}(G + \delta G)^T$. Write $G = BD$, where D is diagonal and B has unit columns in the Euclidean norm, and let $\delta B = \delta G D^{-1}$. Let $\theta \equiv \|\delta B B^\dagger\|_2 < 1$. Then $\tilde{H}$ has the same number of zero eigenvalues as H and $\displaystyle\max_{\lambda_i \neq 0} \frac{|\delta\lambda_i|}{|\lambda_i|} \leq 2\theta + \theta^2$.
4. [Sla98], [Sla02] The factorization $H = G\mathcal{J}G^T$ in Fact 2 is computed by a modification of Bunch–Parlett factorization. Let $\tilde{G}$ be the computed factor and let $\tilde{\mathcal{J}} = \operatorname{diag}(\pm 1)$ be the computed signature matrix. Then
   (a) A backward stability relation $H + \delta H = \tilde{G}\tilde{\mathcal{J}}\tilde{G}^T$ holds with the entry-wise bound $|\delta H| \leq O(n)\boldsymbol{\epsilon}(|H| + |\tilde{G}||\tilde{G}|^T)$.
   (b) Let $\tilde{G}$ have rank n. If $\tilde{\mathcal{J}} = \mathcal{J}$ and if $\hat{\lambda}_1 \geq \cdots \geq \hat{\lambda}_n$ are the exact eigenvalues of the pencil $\tilde{G}^T\tilde{G} - \lambda\mathcal{J}$, then, for all i, $\displaystyle|\lambda_i - \hat{\lambda}_i| \leq \frac{O(n^2)\boldsymbol{\epsilon}}{\sigma_{\min}^2(D^{-1}\tilde{G}\tilde{F})}|\lambda_i|$, where D denotes a diagonal matrix such that $D^{-1}\tilde{G}$ has unit rows in Euclidean norm, $\tilde{F}$ is the eigenvector matrix of $\tilde{G}^T\tilde{G} - \lambda\mathcal{J}$, and $\sigma_{\min}(\cdot)$ denotes the minimal singular value of a matrix.
5. [Ves93] The one-sided (implicit) $\mathcal{J}$-symmetric Jacobi algorithm essentially computes the hyperbolic SVD of $(G, \mathcal{J})$, $(W, \Sigma, F) = \operatorname{HSVD}(G, \mathcal{J})$. It follows the structure of the one-sided Jacobi SVD (Algorithm 2) with the following modifications:
   (a) On input, A is replaced with the pair $(G, \mathcal{J})$.
   (b) In step k, $G^{(k+1)} = G^{(k)}V^{(k)}$ is computed from $G^{(k)}$ using Jacobi plane rotations exactly as in Algorithm 2 if $\mathcal{J}_{ii}$ and $\mathcal{J}_{jj}$ are of the same sign. (Here, $i = i_k$, $j = j_k$ are the pivot indices in $G^{(k)}$.)
   (c) If $\mathcal{J}_{ii}$ and $\mathcal{J}_{jj}$ have opposite signs, then the Jacobi rotation is replaced with hyperbolic rotation
$$\begin{bmatrix} \cosh\zeta_k & \sinh\zeta_k \\ \sinh\zeta_k & \cosh\zeta_k \end{bmatrix}, \quad \tanh 2\zeta_k = -\frac{2\xi}{d_i + d_j},$$
   $\xi = (G^{(k)})_{1:n,i}^T (G^{(k)})_{1:n,j}$, $d_\ell = (G^{(k)})_{1:n,\ell}^T (G^{(k)})_{1:n,\ell}$, $\ell = i, j$. The tangent is determined as $\displaystyle\tanh\zeta_k = \frac{\operatorname{sign}(\tanh 2\zeta_k)}{|\tanh 2\zeta_k| + \sqrt{\tanh^2 2\zeta_k - 1}}$.
   (d) The limit of $G^{(k)}$ is $W\Sigma$, and the accumulated product $V^{(0)}V^{(1)}\cdots V^{(k)}\cdots$ converges to $\mathcal{J}$-orthogonal F, and $G = W\Sigma F^{-1}$ is the hyperbolic SVD of G.
   (e) The iterations are stopped at index k if $\displaystyle\max_{i\neq j} \frac{|(G^{(k)})_{1:n,i}^T (G^{(k)})_{1:n,j}|}{\|(G^{(k)})_{1:n,i}\|_2 \|(G^{(k)})_{1:n,j}\|_2} \leq \tau$. The tolerance τ is usually set to $n\boldsymbol{\epsilon}$.

6. [Ves93] The eigenvalue problem of a symmetric indefinite matrix can be implicitly solved as a hyperbolic SVD problem. Algorithm 6 uses the factorization $H = G\mathcal{J}G^T$ (Fact 2) and hyperbolic SVD HSVD$(G, \mathcal{J})$ (Fact 5) to compute the eigenvalues and eigenvectors of H.

Algorithm 6: Hyperbolic Jacobi

```
$(\lambda, U) = \mathrm{EIG0}(H)$
  Input: $H \in \mathcal{S}_n$
    $H = G\mathcal{J}G^T$, $\mathcal{J} = I_p \oplus (I_{n-p})$ ; % Bunch–Parlett factorization (modified).
    $(W, \Sigma, F) = \mathrm{HSVD}(G, \mathcal{J})$ % One-sided $\mathcal{J}$-symmetric Jacobi algorithm.
    $\lambda_i = \mathcal{J}_{ii} \cdot \Sigma_{ii}^2$ ; $U_{1:n,i} = W_{1:n,i}$, $i = 1, \ldots, n$ ;
  Output: $\lambda = (\lambda_1, \ldots, \lambda_n)$ ; $U$
```

7. [Sla02] Let $\tilde{G}^{(0)} = \tilde{G}$, $\tilde{G}^{(k)}$, $k = 1, 2, \ldots$ be the sequence of matrices computed by the one-sided $\mathcal{J}$-symmetric Jacobi algorithm in floating point arithmetic. Write each $\tilde{G}^{(k)}$ as $\tilde{G}^{(k)} = B^{(k)}D^{(k)}$, where $D^{(k)}$ is the diagonal matrix with Euclidean column norms of $\tilde{G}^{(k)}$ along its diagonal.
   (a) $\tilde{G}^{(k+1)}$ is the result of an exactly $\mathcal{J}$-orthogonal plane transformation of $\tilde{G}^{(k)} + \delta\tilde{G}^{(k)} = (B^{(k)} + \delta B^{(k)})D^{(k)}$, where $\|\delta B^{(k)}\|_F \leq c_k \boldsymbol{\epsilon}$ with moderate factor c_k.
   (b) Let $\tilde{\lambda}_1 \geq \cdots \geq \tilde{\lambda}_n$ be computed as $\mathcal{J}_{ii}(\tilde{G}^{(k)})_{1:n,i}^T(\tilde{G}^{(k)})_{1:n,i}$, $i = 1, \ldots, n$, where $\tilde{G}^{(k)}$ is the first matrix that satisfies stopping criterion. If k' is the index of last applied rotation, then $\max\limits_{1 \leq i \leq n} \dfrac{|\hat{\lambda}_i - \tilde{\lambda}_i|}{|\hat{\lambda}_i|} \leq 2\eta + \eta^2$, with $\hat{\lambda}_i$ as in Fact 4, and $$\eta = O(\boldsymbol{\epsilon}) \sum_{j=0}^{k'} \|(B^{(j)})^\dagger\|_2 + O(n^2)\boldsymbol{\epsilon} + O(\boldsymbol{\epsilon}^2).$$

8. [DMM03] Accurate diagonalization of indefinite matrices can be derived from their accurate SVD decomposition. (See Fact 1.)

Algorithm 7: Signed SVD

```
$(\lambda, Q) = \mathrm{EIG1}(H)$
  Input: $H \in \mathcal{S}_n$
    $H = XDY^T$ ; % rank revealing decomposition.
    $(U, \Sigma, V) = \mathrm{SVD2}(X, D, Y)$ ; % accurate SVD.
    Recover the signs of the eigenvalues, $\lambda_i = \pm\sigma_i$, using the structure of $V^TU$;
    Recover the eigenvector matrix $Q$ using the structure of $V^TU$.
  Output: $\lambda = (\lambda_1, \ldots, \lambda_n)$ ; $Q$
```

Let $H \approx \tilde{U}\tilde{\Sigma}\tilde{V}^T$, $\tilde{\Sigma} = \mathrm{diag}(\tilde{\sigma}_1, \ldots, \tilde{\sigma}_n)$, be the SVD computed by Algorithm 7.
   (a) If all computed singular values $\tilde{\sigma}_i$, $i = 1, \ldots, n$, are well separated, Algorithm 7 chooses $\tilde{\lambda}_i = \tilde{\sigma}_i \mathrm{sign}(\tilde{V}_{1:n,i}^T \tilde{U}_{1:n,i})$, with the eigenvector $\tilde{Q}_{1:n,i} = \tilde{V}_{1:n,i}$.
   (b) If singular values are clustered, then clusters are determined by perturbation theory and the signs are determined inside each individual cluster.

9. [DMM03] If the rank revealing factorization in Step 1 of Algorithm 7 is computed as $H \approx \tilde{X}\tilde{D}\tilde{Y}^T$ with $\|\tilde{X} - X\| \leq \xi$, $\|\tilde{Y} - Y\| \leq \xi$, $\max_{i=1:n} |d_{ii} - \tilde{d}_{ii}|/|d_{ii}| \leq \xi$, then the computed eigenvalues $\tilde{\lambda}_i$ satisfy $|\lambda_i - \tilde{\lambda}_i| \leq \xi' \kappa(L) \max\{\kappa(X), \kappa(Y)\}|\lambda_i|$, $i = 1, \ldots, n$. Here, ξ and ξ' are bounded by the round-off $\boldsymbol{\epsilon}$ times moderate functions of the dimensions, and it is assumed that the traces of the diagonal blocks of $V^T U$ (cf. Fact 1) are computed correctly.
10. [DK06b] An accurate symmetric rank revealing decomposition $H = XDX^T$ can be given as input to Algorithm 7 or it can replace Step 1 in Algorithm 6 by defining $G = X\sqrt{|D|}$, $\mathcal{J} = \operatorname{diag}(\operatorname{sign}(d_{11}), \ldots, \operatorname{sign}(d_{nn}))$. Once an accurate SRRD is available, the eigenvalues are computed to high relative accuracy. For the following structured matrices, specially tailored algorithms compute accurate SRRDs:

    (a) Symmetric scaled Cauchy matrices, $H = DCD$, D diagonal, C Cauchy matrix.

    (b) Symmetric Vandermonde matrices, $V = (\nu^{(i-1)(j-1)})_{i,j=1}^n$, where $\nu \in \mathbb{R}$.

    (c) Symmetric totally nonnegative matrices.

11. [DKM09] Given a symmetric rank revealing decomposition $H = XDX^T \equiv G\mathcal{J}G^T$ (Fact 10) of nonsingular H, with diagonal D and square well-conditioned X, one can use an implicit Jacobi algorithm, as in Section 59.1 (Fact 6), and similarly as in Fact 5. The classical symmetric Jacobi algorithm (Section 55.7) generates the sequence $H^{(k+1)} = (V^{(k)})^T H^{(k)} V^{(k)}$ with $H^{(0)} = H$. If $H^{(k)} = G^{(k)}\mathcal{J}(G^{(k)})^T$, then $H^{(k+1)} = G^{(k+1)}\mathcal{J}(G^{(k+1)})^T$ with $G^{(k+1)} = (V^{(k)})^T G^{(k)}$. At each step, only the 2×2 pivot submatrix of $H^{(k)}$ is computed and the advance to $H^{(k+1)}$ is implicit by computing $G^{(k+1)}$. The iterations are stopped if (implicitly) $\max\limits_{i \neq j} \dfrac{H_{ij}^{(k)}}{\sqrt{|H_{ii}^{(k)} H_{jj}^{(k)}|}} \leq \boldsymbol{\epsilon} \max\{n, \hat{\kappa}_2(X)\}$ and $\max_i \frac{\|G_{i,1:n}^{(k)}\|_2^2}{|H_{ii}^{(k)}|} \leq 2\hat{\kappa}_2(X)$. Here $\boldsymbol{\epsilon}$ is the round-off and $\hat{\kappa}_2(X)$ is an estimate of the condition number $\kappa_2(X) = \|X\|_2 \|X^{-1}\|_2$, which is assumed moderate (much smaller than $1/\boldsymbol{\epsilon}$). The diagonal entries of the last iterate approximate the corresponding eigenvalues to a relative error of order $O(\boldsymbol{\epsilon}\kappa_2(X))$. The algorithm and the provable accuracy easily generalize to rectangular full column rank X.
12. [PM06] For any real symmetric matrix which is, in addition, DSTU or TSC, all eigenvalues and eigenvectors can be computed to high relative accuracy. An SRRD of such a matrix is obtained via an accurate pivoted block LDU (i.e., Bunch–Parlett) factorization. To guarantee high relative accuracy, the worst case scenario has $O(n^4)$ complexity for $n \times n$ matrices.

Examples:

1. [Ves96] Initial factorization or rank revealing decomposition is the key for success or failure of the algorithms presented in this section. Let $\varepsilon = 10^{-7}$ and

$$H = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 0 & 0 \\ 1 & 0 & \varepsilon \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 1 & \sqrt{\varepsilon} \end{bmatrix} \begin{bmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 1 \\ 0 & 0 & \sqrt{\varepsilon} \end{bmatrix}.$$

This factorization implies that all eigenvalues of H are determined to high relative accuracy. Whether or not they will be determined to that accuracy by Algorithm 6 (or any other algorithm depending on initial factorization) depends on the factorization. In Algorithm 6, the factorization in Step 1 chooses to start with 1 × 1 pivot, which after the first step gives

$$\begin{bmatrix} 1 & 0 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & -1 & -1 \\ 0 & -1 & -1+\varepsilon \end{bmatrix} \begin{bmatrix} 1 & 1 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

The 2×2 Schur complement is ill-conditioned (entry-wise ε close to singularity, the condition number behaving as $1/\varepsilon$) and the smallest eigenvalue is lost.

This chapter considers the nonlinear eigenvalue problem to find a parameter λ such that the linear system

$$T(\lambda)\mathbf{x} = 0 \tag{60.1}$$

has a nontrivial solution $\mathbf{x}$, where $T(\cdot) : D \to \mathbb{C}^{n\times n}$ is a family of matrices depending on a complex parameter $\lambda \in D$.

It generalizes the linear eigenvalue problem $A\mathbf{x} = \lambda\mathbf{x}$, $A \in \mathbb{C}^{n\times n}$, where $T(\lambda) = \lambda I - A$, and the generalized linear eigenvalue problem where $T(\lambda) = \lambda B - A$, $A, B \in \mathbb{C}^{n\times n}$.

Nonlinear eigenvalue problems $T(\lambda)\mathbf{x} = 0$ arise in a variety of applications in science and engineering, such as the dynamic analysis of structures, vibrations of fluid–solid structures, the electronic behavior of quantum dots, and delay eigenvalue problems, to name just a few. Due to its wide range of applications, the quadratic eigenvalue problem $T(\lambda)\mathbf{x} = \lambda^2 M\mathbf{x} + \lambda C\mathbf{x} + K\mathbf{x} = 0$ is of particular interest, but also polynomial, rational, and more general eigenvalue problems appear. A standard approach for investigating or numerically solving polynomial eigenvalue problems is linearization where the original problem is transformed into a generalized linear eigenvalue problem with the same spectrum. Details on linearization and structure preservation are discussed in Chapter 18.

This chapter is concerned with the general nonlinear eigenvalue problem, which in general cannot be linearized. Unlike for linear and polynomial eigenvalue problems, there may exist infinitely many eigenvalues. In practice, however, one is usually interested only in a few eigenvalues close to a target value or a line in the complex plane.

If T is linear, then $T(\lambda) = T(0)+\lambda T'(0)$ has the form of a generalized eigenvalue problem, and in the general case linerization gives the approximation $T(\lambda) = T(0) + \lambda T'(0) + O(\lambda^2)$, which is again a generalized linear eigenvalue problem. Hence, it is not surprising that the (elementwise) derivative $T'(\lambda)$ of $T(\lambda)$ plays an important role in the analysis of nonlinear eigenvalue problems.

We tacitly assume in the whole chapter that whenever a derivative $T'(\hat\lambda)$ appears, T is analytic in a neighborhood of $\hat\lambda$ or in the real case $T : D \to \mathbb{R}^{n\times n}$, $D \subset \mathbb{R}$ that T is differentiable in a neighborhood of $\hat\lambda$. $\|\cdot\|$ always denotes the Euclidean and spectral norm, respectively, and we use the notation $[\mathbf{x}; \mathbf{y}] := [\mathbf{x}^T, \mathbf{y}^T]^T$ for column vectors.

60.1 Basic Properties

This section presents basic properties of the nonlinear eigenvalue problem (60.1)

Definitions:

As for a linear eigenvalue problem, $\hat{\lambda} \in D$ is called an **eigenvalue** of $T(\cdot)$ if $T(\hat{\lambda})\mathbf{x} = 0$ has a nontrivial solution $\hat{\mathbf{x}} \neq 0$. Then $\hat{\mathbf{x}}$ is called a corresponding **eigenvector** or **right eigenvector**, and $(\hat{\lambda}, \hat{\mathbf{x}})$ is called **eigenpair** of $T(\cdot)$.

Any nontrivial solution $\hat{\mathbf{y}} \neq 0$ of the adjoint equation $T(\hat{\lambda})^*\mathbf{y} = 0$ is called **left eigenvector** of $T(\cdot)$ and the vector-scalar-vector triplet $(\hat{\mathbf{y}}, \hat{\lambda}, \hat{\mathbf{x}})$ is called **eigentriplet** of $T(\cdot)$.

The eigenvalue problem (60.1) is **regular** if $\det T(\lambda) \not\equiv 0$, and otherwise it is called **singular**.

The **spectrum** $\sigma(T(\cdot))$ of $T(\cdot)$ is the set of all eigenvalues of $T(\cdot)$.

An eigenvalue $\hat{\lambda}$ of $T(\cdot)$ has **algebraic multiplicity** k if $\frac{d^\ell}{d\lambda^\ell} \det(T(\lambda))\Big|_{\lambda=\hat{\lambda}} = 0$ for $\ell = 0, \dots, k-1$ and $\frac{d^k}{d\lambda^k} \det(T(\lambda))\Big|_{\lambda=\hat{\lambda}} \neq 0$.

An eigenvalue $\hat{\lambda}$ is **simple** if its algebraic multiplicity is one.

The **geometric multiplicity** of an eigenvalue $\hat{\lambda}$ is the dimension of the kernel $\ker(T(\hat{\lambda}))$ of $T(\hat{\lambda})$.

An eigenvalue $\hat{\lambda}$ is called **semisimple** if its algebraic and geometric mutiplicity coincide.

$T(\cdot) : J \to \mathbb{R}^{n\times n}$ is **real symmetric** if $T(\lambda) = T(\lambda)^T$ for every $\lambda \in J \subset \mathbb{R}$.

$T(\cdot) : D \to \mathbb{C}^{n\times n}$ is **complex symmetric** if $T(\lambda) = T(\lambda)^T$ for every $\lambda \in D$.

$T(\cdot) : D \to \mathbb{C}^{n\times n}$ is **Hermitian** if D is symmetric with respect to the real line and $T(\lambda)^* = T(\bar{\lambda})$ for every $\lambda \in D$.

Facts:

1. For $A \in \mathbb{C}^{n\times n}$ and $T(\lambda) = \lambda I - A$, the terms eigenvalue, (left and right) eigenvector, eigenpair, eigentriplet, spectrum, algebraic and geometric multiplicity, and semisimple have their standard meaning.
2. For linear eigenvalue problems,
   (a) eigenvectors corresponding to distinct eigenvalues are linearly independent, which is not the case for nonlinear eigenvalue problems (cf. Example 1).
   (b) for a Hermitian problem, left and right eigenvectors corresponding to distinct eigenvalues are orthogonal, which does not hold for nonlinear eigenproblems (cf. Example 2).
   (c) the algebraic multiplicities of eigenvalues sum up to the dimension of the problem, whereas for nonlinear problems there may exist an infinite number of eigenvalues (cf. Example 2) and an eigenvalue may have any algebraic multiplicity (cf. Example 3).
3. [Sch08] If $\hat{\lambda}$ is an algebraically simple eigenvalue of $T(\cdot)$, then $\hat{\lambda}$ is geometrically simple.
4. [Neu85, Sch08] Let $(\hat{\mathbf{y}}, \hat{\lambda}, \hat{\mathbf{x}})$ be an eigentriplet of $T(\cdot)$. Then $\hat{\lambda}$ is algebraically simple if and only if $\hat{\lambda}$ is geometrically simple and $\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$.
5. [Sch08] Let $D \subset \mathbb{C}$ and $E \subset \mathbb{C}^d$ be open sets. Let $T : D \times E \to \mathbb{C}^{n\times n}$ be continuously differentiable, and let $\hat{\lambda}$ be a simple eigenvalue of $T(\cdot, 0)$ and $\hat{\mathbf{x}}$ and $\hat{\mathbf{y}}$ right and left eigenvectors with unit norm. Then the first order perturbation expansion at $\hat{\lambda}$ reads as follows:

$$\lambda(\varepsilon) - \hat{\lambda} = \frac{1}{\hat{\mathbf{y}}^*T'(\hat{\lambda}, 0)\hat{\mathbf{x}}} \sum_{j=1}^{d} \varepsilon_j \hat{\mathbf{y}}^* \frac{\partial T}{\partial \varepsilon_j}(\hat{\lambda}, 0)\hat{\mathbf{x}} + o(\|\varepsilon\|).$$

The normwise condition number for $\hat{\lambda}$ is given by

$$\kappa(\hat{\lambda}) = \limsup_{\|\varepsilon\|\to 0} \frac{|\lambda(\varepsilon) - \hat{\lambda}|}{\|\varepsilon\|} = \frac{1}{|\hat{\mathbf{y}}^* T'(\hat{\lambda}, 0)\hat{\mathbf{x}}|} \sqrt{\sum_{j=1}^{d} \left| \hat{\mathbf{y}}^* \frac{\partial T}{\partial \varepsilon_j}(\hat{\lambda}, 0)\hat{\mathbf{x}} \right|^2}.$$

6. [Sch08] Let $(\hat{\mathbf{y}}, \hat{\lambda}, \hat{\mathbf{x}})$ be an eigentriplet of $T(\cdot)$ with simple eigenvalue $\hat{\lambda}$. Then for sufficiently small $|\hat{\lambda} - \lambda|$

$$T(\lambda)^{-1} = \frac{1}{\lambda - \hat{\lambda}} \frac{\hat{\mathbf{x}}\hat{\mathbf{y}}^*}{\hat{\mathbf{y}}^* T'(\hat{\lambda})\hat{\mathbf{x}}} + O(1).$$

7. [Neu85] Let $\hat{\lambda}$ be a simple eigenvalue of $T(\cdot)$, and let $\hat{\mathbf{x}}$ be a right eigenvector normalized such that $\mathbf{e}^*\hat{\mathbf{x}} = 1$ for some vector $\mathbf{e}$. Then the matrix $B := T(\hat{\lambda}) + T'(\hat{\lambda})\hat{\mathbf{x}}\mathbf{e}^*$ is nonsingular.
8. If $T(\cdot)$ is real symmetric and λ is a real eigenvalue, then left and right eigenvectors corresponding to λ coincide.
9. If $T(\cdot)$ is complex symmetric and $\mathbf{x}$ is a right eigenvector, then $\bar{\mathbf{x}}$ is a left eigenvector corresponding to the same eigenvalue.
10. If $T(\cdot)$ is Hermitian, then eigenvalues are real (and left and right eigenvectors corresponding to λ coincide) or they come in pairs, i.e., if $(\mathbf{y}, \lambda, \mathbf{x})$ is an eigentriplet of $T(\cdot)$, then this is also true for $(\mathbf{x}, \bar{\lambda}, \mathbf{y})$.

Examples:

1. For the quadratic eigenvalue problem $T(\lambda)\mathbf{x} = 0$ with

$$T(\lambda) := \begin{bmatrix} 0 & 1 \\ -2 & 3 \end{bmatrix} + \lambda \begin{bmatrix} 7 & -5 \\ 10 & -8 \end{bmatrix} + \lambda^2 \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{60.2}$$

the distinct eigenvalues $\lambda = 1$ and $\lambda = 2$ share the eigenvector $[1; 2]$.

2. Let $T(\lambda)\mathbf{x} := \begin{bmatrix} e^{i\lambda^2} & 1 \\ 1 & 1 \end{bmatrix} \mathbf{x}$. Then $T(\lambda)\mathbf{x} = 0$ has a countable set of eigenvalues $\sqrt{2k\pi}$, $k \in \mathbb{N} \cup \{0\}$. $\hat{\lambda} = 0$ is an algebraically double and geometrically simple eigenvalue with left and right eigenvectors $\hat{\mathbf{x}} = \hat{\mathbf{y}} = [1; -1]$, and $\hat{\mathbf{y}}^* T'(0)\hat{\mathbf{x}} = 0$. Every $\hat{\lambda}_k = \sqrt{2k\pi}$, $k \neq 0$ is algebraically and geometrically simple with the same eigenvectors $\hat{\mathbf{x}}, \hat{\mathbf{y}}$ as before, and $\hat{\mathbf{y}}^* T'(\hat{\lambda}_k)\hat{\mathbf{x}} = 2\sqrt{2k\pi} i \neq 0$.
3. $T(\lambda) = (\lambda^k)$, $k \in \mathbb{N}$ has the eigenvalue $\hat{\lambda} = 0$ with algebraic multiplicity k.

60.2 Analytic Matrix Functions

In this section we consider the eigenvalue problem (60.1) where $T(\cdot) : D \to \mathbb{C}^{n\times n}$ is a regular matrix function which is analytic in a neighborhood of an eigenvalue $\hat{\lambda}$.

Definitions:

A sequence of vectors $\mathbf{x}_0, \mathbf{x}_1, \ldots, \mathbf{x}_{r-1}$ is called a **Jordan chain** (of length r) corresponding to $\hat{\lambda}$ if $\mathbf{x}_0 \neq 0$ and

$$\sum_{k=0}^{\ell} \frac{1}{k!} \frac{d^k T(\lambda)}{d\lambda^k}\bigg|_{\lambda=\hat{\lambda}} \mathbf{x}_{\ell-k} = 0 \quad \text{for } \ell = 0, \ldots, r-1.$$

$\mathbf{x}_0$ is an **eigenvector** and $\mathbf{x}_1, \ldots, \mathbf{x}_{r-1}$ are **generalized eigenvectors**.

Let $\mathbf{x}_0$ be an eigenvector corresponding to an eigenvalue $\hat{\lambda}$. The maximal length of a Jordan chain that starts with $\mathbf{x}_0$ is called the **multiplicity of** $\mathbf{x}_0$.

An eigenvalue $\hat{\lambda}$ is is said to be **normal** if it is a discrete point in $\sigma(T(\cdot)))$ and the multiplicity of each corresponding eigenvector is finite.

An analytic function $\mathbf{x} : D \to \mathbb{C}^n$ is called **root function** of $T(\cdot)$ at $\hat{\lambda} \in D$ if $T(\hat{\lambda})\mathbf{x}(\hat{\lambda}) = 0$ and $\mathbf{x}(\hat{\lambda}) \neq 0$.

The multiplicity of $\hat{\lambda}$ as a zero of $T(\lambda)\mathbf{x}(\lambda)$ is called the **multiplicity** of $\mathbf{x}(\cdot)$.

The **rank** of an eigenvector $\mathbf{x}_0$ is the maximum of the multiplicities of all root functions $\mathbf{x}(\cdot)$ such that $\mathbf{x}(\hat{\lambda}) = \mathbf{x}_0$.

A root function $\mathbf{x}(\cdot)$ is called a **maximal root function** if the multiplicity of $\mathbf{x}(\cdot)$ is equal to the rank of $\mathbf{x}_0 := \mathbf{x}(\hat{\lambda})$.

Let $\mathbf{x}_0^{(1)} \in \ker T(\hat{\lambda})$ be an eigenvector with maximal rank and let $\mathbf{x}^{(1)}(\lambda) = \sum_{j=0}^{\infty} \mathbf{x}_j^{(1)}(\lambda - \hat{\lambda})^j$ be a maximal root function such that $\mathbf{x}^{(1)}(\hat{\lambda}) = \mathbf{x}_0^{(1)}$. Suppose that the root functions $\mathbf{x}^{(k)}(\lambda) = \sum_{j=0}^{\infty} \mathbf{x}_j^{(k)}(\lambda - \hat{\lambda})^j$, $k = 1, \ldots, i-1$ are already constructed, and let $\mathbf{x}_0^{(i)}$ be an eigenvector with maximal rank in some direct complement to the linear span of the vectors $\mathbf{x}_0^{(1)}, \ldots, \mathbf{x}_0^{(i-1)}$ in $\ker T(\hat{\lambda})$. Let $\mathbf{x}^{(i)}(\lambda) = \sum_{j=0}^{\infty} \mathbf{x}_j^{(i)}(\lambda - \hat{\lambda})^j$ be a maximal root function such that $\mathbf{x}^{(i)}(\hat{\lambda}) = \mathbf{x}_0^{(i)}$. Then the ordered set

$$\mathbf{x}_0^{(1)}, \ldots, \mathbf{x}_{r_1-1}^{(1)}, \mathbf{x}_0^{(2)}, \ldots, \mathbf{x}_{r_2-1}^{(2)}, \ldots, \mathbf{x}_0^{(k)}, \ldots, \mathbf{x}_{r_k-1}^{(k)},$$

where $k = \dim \ker T(\hat{\lambda})$ and $r_j = \operatorname{rank} \mathbf{x}_0^{(j)}$ is called **canonical set of Jordan chains**, and the ordered set $\mathbf{x}^{(1)}(\lambda), \ldots, \mathbf{x}^{(k)}(\lambda)$ is called **canonical system of root functions**.

Let $X \in \mathbb{C}^{n \times \alpha}$ contain in its columns the vectors of a canonical set of Jordan chains and let $J = \operatorname{diag}(J_1, \ldots, J_k)$, where J_j is a Jordan block of size $r_j \times r_j$ corresponding to $\hat{\lambda}$. Then the pair (X, J) is called a **Jordan pair**.

Let $\mathbf{x}^{(1)}(\lambda), \ldots, \mathbf{x}^{(k)}(\lambda)$ be a canonical system of root functions at $\hat{\lambda}$, and let $\mathbf{x}^{(k+1)}, \ldots, \mathbf{x}^{(n)} \in \mathbb{C}^n$ such that $\mathbf{x}^{(1)}(\hat{\lambda}), \ldots, \mathbf{x}^{(k)}(\hat{\lambda}), \mathbf{x}^{(k+1)}, \ldots, \mathbf{x}^{(n)}$ is a basis of $\mathbb{C}^n$. Then the system $\mathbf{x}^{(1)}(\lambda), \ldots, \mathbf{x}^{(k)}(\lambda), \mathbf{x}^{(k+1)}, \ldots, \mathbf{x}^{(n)}$ is called an **extended canonical system of root functions**. To the constant functions $\mathbf{x}^{(k+1)}, \ldots, \mathbf{x}^{(n)} \in \mathbb{C}^n$ (which are not root functions in the strict sense of the definition) is assigned the multiplicity 0.

Let $\hat{\lambda}$ be an eigenvalue of $T(\cdot)$, and let $\Phi(\cdot)$ be an analytic matrix function such that its columns form an extended canonical system of root functions of $T(\cdot)$ at $\hat{\lambda}$. Then (cf. [GKS93]) in a neighborhood of $\hat{\lambda}$,

$$L(\lambda)\Phi(\lambda) = P(\lambda)D(\lambda), \tag{60.3}$$

where $D(\lambda)$ is a diagonal matrix with diagonal entries $(\lambda - \hat{\lambda})^{\kappa_1}, \ldots, (\lambda - \hat{\lambda})^{\kappa_n}$ and $P(\cdot)$ is a matrix function analytic at $\hat{\lambda}$ such that $\det P(\hat{\lambda}) \neq 0$. Furthermore, the exponents $\kappa_1, \ldots, \kappa_n$ are the multiplicities of the columns of $\Phi(\cdot)$, also called **partial multiplicities** of $T(\cdot)$ at $\hat{\lambda}$. Equation (60.3) is the **local Smith form** of $T(\cdot)$ in a neighborhood of $\hat{\lambda}$.

A pair of matrices $(Y, Z) \in \mathbb{C}^{n \times p} \times \mathbb{C}^{p \times p}$ is a **regular pair** if for some integer $\ell \geq 1$

$$\operatorname{rank} \begin{bmatrix} Y \\ YZ \\ \vdots \\ YZ^{\ell-1} \end{bmatrix} = p.$$

The number p is called the **order** of the regular pair (Y, Z).

Facts:

The following facts for which no specific reference is given can be found in [GLR82, GR93].

1. In contrast to linear eigenvalue problems, the vectors in a Jordan chain need not be linearly independent. Even the zero vector is admissible as a generalized eigenvector.
2. Let $\mathbf{x}(\cdot)$ be a root function at $\hat\lambda$, and let $\mathbf{x}^{(j)}$ denote the jth derivative of $\mathbf{x}$. Then the vectors $\mathbf{x}_j := \mathbf{x}^{(j)}(\hat\lambda)$, $j = 0, \dots, r-1$ form a Jordan chain at $\hat\lambda$, where r denotes the multiplicity of $\mathbf{x}(\cdot)$.
3. The multiplicity of a root function at $\hat\lambda$ (and hence the rank of an eigenvector) is at most the algebraic multiplicity of $\hat\lambda$.
4. The numbers $r_1 \ge \cdots \ge r_k$ in a Jordan pair are uniquely determined.
5. The number $\alpha := r_1 + \cdots + r_k$ is the algebraic multiplicity of the eigenvalue $\hat\lambda$.
6. [GKS93] Let $\mathbf{y}_1, \dots, \mathbf{y}_\ell : D \to \mathbb{C}^n$ be a set of root functions at $\hat\lambda$ with multiplicities $s_1 \ge \cdots \ge s_\ell$ such that $\mathbf{y}_1(\hat\lambda), \dots, \mathbf{y}_\ell(\hat\lambda) \in \ker T(\hat\lambda)$ are linearly independent. If the root functions $\mathbf{x}_1, \dots, \mathbf{x}_k$ define a canonical set of Jordan chains of $T(\cdot)$ at $\hat\lambda$ with multiplicities $r_1 \ge \cdots \ge r_k$, then $k \ge \ell$ and $r_i \ge s_i$ for $i = 1, \dots, \ell$. Moreover, $\mathbf{y}_1, \dots, \mathbf{y}_\ell$ define a canonical set of Jordan chains of $T(\cdot)$ at $\hat\lambda$ if and only if $\ell = k$ and $s_j = r_j$ for $j = 1, \dots, \ell$.
7. Let $S(\cdot)$ be an analytic matrix function with $\det S(\hat\lambda) \ne 0$. $\mathbf{x}_0, \dots, \mathbf{x}_k$ is a Jordan chain of $T(\cdot)S(\cdot)$ corresponding to $\hat\lambda$ if and only if the vectors $\mathbf{y}_0, \dots, \mathbf{y}_k$ given by $\mathbf{y}_j = \sum_{i=0}^{j} \frac{1}{i!} S^{(i)}(\hat\lambda)\mathbf{x}_{j-i}$, $j = 0, \dots, k-1$ are a Jordan chain of $T(\cdot)$ corresponding to $\hat\lambda$.
8. For S as in the last fact, the Jordan chains of $T(\cdot)$ coincide with those of $S(\cdot)T(\cdot)$ corresponding to the same $\hat\lambda$.
9. Two regular analytic matrix functions $T_1(\cdot)$ and $T_2(\cdot)$ have a common Jordan pair at $\hat\lambda$ if and only if $T_2(\lambda)T_1^{-1}(\lambda)$ is analytic and invertible at $\hat\lambda$.
10. [GKS93] Let $T(\cdot)$, $\Phi(\cdot)$, $D(\cdot)$, and $P(\cdot)$ be regular $n \times n$ matrix functions, analytic at $\hat\lambda$, such that $L(\lambda)\Phi(\lambda) = P(\lambda)D(\lambda)$ in a neighborhood of $\hat\lambda$. Assume that $\Phi(\hat\lambda)$ is invertible and that $D(\cdot)$ is a diagonal matrix polynomial with diagonal entries $(\lambda - \hat\lambda)^{\kappa_1}, \dots, (\lambda - \hat\lambda)^{\kappa_n}$, where $\kappa_1 \ge \cdots \ge \kappa_n$. Then the following three conditions are equivalent:

    (i) the columns of $\Phi(\cdot)$ form an extended canonical system of root functions of $T(\cdot)$ at $\hat\lambda$ with partial multiplicities $\kappa_1, \dots, \kappa_n$

    (ii) $\det P(\hat\lambda) \ne 0$

    (iii) $\sum_{j=1}^{n} \kappa_j$ is the the algebraic multiplicity of $\hat\lambda$.

11. [GKS93] Let $\mathbf{x}(\lambda) = \sum_{j=0}^{\infty} (\lambda - \hat\lambda)^j \mathbf{x}_j$ be an analytic $\mathbb{C}^n$-vector function with $\mathbf{x}_0 \ne 0$, and set $X := [\mathbf{x}_0, \dots, \mathbf{x}_p]$. Then $\mathbf{x}(\cdot)$ is a root function of $T(\cdot)$ at $\hat\lambda$ of multiplicity at most p if and only if $T(\lambda)X(\lambda I - J_{\hat\lambda,p})^{-1}$ is an $n \times p$ analytic matrix function. Here $J_{\hat\lambda,p}$ denotes a $p \times p$ Jordan block with eigenvalue $\hat\lambda$.
12. [AST09] $T(\cdot)$ admits a representation $P(\lambda)T(\lambda)Q(\lambda) = D(\lambda)$ where $P(\cdot)$ and $Q(\cdot)$ are regular analytic matrix functions with constant nonzero determinants, and $D(\lambda) = \operatorname{diag}\{d_j(\lambda))_{j=1\dots,n}$ is a diagonal matrix of analytic functions such that $d_j(\lambda)/d_{j-1}(\lambda)$ are analytic for $j = 2, 3, \dots, n$. This representation is also called local Smith form.
13. [AST09] With the representation in the last fact, if $\mathbf{q}_j(\lambda)$ is the jth column of Q, and $\hat\lambda$ a zero of $d_j(\cdot)$, then $(\hat\lambda, \mathbf{q}_j(\hat\lambda))$ is an eigenpair of $T(\cdot)$.
14. The non-zero partial multiplicities κ_j in the local Smith form of $T(\cdot)$ at $\hat\lambda$ coincide with the lengths $r_1 \ge \cdots \ge r_k$ of Jordan chains in a canonical set.
15. A Jordan pair (X, J) of $T(\cdot)$ at an eigenvalue $\hat\lambda$ is regular.
16. [GR93] Let $\hat\lambda$ be an eigenvalue of $T(\cdot)$ with algebraic multiplicity α, and let $(Y, Z) \in \mathbb{C}^{n\times\alpha} \times \mathbb{C}^{\alpha\times\alpha}$ be a pair of matrices such that $\sigma(Z) = \{\hat\lambda\}$. (Y, Z) is similar to a Jordan

pair (X, J) (i.e., $Y = XS$ and $Z = S^{-1}JS$ for some invertible matrix S) if and only if (Y, Z) is regular and the following equation holds:

$$\sum_{i=0}^{\infty} T_j Y(T - \hat{\lambda} I)^j = 0, \quad \text{where } T_j = \frac{1}{j!} T^{(j)}(\hat{\lambda})$$

(note that only a finite number of terms in the left-hand side of the equation is different from zero because $\sigma(Z) = \{\hat{\lambda}\}$).

17. [HL99] Suppose that $A(\lambda)$ and $B(\lambda)$ are analytic matrix-valued functions such that $A(\hat{\lambda})$ and $B(\hat{\lambda})$ are non-singular. Then the partial multiplicities of the eigenvalue $\hat{\lambda}$ of $T(\lambda)$ and $\tilde{T}(\lambda) := A(\lambda)T(\lambda)B(\lambda)$ coincide.
18. [HL99] Suppose that a matrix-valued function $T(\lambda, \tau)$ depends analytically on λ and continuously on τ and that $\hat{\lambda} = 0$ is an eigenvalue of $T(\cdot, 0)$ of algebraic multiplicity α. Then there exists a neighborhood $\mathcal{O}$ of $\hat{\lambda}$ such that, for all τ sufficiently close to the origin, there are exactly α eigenvalues (counting with algebraic multiplicities) of the matrix-valued function $T(\cdot, \tau)$ in $\mathcal{O}$.

Examples:

1. [GLR82] For $T(\lambda) = \begin{bmatrix} \lambda^2 & -\lambda \\ 0 & \lambda^2 \end{bmatrix}$ we have $\det T(\lambda) = \lambda^4$, and hence $\hat{\lambda} = 0$ is an eigenvalue of $T(\cdot)$ with algebraic multiplicity 4 and geometric multiplicity 2.
   For an eigenvector $\mathbf{x}_0 = [x_{01}; x_{02}]$ the first generalized eigenvector $\mathbf{x}_1$ satisfies $T'(0)\mathbf{x}_0 + T(0)\mathbf{x}_1 = 0$, i.e., $\begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \mathbf{x}_0 = 0$, and $\mathbf{x}_1$ exists if and only if $x_{02} = 0$, and $\mathbf{x}_1$ can be taken completely arbitrary. For a second generalized eigenvector $\mathbf{x}_2$ we have $\frac{1}{2}T''(0)\mathbf{x}_0 + T'(0)\mathbf{x}_1 + T(0)\mathbf{x}_2 = 0$, i.e., $\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \mathbf{x}_0 + \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \mathbf{x}_1 = 0$, i.e., $x_{01} = x_{12}$, and if this equation is satisfied, $\mathbf{x}_2$ can be chosen arbitrarily. The condition for the third generalized eigenvector $\mathbf{x}_3$ reads $\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \mathbf{x}_1 + \begin{bmatrix} 0 & -1 \\ 0 & 0 \end{bmatrix} \mathbf{x}_2 = 0$, which implies $x_{12} = 0$ and is contradictory.
   To summarize, the length of a Jordan chain cannot exceed 3. Jordan chains of length 1 are $\mathbf{x}_0$, $\mathbf{x}_0 \neq 0$, Jordan chains of length 2 are $\mathbf{x}_0 = [x_{01}; 0], \mathbf{x}_1$ with $x_{01} \neq 0$ and $\mathbf{x}_1$ arbitrary, and Jordan chains of length 3 are $\mathbf{x}_0 = [x_{01}; 0], \mathbf{x}_1 = [x_{11}; x_{01}], \mathbf{x}_2$, where $x_{01} \neq 0$, and x_{11} and x_2 are arbitrary. One example of a canonical system of Jordan chains is $\mathbf{x}_0^{(1)} = [1; 0]$, $\mathbf{x}_1^{(1)} = [0; 1]$, $\mathbf{x}_2^{(1)} = [1; 1]$, $\mathbf{x}_0^{(2)} = [0; 1]$.
   $T(0) = 0$ implies that $\mathbf{x}(\cdot)$ is a root function at $\hat{\lambda} = 0$, if x_1 and x_2 are analytic and $\mathbf{x}(0) \neq 0$. $T(\lambda)\mathbf{x}(\lambda) = [\lambda^2 x_1(\lambda) - \lambda x_2(\lambda); \lambda^2 x_2(\lambda)] = 0$ yields that $\mathbf{x}$ has at least the multiplicity 2, and if $x_2(\lambda) = \lambda x_1(\lambda)$, then the multiplicity is 3, and a higher multiplicity is not possible. In the latter case one obtains a Jordan chain as $[x_1(0); 0]$, $[x_1'(0); x_1(0)]$, $[x_1''(0); 2x_1'(0)]$.
2. For the quadratic eigenvalue problem in Eq. (60.2), det $T(\lambda) = \lambda^4 - \lambda^3 - 3\lambda^2 + \lambda + 2$. Hence, $\hat{\lambda} = -1$ is an eigenvalue with algebraic multiplicity 2 and geometric multiplicity 1. From

   $$T(-1)\mathbf{x}_0 = \begin{bmatrix} -6 & 6 \\ -12 & 12 \end{bmatrix} \mathbf{x}_0 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \ T(-1)\mathbf{x}_1 + T'(-1)\mathbf{x}_0 = \begin{bmatrix} -6 & 6 \\ -12 & 12 \end{bmatrix} \mathbf{x}_1 + \begin{bmatrix} 5 & -5 \\ 10 & -10 \end{bmatrix} \mathbf{x}_0 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

   it follows that $\mathbf{x} = [1; 1]$ is an eigenvector corresponding to $\hat{\lambda}$, and a generalized eigenvector as well. Then for $X = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ and $J = \begin{bmatrix} -1 & 1 \\ 0 & -1 \end{bmatrix}$ the pair (X, J) is a regular pair of order 2, namely the Jordan pair corresponding to $\hat{\lambda} = -1$.

60.3 Variational Characterization of Eigenvalues

Variational characterizations of eigenvalues are very powerful tools when studying self-adjoint linear operators on a Hilbert space. Many things can be easily proved using these characterizations; for example, bounds for eigenvalues, comparison theorems, interlacing results, and monotonicity of eigenvalues, to name just a few.

This section presents similar results for nonlinear eigenvalue problems. A minmax characterization was first proved in [Duf55] for overdamped quadratic eigenproblems, generalized in [Rog64] to general overdamped, and in [VW82] to non-overdamped problems. Although the characterizations also hold for infinite dimensional problems [Had68, VW82] the presentation here is restricted to the finite dimensional case.

We assume in this whole section that $J \subset \mathbb{R}$ is an open interval (which may be unbounded), and we consider a family of Hermitian matrices $T : J \to \mathbb{C}^{n\times n}$ depending continuously on the parameter $\lambda \in J$, such that the following two conditions are satisfied:

(i) For every $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{x} \neq 0$ the real equation

$$f(\lambda;\mathbf{x}) := \mathbf{x}^*T(\lambda)\mathbf{x} = 0 \tag{60.4}$$

has at most one solution $\lambda =: p(\mathbf{x})$ in J. Then Eq. (60.4) implicitly defines a (nonlinear) functional on some domain $D(p)$.

(ii)

$$(\lambda - p(\mathbf{x}))f(\lambda;\mathbf{x}) > 0 \quad \text{for every } \mathbf{x} \in D(p) \text{ and every } \lambda \in J,\ \lambda \neq p(\mathbf{x}). \tag{60.5}$$

Definitions:

The functional $p : D(p) \to J$ is called the **Rayleigh functional**.

If $D(p) = \mathbb{C}^n \setminus \{0\}$, then the problem $T(\lambda)\mathbf{x} = 0$ is called **overdamped**.

An eigenvalue $\hat{\lambda} \in J$ of $T(\cdot)$ is a **jth eigenvalue** if $\mu = 0$ is the j largest eigenvalue of the matrix $T(\hat{\lambda})$.

Facts:

In this subsection we denote by S_j the set of all j dimensional subspaces of $\mathbb{C}^n$. The following facts for which no specific reference is given can be found in [Had68, VW82, Vos09].

1. $D(p)$ is an open set in $\mathbb{C}^n$.
2. $p(\alpha\mathbf{x}) = p(\mathbf{x})$ for every $\mathbf{x} \in D(p)$ and every $\alpha \in \mathbb{C} \setminus \{0\}$.
3. If $T(\cdot)$ is differentiable in a neighborhood of an eigenvalue $\hat{\lambda}$ and $\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$ for a corresponding eigenvector $\hat{\mathbf{x}}$, then $\hat{\mathbf{x}}$ is a stationary point of p, i.e., $|p(\hat{\mathbf{x}}+\mathbf{h}) - p(\hat{\mathbf{x}})| = o(\|\mathbf{h}\|)$. In the real case $T : J \to \mathbb{R}^{n\times n}$, $J \subset \mathbb{R}$, we have $\nabla p(\hat{\mathbf{x}}) = 0$.
4. For every $j \in \{1,\ldots,n\}$ there is at most one jth eigenvalue of $T(\cdot)$.
5. $T(\cdot)$ has at most n eigenvalues in J.
6. [Rog64] If $T(\cdot)$ is overdamped, then $T(\cdot)$ has exactly n eigenvalues in J.
7. If
$$\lambda_j := \inf_{V\in S_j,\ V\cap D(p)\neq\emptyset}\ \sup_{\mathbf{x}\in V\cap D(p)} p(\mathbf{x}) \in J,$$
then λ_j is a jth eigenvalue of $T(\cdot)$.
8. (minmax characterization) If $\lambda_j \in J$ is a jth eigenvalue of $T(\cdot)$, then
$$\lambda_j := \min_{V\in S_j,\ V\cap D(p)\neq\emptyset}\ \max_{\mathbf{x}\in V\cap D(p)} p(\mathbf{x}) \in J.$$
The minimum is attained for an invariant subspace of the matrix $T(\lambda_j)$ corresponding to its j largest eigenvalues. The maximum is attained for some $\mathbf{x} \in \ker\, T(\lambda_j)$.

9. Let $\lambda_1 := \inf_{\mathbf{x}\in D(p)} p(\mathbf{x}) \in J$ and $\lambda_j \in J$ for some $j \in \{1,\dots,n\}$. Then for every $k \in \{1,\dots,j\}$ there exists $U_k \in S_k$ with $U_k \subset D(p)\cup\{0\}$ and $\lambda_k := \max_{\mathbf{x}\in U_k,\ \mathbf{x}\neq 0}\ p(\mathbf{x})$. Hence,
$$\lambda_k := \min_{V\in S_k,\ V\subset D(p)\cup\{0\}}\ \max_{\mathbf{x}\in V,\ \mathbf{x}\neq 0}\ p(\mathbf{x}) \in J \quad \text{for } k=1,\dots,j.$$
10. [Vos03] (maxmin characterization) Assume that there exists a jth eigenvalue $\lambda_j \in J$. Then
$$\lambda_j = \max_{V\in S_{j-1},\ V^\perp\cap D(p)\neq\emptyset}\ \inf_{\mathbf{x}\in V^\perp\cap D(p)}\ p(\mathbf{x}).$$
The maximum is attained for every invariant subspace of $T(\lambda_j)$ corresponding to its $j-1$ largest eigenvalues.
11. Let $\lambda_j \in J$ be a jth eigenvalue of $T(\cdot)$ and $\lambda \in J$. Then
$$\lambda \begin{Bmatrix} < \\ = \\ > \end{Bmatrix} \lambda_j \qquad \Longleftrightarrow \qquad \max_{V\in S_j}\ \min_{\mathbf{x}\in V,\mathbf{x}\neq 0} \frac{\mathbf{x}^*T(\lambda)\mathbf{x}}{\mathbf{x}^*\mathbf{x}} \begin{Bmatrix} < \\ = \\ > \end{Bmatrix} 0.$$
12. (orthogonality) [Had68] Let $T(\cdot)$ be differentiable in J. Then eigenvectors can be chosen orthogonal with respect to the generalized scalar product
$$[\mathbf{x},\mathbf{y}] := \begin{cases} \mathbf{y}^*\dfrac{T(p(\mathbf{x}))-T(p(\mathbf{y}))}{p(\mathbf{x})-p(\mathbf{y})}\mathbf{x}, & \text{if } p(\mathbf{x})\neq p(\mathbf{y}) \\ \mathbf{y}^*T'(p(\mathbf{x}))\mathbf{x}, & \text{if } p(\mathbf{x}) = p(\mathbf{y}) \end{cases}$$
which is symmetric and homogeneous, but in general is not bilinear.
If $T(\cdot)$ is differentiable and condition (ii) strengthened to $x^*T'(p(x))x > 0$ for every $x \in D$, then $[\cdot,\cdot]$ is positive definite, i.e., $[\mathbf{x},\mathbf{x}] > 0$ for every $x \in D(p)$.
13. (Rayleigh's principle) Assume that J contains $\lambda_1,\dots,\lambda_{j-1}$ where λ_k is a kth eigenvalue of $T(\cdot)$, and let $\mathbf{x}_k$, $k=1,\dots,j-1$ be a corresponding eigenvector. If
$$\lambda_j := \inf\{p(\mathbf{x}) \,:\, \mathbf{x}\in D(p),\ [\mathbf{x},\mathbf{x}_k]=0,\ k=1,\dots,j-1\} \in J,$$
then λ_j is a jth eigenvalue of $T(\cdot)$.
14. [KV13] (Sylvester's law; overdamped case) Assume that $T(\cdot)$ is overdamped. For $\sigma \in J$ let (π,ν,δ) be the inertia of $T(\sigma)$. Then $T(\cdot)$ has π eigenvalues that are smaller than σ, ν eigenvalues that exceed σ, and if $\delta \neq 0$, then σ is an eigenvalue of multiplicity δ.
15. [KV13] (Sylvester's law; extreme eigenvalues) Assume that $T(\mu)$ is negative definite for some $\mu \in J$, and for $\sigma > \mu$ let (π,ν,δ) be the inertia of $T(\sigma)$. Then $T(\cdot)$ has exactly π eigenvalues in J that are smaller than σ.
16. [KV13] (Sylvester's law; general case) Let $\mu \in J$, and assume that for every r dimensional subspace V with $V\cap D(p)\neq\emptyset$ there exists $\mathbf{x}\in V\cap D(p)$ with $p(\mathbf{x}) > \mu$. For $\sigma \in J$, $\sigma > \mu$ let (π,ν,δ) be the inertia of $T(\sigma)$. Then for $j = r,\dots,\pi$ there exists a jth eigenvalue λ_j of $T(\cdot)$ in $[\mu,\sigma)$.

Examples:

1. [Duf55] The quadratic pencil $Q(\lambda) := \lambda^2A + \lambda B + C$ with positive definite $A,B,C \in \mathbb{C}^{n\times n}$ is overdamped if and only if $d(\mathbf{x}) := (\mathbf{x}^*B\mathbf{x})^2 - 4(\mathbf{x}^*A\mathbf{x})(\mathbf{x}^*C\mathbf{x}) > 0$ for every $\mathbf{x}\in\mathbb{C}^n\setminus\{0\}$. For $\mathbf{x}\neq 0$ the quadratic equation $\mathbf{x}^*Q(\lambda)\mathbf{x} = 0$ has two real solutions $p_\pm(\mathbf{x}) = (-\mathbf{x}^*B\mathbf{x} \pm \sqrt{d(\mathbf{x})})/(2\mathbf{x}^*A\mathbf{x})$, and $\gamma_- := \sup_{\mathbf{x}\neq 0} p_-(\mathbf{x}) < \gamma_+ := \inf_{\mathbf{x}\neq 0} p_+(\mathbf{x})$.
$Q(\cdot)$ has n eigenvalues in $(-\infty,\gamma_+)$ which are minmax values of p_- and n eigenvalues in $(\gamma_-,0)$ which are minmax values of p_+.

2. [KV13] Assume that $Q(\cdot)$ as in the last example is not necessarily overdamped, and let $\text{in}(Q(\sigma)) = (\pi, \nu, \delta)$ denote the inertia of $Q(\sigma)$. If $\sigma < \gamma_+ := \inf_{\mathbf{x}\neq 0}\{p_+(\mathbf{x}) : p_+(\mathbf{x}) \in \mathbb{R}\}$, then $Q(\cdot)$ has exactly ν eigenvalues in $(-\infty, \sigma)$, and if $\sigma > \gamma_- := \sup_{\mathbf{x}\neq 0}\{p_-(\mathbf{x}) : p_-(\mathbf{x}) \in \mathbb{R}\}$, then $Q(\cdot)$ has ν eigenvalues in $(\sigma, 0)$.
   If $\mu_{\min}$ and $\mu_{\max}$ are the minimal and maximal eigenvalues of $C\mathbf{x} = \mu A\mathbf{x}$, then $-\sqrt{\mu_{\max}} \leq \gamma_+$ and $-\sqrt{\mu_{\min}} \geq \gamma_-$.
   If $\kappa_{\min}$ and $\kappa_{\max}$ are the minimal and maximal eigenvalues of $C\mathbf{x} = \kappa B\mathbf{x}$, respectively, then $-2\kappa_{\max} \leq \gamma_+$ and $-2\kappa_{\min} \geq \gamma_-$.

60.4 General Rayleigh Functionals

Whereas Section 60.3 presupposes the existence and uniqueness of a Rayleigh functional for problems allowing for a variational characterization, this section extends its definition to more general eigenproblems. It collects results on the existence and approximation properties of a Rayleigh functional in a vicinity of eigenvectors corresponding to algebraically simple eigenvalues. The material in this section is mostly taken from [Sch08, SS12].

Definitions:

Let $T : D \to \mathbb{C}^{n\times n}$ be a matrix valued mapping, which is analytic, or which is differentiable with Lipschitz continuous derivative in the real case.

Let $(\hat\lambda, \hat{\mathbf{x}})$ be an eigenpair of $T(\cdot)$, and define neighborhoods $B(\hat\lambda, \tau) := \{\lambda \in \mathbb{C} : |\lambda - \hat\lambda| < \tau\}$ and $\mathcal{K}_\varepsilon(\hat{\mathbf{x}}) := \{\mathbf{x} \in \mathbb{C}^n : \angle(\text{Span}\{\mathbf{x}\}, \text{Span}\{\hat{\mathbf{x}}\}) \leq \varepsilon\}$ of $\hat\lambda$ and $\hat{\mathbf{x}}$, respectively.

$p : \mathcal{K}_\varepsilon \to B(\hat\lambda, \tau)$ is a **(one-sided) Rayleigh functional** if the following conditions hold:

(i) $p(\alpha\mathbf{x}) = p(\mathbf{x})$ for every $\alpha \in \mathbb{C}$, $\alpha \neq 0$
(ii) $\mathbf{x}^*T(p(\mathbf{x}))\mathbf{x} = 0$ for every $\mathbf{x} \in \mathcal{K}_\varepsilon(\hat{\mathbf{x}})$
(iii) $\mathbf{x}^*T'(p(\mathbf{x}))\mathbf{x} \neq 0$ for every $\mathbf{x} \in \mathcal{K}_\varepsilon(\hat{\mathbf{x}})$.

Let $(\hat{\mathbf{y}}, \hat\lambda, \hat{\mathbf{x}})$ be an eigentriplet of $T(\cdot)$.

$p : \mathcal{K}_\varepsilon(\hat{\mathbf{x}}) \times \mathcal{K}_\varepsilon(\hat{\mathbf{y}}) \to B(\hat\lambda, \tau)$ is a **two-sided Rayleigh functional** if the following conditions hold for every $\mathbf{x} \in \mathcal{K}_\varepsilon(\hat{\mathbf{x}})$ and $\mathbf{y} \in \mathcal{K}_\varepsilon(\hat{\mathbf{y}})$:

(i) $p(\alpha\mathbf{x}, \beta\mathbf{y}) = p(\mathbf{x}, \mathbf{y})$ for every $\alpha, \beta \in \mathbb{C} \setminus \{0\}$,
(ii) $\mathbf{y}^*T(p(\mathbf{x}, \mathbf{y}))\mathbf{x} = 0$,
(iii) $\mathbf{y}^*T'(p(\mathbf{x}, \mathbf{y}))\mathbf{x} \neq 0$.

The **generalized Rayleigh quotient** (which was introduced in [Lan61] only for polynomial eigenvalue problems) is defined as

$$p_L : \mathcal{K}_\varepsilon(\hat{\mathbf{x}}) \times B(\hat\lambda, \tau) \times \mathcal{K}_\varepsilon(\hat{\mathbf{y}}) \to B(\hat\lambda, \tau),\ p_L(\mathbf{y}, \lambda, \mathbf{x}) := \lambda - \frac{\mathbf{y}^*T(\lambda)\mathbf{x}}{\mathbf{y}^*T'(\lambda)\mathbf{x}}.$$

Facts:

The following facts can be found in [Sch08, SS12].

1. Let $(\hat{\mathbf{y}}, \hat\lambda, \hat{\mathbf{x}})$ be an eigentriplet of $T(\cdot)$ with $\|\hat{\mathbf{x}}\| = \|\hat{\mathbf{y}}\| = 1$, and assume that $\hat{\mathbf{y}}^*T'(\hat\lambda)\hat{\mathbf{x}} \neq 0$. Then there exist $\varepsilon > 0$ and $\tau > 0$ such that the two-sided Rayleigh functional is defined in $\mathcal{K}_\varepsilon(\hat{x}) \times \mathcal{K}_\varepsilon(\hat{\mathbf{y}})$, and

$$|p(\mathbf{x}, \mathbf{y}) - \hat\lambda| \leq \frac{8}{3}\frac{\|T(\hat\lambda)\|}{|\hat{\mathbf{y}}^*T'(\hat\lambda)\hat{\mathbf{x}}|}\tan\xi\tan\eta,$$

   where $\xi := \angle(\text{Span}\{\mathbf{x}\}, \text{Span}\{\hat{\mathbf{x}}\})$ and $\eta := \angle(\text{Span}\{\mathbf{y}\}, \text{Span}\{\hat{\mathbf{y}}\})$.

2. Under the conditions of Fact 1 let $\xi < \pi/3$ and $\eta < \pi/3$. Then
$$|p(\mathbf{x},\mathbf{y}) - \hat{\lambda}| \leq \frac{32}{3}\frac{\|T(\hat{\lambda})\|}{|\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}}|}\|\mathbf{x}-\hat{\mathbf{x}}\|\|\mathbf{y}-\hat{\mathbf{y}}\|.$$
3. Under the conditions of Fact 1 the two-sided Rayleigh functional is stationary at $(\hat{\mathbf{x}},\hat{\mathbf{y}})$, i.e., $|p(\hat{\mathbf{x}}+\mathbf{s},\hat{\mathbf{y}}+\mathbf{t}) - \hat{\lambda}| = O((\|\mathbf{s}\| + \|\mathbf{t}\|)^{\mathbf{2}})$.
4. Let $(\hat{\lambda},\hat{\mathbf{x}})$ be an eigenpair of $T(\cdot)$ with $\|\hat{\mathbf{x}}\| = 1$ and $\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$, and suppose that $T(\hat{\lambda}) = T(\hat{\lambda})^*$. Then there exist $\varepsilon > 0$ and $\tau > 0$ such that the one-sided Rayleigh functional $p(\cdot)$ is defined in $\mathcal{K}_\varepsilon(\hat{\mathbf{x}})$, and
$$|p(\mathbf{x}) - \hat{\lambda}| \leq \frac{8}{3}\frac{\|T(\hat{\lambda})\|}{|\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}}|}\tan^2\xi,$$
where $\xi := \angle(\text{Span}\{\mathbf{x}\}, \text{Span}\{\hat{\mathbf{x}}\})$.
5. Let $(\hat{\lambda},\hat{\mathbf{x}})$ be an eigenpair of $T(\cdot)$ with $\|\hat{\mathbf{x}}\| = 1$ and $\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$. Then there exist $\varepsilon > 0$ and $\tau > 0$ such that the one-sided Rayleigh functional $p(\cdot)$ is defined in $\mathcal{K}_\varepsilon(\hat{\mathbf{x}})$, and
$$|p(\mathbf{x}) - \hat{\lambda}| \leq \frac{10}{3}\frac{\|T(\hat{\lambda})\|}{|\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}}|}\tan\xi,$$
where $\xi := \angle(\text{Span}\{\mathbf{x}\}, \text{Span}\{\hat{\mathbf{x}}\})$.
6. Let $\hat{\mathbf{x}}$ be a right eigenvector of $T(\cdot)$ corresponding to $\hat{\lambda}$, and $\hat{\mathbf{x}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$. The one-sided Rayleigh functional p is only stationary at $\hat{\mathbf{x}}$ if $\hat{\mathbf{x}}$ is also a left eigenvector.
7. The generalized Rayleigh quotient p_L is obtained when applying Newton's method to the equation defining the two-sided Rayleigh functional for fixed $\mathbf{x}$ and $\mathbf{y}$.
8. [Lan61] Let $(\hat{\mathbf{y}},\hat{\lambda},\hat{\mathbf{x}})$ be an eigentriplet of $T(\cdot)$ with $\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$. Then the generalized Rayleigh quotient p_L is stationary at $(\hat{\mathbf{y}},\hat{\lambda},\hat{\mathbf{x}})$.
9. Under the conditions of Fact 1 the generalized Rayleigh quotient p_L is defined for all $\lambda \in B(\hat{\lambda},\tau)$ and $(\mathbf{x},\mathbf{y}) \in \mathcal{K}_\varepsilon(\hat{\mathbf{x}}) \times \mathcal{K}_\varepsilon(\hat{\mathbf{y}})$, and
$$|p_L(\mathbf{y},\lambda,\mathbf{x}) - \hat{\lambda}| \leq \frac{4\|T(\hat{\lambda})\|}{|\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}}|}\tan\xi\tan\eta + \frac{2L}{|\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}}|}\frac{|\lambda-\hat{\lambda}|^2}{\cos\xi\cos\eta},$$
where L denotes the Lipschitz constant of $T'(\cdot)$.

60.5 Methods for Dense Eigenvalue Problems

The size of the eigenvalue problems that can be treated with the numerical methods considered in this section is limited to a few thousand depending on the available storage capacities. Moreover, they require several factorizations of varying matrices to approximate one eigenvalue and, therefore, they are not appropriate for large and sparse problems. However, they are needed to solve the projected eigenproblem in most of the iterative projection methods for sparse problems.

For general nonlinear eigenvalue problems, the classical approach is to formulate the eigenvalue problem as a system of nonlinear equations and to use variations of Newton's method or the inverse iteration method. Thus, these methods are local and therefore not guaranteed to converge, but as for linear eigenvalue problems their basin of convergence can be enlarged using homotopy methods [DP01] or trust region strategies [YMW07].

Facts:

1. [Kub70] Let $T(\lambda)P(\lambda) = Q(\lambda)R(\lambda)$ be the QR factorization of $T(\lambda)$, where $P(\lambda)$ is a permutation matrix which is chosen such that the diagonal elements $r_{jj}(\lambda)$ of $R(\lambda)$ are decreasing in magnitude, i.e., $|r_{11}(\lambda)| \geq |r_{22}(\lambda)| \geq \cdots \geq |r_{nn}(\lambda)|$. Then λ is an eigenvalue of $T(\cdot)$ if and only if $r_{nn}(\lambda) = 0$.
   Applying Newton's method to this equation, one obtains the iteration
   $$\lambda_{k+1} = \lambda_k - \frac{1}{\mathbf{e}_n^T Q(\lambda_k)^* T'(\lambda_k) P(\lambda_k) R(\lambda_k)^{-1} \mathbf{e}_n}$$
   for approximations to an eigenvalue of problem $T(\lambda)x = 0$, where $\mathbf{e}_n$ denotes the nth unit vector.
   Approximations to left and right eigenvectors can be obtained from $\mathbf{y}_k = Q(\lambda_k)\mathbf{e}_n$ and $\mathbf{x}_k = P(\lambda_k)R(\lambda_k)^{-1}\mathbf{e}_n$.
   However, this relatively simple idea is not efficient, since it computes eigenvalues one at a time and needs several $O(n^3)$ factorizations per eigenvalue. It is, however, useful in the context of iterative refinement of computed eigenvalues and eigenvectors.
2. [AR68] Applying Newton's method to the nonlinear system
   $$F(\mathbf{x}, \lambda) := \begin{pmatrix} T(\lambda)\mathbf{x} \\ \mathbf{v}^*\mathbf{x} - 1 \end{pmatrix} = 0$$
   where $\mathbf{v} \in \mathbb{C}^n$ is suitably chosen one obtains the *inverse iteration* given in Algorithm 1. Being a variant of Newton's method it converges locally and quadratically for simple eigenpairs.

Algorithm 1: Inverse iteration

```
Require: Initial pair $(\lambda_0, \mathbf{x}_0)$ and normalization vector $\mathbf{v}$ with $\mathbf{v}^*\mathbf{x}_0 = 1$
for $k = 0, 1, 2, \ldots$ until convergence do
    solve $T(\lambda_k)\mathbf{u}_{k+1} = T'(\lambda_k)\mathbf{x}_k$ for $\mathbf{u}_{k+1}$
    $\lambda_{k+1} \leftarrow \lambda_k - (\mathbf{v}^*\mathbf{x}_k)/(\mathbf{v}^*\mathbf{u}_{k+1})$
    normalize $\mathbf{x}_{k+1} \leftarrow \mathbf{u}_{k+1}/\mathbf{v}^*\mathbf{u}_{k+1}$
end for
```

3. If $T(\cdot)$ is Hermitian such that the general conditions of Section 60.3 are satisfied, one obtains the *Rayleigh functional iteration* if the update of λ_{k+1} in Step 3 of Algorithm 1 is replaced with $\lambda_{k+1} \leftarrow p(\mathbf{u}_{k+1})$. This method converges locally and cubically [Rot89] for simple eigenpairs.
4. [Lan61, Ruh73] Replacing the vector $\mathbf{v}$ in the normalization step of inverse iteration for a general matrix function $T(\cdot)$ with $\mathbf{v}_k = T(\lambda_k)^*\mathbf{y}_k$, where $\mathbf{y}_k$ is an approximation to a left eigenvector, the update for λ becomes
   $$\lambda_{k+1} \leftarrow \lambda_k - \frac{\mathbf{y}_k^* T(\lambda_k)\mathbf{x}_k}{\mathbf{y}_k^* T'(\lambda_k)\mathbf{x}_k},$$
   which is the generalized Rayleigh quotient p_L.
5. [Sch08] For general $T(\cdot)$ and simple eigentriplets $(\hat{\mathbf{y}}, \hat{\lambda}, \hat{\mathbf{x}})$ cubic convergence is also achieved by the *two-sided Rayleigh functional iteration* in Algorithm 2. If the linear system in Step 2 is solved by factorizing $T(\lambda_k)$, then taking the conjugate transpose the factorization can be reused for the system in Step 3. So, the cost of one iteration step is similar to the one of the one-sided Rayleigh functional iteration.

```
Algorithm 2: Two-sided Rayleigh functional iteration
Require: Initial triplet $(\mathbf{y}_0, \lambda_0, \mathbf{x}_0)$ where $\mathbf{x}_0^*\mathbf{x}_0 = \mathbf{y}_0^*\mathbf{y}_0 = 1$
1: for $k = 0, 1, 2, \ldots$ until convergence do
2:     solve $T(\lambda_k)\mathbf{u}_{k+1} = T'(\lambda_k)\mathbf{x}_k$ for $\mathbf{u}_{k+1}$; $\mathbf{x}_{k+1} \leftarrow \mathbf{u}_{k+1}/\|\mathbf{u}_{k+1}\|$
3:     solve $T(\lambda_k)^*\mathbf{v}_{k+1} = T'(\lambda_k)^*\mathbf{y}_k$ for $\mathbf{v}_{k+1}$; $\mathbf{y}_{k+1} \leftarrow \mathbf{v}_{k+1}/\|\mathbf{v}_{k+1}\|$
4:     solve $\mathbf{y}_{k+1}^*T(\lambda_{k+1})\mathbf{x}_{k+1} = 0$ for $\lambda_{k+1}$
5: end for
```

6. [Neu85] The cost for solving a linear system in each iteration step with a varying matrix is avoided in the *residual inverse iteration* in Algorithm 3 where the matrix $T(\lambda_0)$ is fixed during the whole iteration (or at least for several steps).

```
Algorithm 3: Residual inverse iteration
Require: Initial pair $(\lambda_0, \mathbf{x}_0)$ and normalization vector $\mathbf{w}$ with $\mathbf{w}^*\mathbf{x}_0 = 1$
1: for $k = 0, 1, 2, \ldots$ until convergence do
2:     solve $\mathbf{w}^*T(\lambda_0)^{-1}T(\lambda_{k+1})\mathbf{x}_k = 0$ for $\lambda_{k+1}$
3:     solve $T(\lambda_0)\mathbf{u}_k = T(\lambda_{k+1})\mathbf{x}_k$ for $\mathbf{u}_k$
4:     set $\mathbf{v}_{k+1} \leftarrow \mathbf{x}_k - \mathbf{u}_k$ and normalize $\mathbf{x}_{k+1} \leftarrow \mathbf{v}_{k+1}/\mathbf{w}^*\mathbf{v}_{k+1}$
5: end for
```

If $T(\cdot)$ is Hermitian and $\hat{\lambda} \in \mathbb{R}$, then the convergence can be improved by determining λ_{k+1} in Step 1 via the Rayleigh functional, i.e., solving $\mathbf{x}_k^*T(\lambda_{k+1})\mathbf{x}_k = 0$ for λ_{k+1}. If $T(\cdot)$ is twice continuously differentiable and $\hat{\lambda}$ is algebraically simple, then the residual inverse iteration converges for all $(\lambda_0, \mathbf{x}_0)$ sufficiently close to $(\hat{\lambda}, \hat{\mathbf{x}})$, and

$$\frac{\|\mathbf{x}_{k+1} - \hat{\mathbf{x}}\|}{\|\mathbf{x}_k - \hat{\mathbf{x}}\|} = O(|\lambda_0 - \hat{\lambda}|) \quad \text{and} \quad |\lambda_{k+1} - \hat{\lambda}| = O(\|\mathbf{x}_k - \hat{\mathbf{x}}\|^t)$$

where $t = 2$ in the Hermitian case if λ_{k+1} is updated via the Rayleigh functional, and $t = 1$ in the general case.

7. [Ruh73] The first order approximation $T(\lambda + \sigma)\mathbf{x} = T(\lambda)\mathbf{x} + \sigma T'(\lambda)\mathbf{x} + o(|\sigma|)$ suggests the *method of successive linear problems* in Algorithm 4, which also converges quadratically for simple eigenvalues.

```
Algorithm 4: Method of successive linear problems
Require: Initial approximation $\lambda_0$
1: for $k = 0, 1, \ldots$ until convergence do
2:     solve the linear eigenproblem $T(\lambda_k)\mathbf{u} = \theta T'(\lambda_k)\mathbf{u}$
3:     choose an eigenvalue $\theta$ smallest in modulus
4:     $\lambda_{k+1} = \lambda_k - \theta$
5: end for
```

If $\hat{\lambda}$ is a semisimple eigenvalue, $\mathbf{x}_k$ converges to a right eigenvector $\hat{\mathbf{x}}$. If $\hat{\mathbf{y}}$ is a left eigenvector corresponding to $\hat{\lambda}$ such that $\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}} \neq 0$ (which is guaranteed for a simple eigenvalue), then the convergence factor is given by (cf. [Jar12])

$$c := \lim_{k\to\infty} \frac{\lambda_{k+1} - \hat{\lambda}}{(\lambda_k - \hat{\lambda})^2} = \frac{1}{2}\frac{\hat{\mathbf{y}}^*T''(\hat{\lambda})\hat{\mathbf{x}}}{\hat{\mathbf{y}}^*T'(\hat{\lambda})\hat{\mathbf{x}}}.$$

8. [Wer70] If the nonlinear eigenvalue problem allows for a variational characterization of its eigenvalues, then the *safeguarded iteration*, which aims at a particular eigenvalue, is a natural choice.

```
Algorithm 5: Safeguarded iteration for determining an $m$th eigenvalue
Require: Approximation $\lambda_0$ to an $m$th eigenvalue
for $k = 0, 1, \dots$ until convergence do
    determine an eigenvector $\mathbf{x}_k$ corresponding to the $m$-largest eigenvalue of $T(\lambda_k)$
    solve $\mathbf{x}_k^* T(\lambda_{k+1})\mathbf{x}_k = 0$ for $\lambda_{k+1}$
end for
```

Under the conditions of Section 60.3, the safeguarded iteration has the following properties [NV10]:

(i) If $\hat{\lambda}_1 := \inf_{\mathbf{x}\in D(p)} p(\mathbf{x}) \in J$ and $\mathbf{x}_0 \in D$, then the safeguarded iteration with $m = 1$ converges globally to $\hat{\lambda}_1$.

(ii) If $T(\cdot)$ is continuously differentiable and $\hat{\lambda}_m$ is a simple eigenvalue, then the safeguarded iteration converges locally and quadratically to $\hat{\lambda}_m$.

(iii) Let $T(\cdot)$ be twice continuously differentiable and $T'(\hat{\lambda}_m)$ be positive definite. If $\mathbf{x}_k$ in Step 3 is chosen to be an eigenvector corresponding to the m largest eigenvalue of the generalized eigenvalue problem $T(\lambda_k)\mathbf{x} = \mu T'(\lambda_k)\mathbf{x}$, then the convergence is even cubic.

9. [SX11] For higher dimensions n it is too costly to solve the occurring linear systems exactly. Szyld and Xue [SX11] studied inexact versions of inverse iteration and residual inverse iteration and proved that the same order of convergence can be achieved as for the exact methods if the respective linear systems are solved sufficiently accurately.

60.6 Iterative Projection Methods

For sparse linear eigenvalue problems $A\mathbf{x} = \lambda\mathbf{x}$ iterative projection methods like the Lanczos, Arnoldi, rational Krylov, or Jacobi–Davidson method are very efficient. Here the dimension of the eigenproblem is reduced by projecting it to a subspace of much smaller dimension, and the reduced problem is solved by a fast technique for dense problems. The subspaces are expanded in the course of the algorithm in an iterative way with the aim that some of the eigenvalues of the reduced matrix become good approximations to some of the wanted eigenvalues of the given large matrix.

Two types of iterative projection methods are in use: methods that expand the subspaces independently of the eigenpair of the projected problem and that take advantage of a normal form of A like the Arnoldi, Lanczos, and rational Krylov method, and methods that aim at a particular eigenpair and choose the expansion such that it has a high approximation potential for a wanted eigenvector like the Jacobi–Davidson method.

For general nonlinear eigenproblems, a normal form does not exist. Therefore, generalizations of iterative projection methods to general nonlinear eigenproblems always have to be of the second type. There are essentially two types of these methods — the Jacobi–Davidson method (and its two–sided version), which is based on inverse iteration, and the nonlinear Arnoldi method, which is based on residual inverse iteration.

Jacobi–Davidson Method

Assume that we are given a search space $\mathcal{V}$ and a matrix V with orthonormal columns containing a basis of $\mathcal{V}$. Let $(\mathbf{y}, \theta)$ be an eigenpair of the projected problem $V^*T(\lambda)V\mathbf{y} = 0$ and $\mathbf{x} = V\mathbf{y}$ be the corresponding Ritz vector. A direction with high approximation potential is given by inverse iteration $\mathbf{v} = T(\theta)^{-1}T'(\theta)\mathbf{x}$, however replacing $\mathbf{v}$ with an inexact solution of the linear system $T(\theta)\mathbf{v} = T'(\theta)\mathbf{x}$ will spoil the favorable approximation properties of inverse iteration.

Actually, we are not interested in the direction $\mathbf{v}$ but in an expansion of $\mathcal{V}$, which contains $\mathbf{v}$, and for every $\alpha \neq 0$ the vector $\mathbf{t} = \mathbf{x} + \alpha\mathbf{v}$ is as qualified as $\mathbf{v}$. It was shown in [Vos07a] that the most robust expansion of this type is obtained if $\mathbf{x}$ and $\mathbf{t} := \mathbf{x} + \alpha\mathbf{v}$ are orthogonal, and it is easily seen that this $\mathbf{t}$ solves the so-called correction equation

$$\left(I - \frac{T'(\theta)\mathbf{x}\mathbf{x}^*}{\mathbf{x}^*T'(\theta)\mathbf{x}}\right) T(\theta) \left(I - \frac{\mathbf{x}\mathbf{x}^*}{\mathbf{x}^*\mathbf{x}}\right) \mathbf{t} = T(\theta)\mathbf{x}, \quad \mathbf{t} \perp \mathbf{x}.$$

The resulting iterative projection method is called the **Jacobi–Davidson method**, a template of which is given in Algorithm 6.

Algorithm 6: Nonlinear Jacobi–Davidson method

```
Require: Initial basis $V$, $V^*V = I$; $m = 1$
determine preconditioner $K \approx T(\sigma)^{-1}$, $\sigma$ close to first wanted eigenvalue
while $m \leq$ number of wanted eigenvalues do
    compute an approximation $\theta$ to the $m$th wanted eigenvalue and corresponding
      eigenvector $\mathbf{y}$ of the projected problem $T_V(\theta)\mathbf{y} := V^*T(\theta)V\mathbf{y} = 0$
    determine the Ritz vector $\mathbf{u} = V\mathbf{y}$ and the residual $\mathbf{r} = T(\theta)\mathbf{u}$
    if $\|\mathbf{r}\|/\|\mathbf{u}\| < \epsilon$ then
        accept approximate eigenpair $(\lambda_m, \mathbf{x}_m) := (\theta, \mathbf{u})$; increase $m \leftarrow m + 1$;
        reduce search space $V$ if indicated
        determine new preconditioner $K \approx T(\lambda_m)^{-1}$ if necessary
        choose approximation $(\theta, \mathbf{u})$ to next eigenpair
        compute residual $\mathbf{r} = T(\theta)\mathbf{u}$;
    end if
    Find approximate solution of correction equation

        $(I - \frac{T'(\theta)\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)\mathbf{u}})T(\theta)(I - \frac{\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*\mathbf{u}})\mathbf{t} = -\mathbf{r}, \quad \mathbf{t} \perp \mathbf{u}$        (60.6)

    (by preconditioned Krylov solver, e.g.)
    orthogonalize $\mathbf{t} = \mathbf{t} - VV^*\mathbf{t}$, $\mathbf{v} = \mathbf{t}/\|\mathbf{t}\|$, and expand subspace $V = [V, \mathbf{v}]$
    update projected problem
end while
```

Facts:

1. The Jacobi–Davidson method was introduced for polynomial eigenproblem in [SBF96] and studied for general nonlinear eigenvalue problems in [BV04, Vos07b].
2. As in the linear case the correction equation (60.6) does not have to be solved exactly to maintain fast convergence, but usually a few steps of a Krylov subspace solver with an appropriate preconditioner suffice to obtain a good expansion direction of the search space.
3. In the correction equation (60.6) the operator $T(\theta)$ is restricted to map the subspace $\mathbf{u}^{\perp}$ into itself. Hence, if $K^{-1} \approx T(\theta)$ is a preconditioner of $T(\theta)$, then a preconditioner

for an iterative solver of Eq. (60.6) should be modified correspondingly to

$$\tilde{K} := (I - \frac{T'(\theta)\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)\mathbf{u}})K^{-1}(I - \frac{\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*\mathbf{u}}).$$

With left-preconditioning, Eq. (60.6) becomes

$$\tilde{K}^{-1}\tilde{T}(\theta)\mathbf{t} = -\tilde{K}^{-1}\mathbf{r},\ \mathbf{t} \perp \mathbf{u} \text{ where } \tilde{T}(\theta) := (I - \frac{T'(\theta)\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)\mathbf{u}})T(\theta)(I - \frac{\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*\mathbf{u}}).$$

Taking into account the projectors in the preconditioner, i.e., using $\tilde{K}$ instead of K in a preconditioned Krylov solver, raises the cost only slightly. In every step one has to solve one linear system $K\mathbf{w} = \mathbf{y}$, and to initialize the solver requires only one additional solve.

4. In Step 1 of Algorithm 6 any preinformation such as a small number of known approximate eigenvectors of problem (60.1) corresponding to eigenvalues close to σ or of eigenvectors of a contiguous problem can and should be used. If no information on eigenvectors is at hand, and if one is interested in eigenvalues close to the parameter $\sigma \in D$, one can choose an initial vector at random, execute a few Arnoldi steps for the linear eigenproblem $T(\sigma)\mathbf{u} = \theta\mathbf{u}$ or $T(\sigma)\mathbf{u} = \theta T'(\sigma)\mathbf{u}$, and choose the eigenvector corresponding to the smallest eigenvalue in modulus or a small number of Schur vectors as initial basis of the search space. Starting with a random vector without this preprocessing usually will yield a value λ_m in Step 4, which is far away from σ and will avert convergence.
5. As the subspaces expand in the course of the algorithm the increasing storage or the computational cost for solving the projected eigenvalue problems may make it necessary to restart the algorithm and purge some of the basis vectors. Since a restart destroys information on the eigenvectors and particularly on the one the method is just aiming at, the method is restarted only if an eigenvector has just converged. An obvious way to restart is to determine a Ritz pair $(\mu, \mathbf{u})$ from the projection to the current search space span(V) approximating an eigenpair wanted next, and to restart the Jacobi–Davidson method with this single vector $\mathbf{u}$. However, this may discard too much valuable information contained in span(V), and may slow down the speed of convergence too much. Therefore, thick restarts with subspaces spanned by the Ritz vector $\mathbf{u}$ and a small number of eigenvector approximations obtained in previous steps which correspond to eigenvalues closest to μ are preferable.
6. A crucial point in iterative methods for general nonlinear eigenvalue problems when approximating more than one eigenvalue is to inhibit the method from converging to the same eigenvalue repeatedly. For linear eigenvalue problems locking of already converged eigenvectors can be achieved using an incomplete Schur factorization. For nonlinear problems allowing for a variational characterization of its eigenvalues one can determine the eigenpairs one after another solving the projected problem by safeguarded iteration [BV04]. For general nonlinear eigenproblems a locking procedure based on invariant pairs was introduced in [Eff12] (cf. Section 60.7).
7. Often the matrix function $T(\cdot)$ is given in the following form: $T(\lambda) := \sum_{j=1}^{m} f_j(\lambda)A_j$ where $f_j : \Omega \to \mathbb{C}$ are continuous functions and $A_j \in \mathbb{C}^{n\times n}$ are fixed matrices. Then the projected problem can be updated easily appending one row and column to each of the projected matrices V^*A_jV.

Two-Sided Jacobi–Davidson Method

In Algorithm 6 approximations to an eigenvalue are obtained in Step 3 from a Galerkin projection of $T(\lambda)\mathbf{x} = 0$ to the search space Span$\,(V)$ for right eigenvectors. Computing a left search space also with a correction equation for left eigenvectors and applying a Petrov-Galerkin projection one arrives at the *two-sided Jacobi-Davidson method* in Algorithm 7 (where only the computation of one eigentriplet is considered):

Algorithm 7: Two-sided Jacobi–Davidson method

```
Require: Initial bases $U$ with $U^*U = I$ and $V$ with $V^*V = I$
 1: while not converged do
 2:    solve $V^*T(\theta)U\mathbf{c} = 0$ and $U^*T(\theta)^*V\mathbf{d} = 0$ for $(\theta, \mathbf{c}, \mathbf{d})$
 3:    determine Ritz vectors $\mathbf{u} = U\mathbf{c}$ and $\mathbf{v} = V\mathbf{d}$ and residuals $\mathbf{r}_u = T(\theta)\mathbf{u}$, $\mathbf{r}_v = T(\theta)^*\mathbf{v}$
 4:    if $\min(\|\mathbf{r_u}\|/\|\mathbf{u}\|, \|\mathbf{r_v}\|/\|\mathbf{v}\|) < \epsilon$ then
 5:       accept approximate eigentriplet $(\mathbf{v}, \theta, \mathbf{u})$; STOP
 6:    end if
 7:    Solve (approximately) correction equations
          $(I - \frac{T'(\theta)\mathbf{u}\mathbf{v}^*}{\mathbf{v}^*T'(\theta)\mathbf{u}})T(\theta)(I - \frac{\mathbf{u}\mathbf{u}^*}{\mathbf{u}^*\mathbf{u}})\mathbf{s} = -\mathbf{r}_u, \quad \mathbf{s} \perp \mathbf{u},$
          $(I - \frac{T'(\theta)^*\mathbf{v}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)^*\mathbf{v}})T(\theta)^*(I - \frac{\mathbf{v}\mathbf{v}^*}{\mathbf{v}^*\mathbf{v}})\mathbf{t} = -\mathbf{r}_v, \quad \mathbf{t} \perp \mathbf{v}$
 8:    orthogonalize $\mathbf{s} = \mathbf{s} - UU^*\mathbf{s}$, $\mathbf{s} = \mathbf{s}/\|\mathbf{s}\|$, and expand left search space $U = [U, \mathbf{s}]$
 9:    orthogonalize $\mathbf{t} = \mathbf{t} - VV^*\mathbf{t}$, $\mathbf{t} = \mathbf{t}/\|\mathbf{t}\|$, and expand right search space $V = [V, \mathbf{t}]$
10: end while
```

Facts:

8. [Sch08] θ as computed in Step 2 is the value of the two-sided Rayleigh functional at $(\mathbf{u}, \mathbf{v})$, and one therefore may expect local cubic convergence for simple eigenvalues.
9. [HS03] The correction equation in Step 7 of Algorithm 7 can be replaced with

$$(I - \frac{T'(\theta)\mathbf{u}\mathbf{v}^*}{\mathbf{v}^*T'(\theta)\mathbf{u}})T(\theta)(I - \frac{T'(\theta)\mathbf{u}\mathbf{v}^*}{\mathbf{v}^*T'(\theta)\mathbf{u}})\mathbf{s} = -\mathbf{r}_u, \quad \mathbf{s} \perp \mathbf{u},$$

$$(I - \frac{T'(\theta)^*\mathbf{v}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)^*\mathbf{v}})T(\theta)^*(I - \frac{T'(\theta)^*\mathbf{v}\mathbf{u}^*}{\mathbf{u}^*T'(\theta)^*\mathbf{v}})\mathbf{t} = -\mathbf{r}_v, \quad \mathbf{t} \perp v.$$

   This variant was suggested in [HS03] for linear eigenvalue problems, and its generalization to the nonlinear problem is obvious. Since again θ is the value of the two-sided Rayleigh functional the convergence should also be cubic.
10. [SS06] Replacing the correction equations with

$$(I - \mathbf{v}\mathbf{v}^*)T(\theta)(I - \mathbf{u}\mathbf{u}^*)\mathbf{s} = -\mathbf{r}_u, \quad \mathbf{s} \perp \mathbf{u},$$

$$(I - \mathbf{u}\mathbf{u}^*)T(\theta)^*(I - \mathbf{v}\mathbf{v}^*)\mathbf{t} = -\mathbf{r}_v, \quad \mathbf{t} \perp \mathbf{v}$$

   one obtains the **primal-dual Jacobi-Davidson method**, which was shown to be quadratically convergent.

Nonlinear Arnoldi Method

Expanding the current search space $\mathcal{V}$ by the direction $\hat{\mathbf{v}} = \mathbf{x} - T^{-1}(\sigma)T(\theta)\mathbf{x}$ as suggested by residual inverse iteration generates similar robustness problems as for inverse iteration. If $\hat{\mathbf{v}}$ is close to the desired eigenvector, then an inexact evaluation of $\hat{\mathbf{v}}$ spoils the favorable approximation properties of residual inverse iteration.

Similarly as in the Jacobi–Davidson method one could replace $\hat{\mathbf{v}}$ by $\mathbf{z} := \mathbf{x} + \alpha\hat{\mathbf{v}}$ where α is chosen such that $\mathbf{x}^*\mathbf{z} = 0$, and one could determine an approximation to $\mathbf{z}$ solving a correction equation. However, since the new search direction is orthonormalized against the previous search space $\mathcal{V}$ and since $\mathbf{x}$ is contained in $\mathcal{V}$ we may choose the new direction $\mathbf{v} = T(\sigma)^{-1}T(\theta)\mathbf{x}$ as well. This direction satisfies the orthogonality condition $\mathbf{x}^*\mathbf{v} = 0$ at least in the limit as θ approaches a simple eigenvalue $\hat{\lambda}$ (cf. [Vos07a]), i.e., $\lim_{\theta\to\hat{\lambda}} \mathbf{x}^*T(\sigma)^{-1}T(\theta)\mathbf{x} = 0$.

A template for the preconditioned **nonlinear Arnoldi method** with restarts and varying preconditioner is just like Algorithm 6. Only Step 12 has to be replaced with $\mathbf{t} = K\mathbf{r}$.

Facts:

11. The general remarks about the initial approximation to the eigenvector, restarts, and locking following the Jacobi–Davidson method apply to the nonlinear Arnoldi method also.
12. Since the residual inverse iteration with fixed pole σ converges (at least) linearly, and the contraction rate satisfies $O(|\sigma - \lambda_m|)$, it is reasonable to update the preconditioner if the convergence (measured by the quotient of the last two residual norms before convergence) has become too slow.
13. The nonlinear Arnoldi method was introduced for quadratic eigenvalue problems in [Mee01] and for general nonlinear eigenvalue problems in [Vos04].
14. [LBL10] studies a variant that avoids complex arithmetic augmenting the search space by two vectors, the real and imaginary part of the expansion $\mathbf{t} = K\mathbf{r}$.

60.7 Methods Using Invariant Pairs

One of the most important problems when determining more than one eigenpair of a nonlinear eigenvalue problem is to prevent the method from determining the same pair repeatedly. Jordan chains are conceptually elegant but unstable under perturbations. More robust concepts for computing several eigenvalues along with the corresponding (generalized) eigenvectors were introduced only recently and are based on invariant pairs [Kre09, BT09].

It is convenient to consider the nonlinear eigenvalue problem in the following form:

$$T(\lambda)\mathbf{x} := \sum_{j=1}^{m} f_j(\lambda)A_j\mathbf{x} = 0 \qquad (60.7)$$

where $f_j : \Omega \to \mathbb{C}$ are analytic functions and $A_j \in \mathbb{C}^{n\times n}$ are fixed matrices.

Definitions:

Let the eigenvalues of $S \in \mathbb{C}^{k\times k}$ be contained in Ω and let $X \in \mathbb{C}^{n\times k}$. Then (X, S) is called **invariant pair** of the nonlinear eigenvalue problem (60.7) if

$$\sum_{j=1}^{m} A_j X f_j(S) = 0.$$

A pair $(X, S) \in \mathbb{C}^{n\times k} \times \mathbb{C}^{k\times k}$ is **minimal** if there is $\ell \in \mathbb{N}$ such that the matrix

$$V_\ell(X,S) := \begin{bmatrix} X \\ XS \\ \vdots \\ XS^{\ell-1} \end{bmatrix}$$

has rank k.

The smallest such ℓ is called the **minimality index** of (X, S).

An invariant pair (X, S) is called **simple** if (X, S) is minimal and the algebraic multiplicities of the eigenvalues of S are identical to the ones of the corresponding eigenvalues of $T(\cdot)$.

Facts:

The following facts for which no specific reference is given can be found in [Kre09].

1. Let (X, S) be a minimal invariant pair of Eq. (60.7). Then the eigenvalues of S are eigenvalues of $T(\cdot)$.
2. By the Cayley–Hamilton theorem the minimality index of a minimal pair cannot exceed k.
3. [BK11] For a regular matrix polynomial of degree m the minimality index of a minimal invariant pair cannot exceed m.
4. [Eff12] Let $p_0, \ldots, p_{\ell-1}$ be a basis for the polynomials of degree less than ℓ. Then the pair (X, S) is minimal with minimality index at most ℓ if and only if

$$V_\ell^p(X,S) = \begin{bmatrix} Xp_0(S) \\ \vdots \\ Xp_{\ell-1}(S) \end{bmatrix}$$

   has full column rank.
5. [BK11] If $V_\ell(X, S)$ has rank $\tilde{k} < k$, then there is a minimal pair $(\tilde{X}, \tilde{S}) \in \mathbb{C}^{n\times\tilde{k}} \times \mathbb{C}^{\tilde{k}\times\tilde{k}}$ such that $\mathrm{Span}(\tilde{X}) = \mathrm{Span}(X)$ and $\mathrm{Span}(V_\ell(\tilde{X}, \tilde{S})) = \mathrm{Span}(V_\ell(X, S))$.
6. If (X, S) is a minimal invariant pair, then $(XZ, Z^{-1}SZ)$ is also a minimal invariant pair for every invertible matrix $Z \in \mathbb{C}^{k\times k}$.
7. Let (X, S) be a minimal invariant pair, and let $p_j \in \Pi_k$ be the Hermite interpolating polynomials of f_j at the spectrum of S of maximum degree k. Then (X, S) is a minimal invariant pair of $P(\lambda)\mathbf{x} := \sum_{j=1}^m p_j(\lambda)A_j\mathbf{x} = 0$.
8. Let $(\lambda_j, \mathbf{x}_j)$, $j = 1, \ldots, k$ be eigenpairs of $T(\cdot)$ with $\lambda_i \neq \lambda_j$ for $i \neq j$. Then the invariant pair $(X, S) := ([\mathbf{x}_1, \ldots, \mathbf{x}_k], \mathrm{diag}(\lambda_1, \ldots, \lambda_k))$ is minimal.
9. Consider the nonlinear matrix operator

$$\mathbb{T} : \begin{cases} \mathbb{C}^{n\times k} \times \mathbb{C}_\Omega^{k\times k} \to \mathbb{C}^{n\times k} \\ (X,S) \mapsto \sum_{j=1}^m A_j X f_j(S) \end{cases} \tag{60.8}$$

   where $\mathbb{C}_\Omega^{k\times k}$ denotes the set of $k \times k$ matrices with eigenvalues in Ω. Then an invariant pair (X, S) satisfies $\mathbb{T}(X, S) = 0$, but this relation is not sufficient to characterize (X, S). To define a scaling condition, choose ℓ such that the matrix $V_\ell(X, S)$ has rank k, and define the partition

$$W = \begin{bmatrix} W_0 \\ W_1 \\ \vdots \\ W_{\ell-1} \end{bmatrix} := V_\ell(X,S)\left(V_\ell(X,S)^* V_\ell(X,S)\right)^{-1} \in \mathbb{C}^{nk\times k}$$

with $W_j \in \mathbb{C}^{n\times k}$. Then $\mathbb{V}(X,S)=0$ for the operator

$$\mathbb{V} : \mathbb{C}^{n\times k} \times \mathbb{C}^{k\times k}_{\Omega} \to \mathbb{C}^{n\times k},\ \mathbb{V}(X,S) := W^* V_\ell(X,S) - I_k.$$

If (X,S) is a minimal invariant pair for the nonlinear eigenvalue problem $T(\lambda)\mathbf{x}=0$, then (X,S) is simple if and only if the linear matrix operator

$$\mathbb{L} : \mathbb{C}^{n\times k} \times \mathbb{C}^{k\times k} \to \mathbb{C}^{n\times k} \times \mathbb{C}^{k\times k}, (\Delta X, \Delta S) \mapsto (\mathbb{DT}(\Delta X,\Delta S), \mathbb{DV}(\Delta X,\Delta S))$$

is invertible, where $\mathbb{DT}$ and $\mathbb{DV}$ denote the Fréchet derivative of $\mathbb{T}$ and $\mathbb{V}$, respectively.

10. [Kre09] The last fact motivates to apply Newton's method to the system $\mathbb{T}(X,S)=0$, $\mathbb{V}(X,S)=0$ which can be written as

$$(X_{p+1}, S_{p+1}) = (X_p, S_p) - \mathbb{L}^{-1}(\mathbb{T}(X_p,S_p), \mathbb{V}(X_p,S_p))$$

where $\mathbb{L} = (\mathbb{DT}, \mathbb{DV})$ is the Jacobian matrix of $\mathbb{T}(X,S)=0, \mathbb{V}(X,S)=0$.

$$\mathbb{DT}(\Delta X, \Delta S) = \mathbb{T}(\Delta X, S) + \sum_{j=1}^{m} A_j X [\mathbb{D} f_j(S)](\Delta S),$$

$$\mathbb{DV}(\Delta X, \Delta S) = W_0^* \Delta X + \sum_{j=1}^{m} W_j^* (\Delta X S^j + X[\mathbb{D}S^j](\Delta S)).$$

Algorithm 8: Newton's method for computing invariant pairs

```
Require: Initial pair $(X_0,S_0) \in \mathbb{C}^{n\times k} \times \mathbb{C}^{k\times k}$ such that $V_\ell(X_0,S_0)^* V_\ell(X_0,S_0) = I_k$
$p \leftarrow 0$, $W \leftarrow V_\ell(X_0,S_0)$
repeat
    Res $\leftarrow \mathbb{T}(X_p,S_p)$
    Solve linear matrix equation $\mathbb{L}(\Delta X, \Delta S) = (\mathrm{Res}, O)$
    $\tilde{X}_{p+1} \leftarrow X_p - \Delta X$, $\tilde{S}_{p+1} \leftarrow S_p - \Delta S$
    Compute compact QR decomposition $V_\ell(\tilde{X}_{p+1}, \tilde{S}_{p+1}) = WR$
    $X_{p+1} \leftarrow \tilde{X}_{p+1} R^{-1}$, $S_{p+1} \leftarrow R \tilde{S}_{p+1} R^{-1}$
until convergence
```

11. [Bey12, BEK11]

$$\mathbb{T}(X,S) = \frac{1}{2\pi i} \int_{\Gamma} T(z) X (zI - S)^{-1}\, dz$$

where Γ is a contour (i.e., a simply closed curve) in Ω containing the spectrum of S in its interior.

12. [BEK11]

$$\mathbb{DT}(X,S)(\Delta X, \Delta S) = \frac{1}{2\pi i} \int_{\Gamma} (\Delta X + X(zI-S)^{-1}\Delta S)(zI-S)^{-1}\, dz.$$

13. [Eff12] Let (X,S) be a minimal (index ℓ) invariant pair of $T(\cdot)$. If $([\begin{smallmatrix} Y \\ V \end{smallmatrix}], M)$ is a minimal invariant pair of the augmented analytic matrix function

$$\hat{T} : \begin{cases} \Omega \to \mathbb{C}^{(n+k)\times(n+k)}, \\ \hat{T}(\mu)\begin{bmatrix} y \\ v \end{bmatrix} = \begin{bmatrix} \mathbb{T}([X,y], [\begin{smallmatrix} S & v \\ 0 & \mu \end{smallmatrix}]) \\ [V^p_{\ell+1}(X,S)]^* V^p_{\ell+1}([X,y], [\begin{smallmatrix} S & v \\ 0 & \mu \end{smallmatrix}]) \end{bmatrix} e_{k+1} \end{cases}$$

with $\mathbb{T}$ as in Fact 11, $V^p_{\ell+1}$ analogous to Fact 4, and $e_{k+1} = (0,\dots,0,1)^T \in \mathbb{R}^{k+1}$, then $([X,Y],[\begin{smallmatrix} S & V \\ 0 & M \end{smallmatrix}])$ is a minimal invariant pair of $T(\cdot)$. Conversely, for any minimal invariant pair $([X,Y],[\begin{smallmatrix} S & V \\ 0 & M \end{smallmatrix}])$ of $T(\cdot)$ there exists a unique F such that $([\begin{smallmatrix} Y-XF \\ V-(SF-FM) \end{smallmatrix}], M)$ is a minimal invariant pair of $\hat{T}(\cdot)$.

14. The previous fact suggests that working with $\hat{T}(\cdot)$ deflates the minimal invariant pair (X,S) from $T(\cdot)$.
15. [Eff12] Effenberger combined the deflation in Fact 13 with the Jacobi–Davidson method to determine several eigenpairs of a nonlinear eigenvalue problem one after another in a safe way.
16. [GKS93] The pair (X,S) is minimal if and only if

$$\operatorname{rank}\begin{bmatrix} \lambda I - S \\ X \end{bmatrix}$$

has full rank for every $\lambda \in \mathbb{C}$ (or, equivalently, for every eigenvalue λ of S).

17. [GKS93] Let $\hat{\lambda}$ be an eigenvalue of $T(\cdot)$ and $X := [\mathbf{x}_0,\dots,\mathbf{x}_{k-1}] \in \mathbb{C}^{k\times k}$ with $\mathbf{x}_0 \neq 0$. Then $\mathbf{x}_0,\dots,\mathbf{x}_{k-1}$ is a Jordan chain at $\hat{\lambda}$ if and only if $(X, J_k(\hat{\lambda}))$ is an invariant pair of $T(\cdot)$, where $J_k(\hat{\lambda})$ denotes a $k\times k$ Jordan block corresponding to $\hat{\lambda}$.
18. [BEK11] Let $\hat{\lambda}$ be an eigenvalue of $T(\cdot)$ and consider a matrix $X = [X^{(1)},\dots,X^{(p)}]$, $X^{(i)} = [\mathbf{x}_0^{(i)},\dots,\mathbf{x}_{m_i}^{(i)}]$, with $\mathbf{x}_0^{(i)} \neq 0$. Then every $\mathbf{x}_0^{(i)},\dots,\mathbf{x}_{m_i}^{(i)}$ for $i = 1,\dots,p$ is a Jordan chain if and only if (X,J) with $J := \operatorname{diag}(J_{m_1}(\hat{\lambda}),\dots,J_{m_p}(\hat{\lambda}))$ is an invariant pair of $T(\cdot)$. Moreover, (X,J) is minimal if and only if $\mathbf{x}_0^{(1)},\dots,\mathbf{x}_0^{(p)}$ are linearly independent.
19. [SX12] Suppose that (X,S) is a simple invariant pair of Eq. (60.7), $\hat{\lambda}$ is an eigenvalue of S, and $J = Z^{-1}SZ$ is the Jordan canonical form of S. Assume that J has m Jordan blocks corresponding to $\hat{\lambda}$, each of size $k_i \times k_i$, $1 \leq i \leq m$. Then there are exactly m Jordan chains of $T(\cdot)$ corresponding to $\hat{\lambda}$, the length of each is k_i, and the geometric multiplicity of $\hat{\lambda}$ is m. This fact demonstrates that the spectral structure of an eigenvalue $\hat{\lambda}$ of a matrix function $T(\cdot)$, including the algebraic, partial, and geometric multiplicities together with all Jordan chains, is completely represented in a simple invariant pair (X,S) for which $\hat{\lambda}$ is an eigenvalue of S.

Examples:

1. For the quadratic eigenvalue problem (60.2) with eigenvalue $\hat{\lambda} = -1$ and eigenvector $\mathbf{x} = [1;1]$ the pair $(X,S) := (\mathbf{x},\hat{\lambda})$ is a minimal invariant pair with minimality index 1, which is not simple because the algebraic multiplicity of $\hat{\lambda}$ is 2 as an eigenvalue of $T(\lambda)x = 0$ and only 1 as an eigenvalue of S. The Jordan pair $(X1, S1)$ with $X1 = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$ and $S1 = \begin{bmatrix} -1 & 1 \\ 0 & -1 \end{bmatrix}$ is a minimal invariant pair with minimality index 2, which is simple, and the same is true for the pairs $(X2, S2)$ with $X2 = \begin{bmatrix} 1 & 2 \\ 1 & 2 \end{bmatrix}$ and $S1 = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix}$, and $(X3, S3)$ with $X3 := [X1, X2]$ and $S3 := \operatorname{diag}(X1, X2)$.

60.8 The Infinite Arnoldi Method

Let $T : \Omega \to \mathbb{C}^{n\times n}$ be analytic on a neighborhood Ω of the origin, and assume that $\lambda = 0$ is not an eigenvalue of $T(\cdot)$. To determine eigenvalues close to 0 [JMM12] use the equivalence of $T(\lambda)\mathbf{x} = 0$ to a linear, infinite dimensional eigenvalue problem, and apply the linear

Arnoldi method, which can be reformulated to an iteration involving only standard linear algebra operations on matrices and vectors of finite dimension.

Definitions:

$B(\lambda) := T(0)^{-1}(T(0) - T(\lambda))/\lambda$ for $\lambda \neq 0$ and $B(0) := -T(0)^{-1}T'(0)$ is analytic on Ω, and $\hat{\lambda}$ is an eigenvalue of $T(\cdot)$ if and only if $\hat{\lambda}$ is an eigenvalue of $\lambda B(\lambda)\mathbf{x} = \mathbf{x}$.

Let $D(\mathcal{B}) := \{\phi \in C^\infty(\mathbb{R}, \mathbb{C}^n) : \sum_{i=0}^\infty B^{(i)}(0)\phi^{(i)}(0) < \infty\}$, and define

$$\mathcal{B}(\theta) := \int_0^\theta \phi(\hat{\theta})\, d\hat{\theta} + C(\phi), \quad C(\phi) := \sum_{i=0}^\infty \frac{B^{(i)}(0)}{i!}\phi^{(i)}(0) = \left(B(\frac{d}{d\theta})\phi\right)(0). \tag{60.9}$$

$(\Psi, R) \in D(\mathcal{B})^p \times \mathbb{C}^{p\times p}$ is an **invariant pair of the operator** $\mathcal{B}$ if $(\mathcal{B}\Psi)(\theta) = \Psi(\theta)R$.

Facts:

The following facts can be found in [JMM12].

1. Let $\mathbf{x} \in \mathbb{C}^n \setminus \{0\}$, $\lambda \in \Omega$ and denote $\phi(\theta) := \mathbf{x}e^{\lambda\theta}$. Then the following two statements are equivalent:
    - (i) $(\hat{\lambda}, \hat{\mathbf{x}})$ is an eigenpair of $T(\cdot)$
    - (ii) $(\hat{\lambda}, \phi)$ is an eigenpair of the linear, infinite dimensional eigenvalue problem $\lambda\mathcal{B}\phi = \phi$.
2. All eigenfunctions of $\mathcal{B}$ depend exponentially on θ, i.e., if $\lambda\mathcal{B}\psi = \psi$, then $\psi(\theta) = \mathbf{x}e^{\lambda\theta}$.
3. The (linear) Arnoldi method for the operator $\mathcal{B}$ is given in Algorithm 9. Here $\langle\cdot,\cdot\rangle$ denotes a scalar product on $C^\infty(\mathbb{R}, \mathbb{C}^n)$, and $H_k = (h_{ik}) \in \mathbb{C}^{k\times k}$ a Hessenberg matrix constructed in the algorithm.

```
Algorithm 9: Arnoldi method for $\mathcal{B}$
Require: Initial function $\phi_1$ with $\langle\phi_1, \phi_1\rangle = 1$
for $k = 1, 2, \ldots$ until convergence do
    $\psi \leftarrow \mathcal{B}\psi_k$
    for i=1,...,k do
        $h_{ik} \leftarrow \langle\psi, \phi_i\rangle$
        $\psi \leftarrow \psi - h_{ik}\phi_i$
    end for
    $h_{k+1,k} \leftarrow \sqrt{\langle\psi, \psi\rangle}$
    $\phi_{k+1} \leftarrow \psi/h_{k+1,k}$
end for
Compute eigenvalues $\mu_i$ of Hessenberg matrix $H_k$
Return eigenvalue approximations $1/\mu_i$ of $\mathcal{B}$
```

4. Since the Arnoldi method favors extreme eigenvalues of $\mathcal{B}$, $1/\mu_i$ will approximate eigenvalues of $T(\cdot)$ close to the origin.
5. If ϕ_1 is a polynomial of degree k, then $\mathcal{B}\phi$ is a polynomial of degree $k+1$. Hence, if ϕ_1 is a constant function, then Algorithm 9 after N steps arrives at a Krylov space $\mathcal{K}_N(\mathcal{B}, \phi_1) = \text{Span}\{\phi_1, \ldots, \phi_N\}$ of vectors of polynomials of degree $N-1$.
6. Let $\{q_i\}_{i=0,1,\ldots}$ be a sequence of polynomials such that q_i is of degree i with non-zero leading coefficient, and let $q_0 \equiv 1$. Let $L_N \in \mathbb{R}^{N\times N}$ be an integration map

corresponding to $\{q_i\}$ such that

$$\begin{bmatrix} q_0(\theta) \\ \vdots \\ q_{N-1}(\theta) \end{bmatrix} = L_N \begin{bmatrix} q_1'(\theta) \\ \vdots \\ q_N'(\theta) \end{bmatrix}.$$

Let the columns of $[\mathbf{x}_0, \dots, \mathbf{x}_{N-1}] =: X \in \mathbb{C}^{n \times N}$ denote the vector coefficients in the basis $\{q_i\}$, and denote a vector of polynomials $\phi(\theta) := \sum_{i=0}^{N-1} q_i(\theta)\mathbf{x}_i$. If $\psi(\theta) = (\mathcal{B}\phi)(\theta) =: \sum_{i=0}^{N} q_i(\theta)\mathbf{y}_i$, then the coefficients $\mathbf{y}_i$ of $\mathcal{B}\phi$ are given by $[\mathbf{y}_1, \dots, \mathbf{y}_N] = XL_N$ and $\mathbf{y}_0 = \left(\sum_{i=0}^{N-1} B(\frac{d}{d\theta})q_i(\theta)\mathbf{x}_i\right)(0) - \sum_{i=1}^{N} q_i(0)\mathbf{y}_i$. This fact permits to reformulate Algorithm 9 to an iteration involving only standard linear algebra operations on matrices and vectors of finite dimension. In [JMM12] the details are worked out for two polynomial bases, the monomial basis $q_i = \theta^i$ and Chebyshev polynomials.

7. [JMM11] Suppose that $S \in \mathbb{C}^{p \times p}$ is invertible and suppose that (Ψ, S^{-1}) is an invariant pair of $\mathcal{B}$. Then Ψ can be expressed as $\Psi(\theta) = X \exp(\theta S)$ for some matrix $X \in \mathbb{C}^{p \times p}$.
8. [JMM11] Assume that $T(\lambda) := \sum_{j=1}^{m} f_j(\lambda)A_j$. Let $S \in \mathbb{C}^{p \times p}$ be nonsingular and $X \in \mathbb{C}^{n \times p}$. The following two statements are equivalent:
   - (i) (Ψ, S^{-1}), $\Psi(\theta) := X \exp(\theta S)$ is an invariant pair of the operator $\mathcal{B}$.
   - (ii) (X, S) is an invariant pair of $T(\cdot)$, i.e., $\sum_{j=1}^{m} A_j X f_j(S) = 0$.
9. Inspired by the implicitly restarted Arnoldi method for linear eigenproblems [JMM11] proposes a variant of the infinite Arnoldi method for the nonlinear eigenvalue problem $T(\lambda)x = 0$, which allows for locking already converged eigenpairs. The locked part of the partial Schur factorization for linear problems is replaced by invariant pairs. The method uses functions $\phi(\theta) = Xe^{S\theta}c + q(\theta)$ where $X \in \mathbb{C}^{n \times p}$, $S \in \mathbb{C}^{p \times p}$, $c \in \mathbb{C}^p$ and $q : \mathbb{C} \to \mathbb{C}^n$ is a vector of polynomials.

Dario A. Bini
Università di Pisa

Multiplying matrices is an important problem from both the theoretical and the practical point of view. Determining the arithmetic complexity of this problem, that is, the minimum number of arithmetic operations sufficient for computing an $n \times n$ matrix product, is still an open issue. Other important computational problems like computing the inverse of a nonsingular matrix, solving a linear system, computing the determinant, or more generally the coefficients of the characteristic polynomial of a matrix have a complexity related to that of matrix multiplication. Certain combinatorial problems, like the all pair shortest distance problem of a digraph, are strictly related to matrix multiplication. This chapter deals with fast algorithms for multiplication of unstructured matrices. Fast algorithms for structured matrix computations are presented in Chapter 62. Analyzing the complexity of matrix multiplication, and more generally of the evaluation of a set of bilinear form, is related to computing the rank of a three-way array (tensor). The subject of tensor analysis is treated in Chapters 14 and 15. For more details on relationships between tensor rank and complexity of bilinear maps, including matrix multiplication, we refer the reader to the book [BCS97].

61.1 Basic Concepts

Let $A = [a_{ij}]$, $B = [b_{ij}]$, and $C = [c_{ij}]$ be $n \times n$ matrices over the field $\mathbb{F}$ such that $C = AB$, that is, C is the matrix product of A and B.

Facts:

1. The elements of the matrices A, B, and C are related by the following equations:

$$c_{ij} = \sum_{k=1}^{n} a_{ik} b_{kj}, \quad i, j = 1, \ldots, n.$$

2. Each element c_{ij} is the scalar product of the ith row of A and the jth column of B and can be computed by means of n multiplications and $n - 1$ additions. This computation is described in Algorithm 1.

3. The overall cost of computing the n^2 elements of C is n^3 multiplications and $n^3 - n^2$ additions, that is $2n^3 - n^2$ arithmetic operations.

```
Algorithm 1. Conventional matrix multiplication
Input: the elements $a_{ij}$ and $b_{ij}$ of two $n \times n$ matrices $A$ and $B$;
Output: the elements $c_{ij}$ of the matrix product $C = AB$;
for $i = 1$ to $n$ do
  for $j = 1$ to $n$ do
    $c_{ij} = 0$
    for $k = 1$ to $n$ do
      $c_{ij} = c_{ij} + a_{ik}b_{kj}$
    end for
  end for
end for
```

4. [Hig02, p. 71] The computation of c_{ij} by means of Algorithm 1 is element-wise forward numerically stable. More precisely, if $\widetilde{C}$ denotes the matrix actually computed by performing Algorithm 1 in floating point arithmetic with machine precision ϵ, then $|C - \widetilde{C}| \leq n\epsilon|A||B| + O(\epsilon^2)$, where $|A|$ denotes the matrix with elements $|a_{ij}|$ and the inequality holds element-wise.
5. For 2×2 matrices Algorithm 1 requires 8 multiplications and 4 additions. For 5×5 matrices Algorithm 1 requires 125 multiplications and 100 additions.

61.2 Fast Algorithms

Definitions:

Define $\omega \in \mathbb{R}$ as the infimum of the real numbers w such that there exists an algorithm for multiplying $n \times n$ matrices with $O(n^w)$ arithmetic operations. ω is called the **exponent of matrix multiplication complexity**.

Algorithms for multiplying the $p \times p$ matrices A and B of the form

$$m_k = \left(\sum_{i,j=1}^{p} \alpha_{i,j,k} a_{ij}\right)\left(\sum_{i,j=1}^{p} \beta_{i,j,k} b_{ij}\right), \quad k = 1, \dots t,$$

$$c_{ij} = \sum_{k=1}^{t} \gamma_{i,j,k} m_k,$$

where $\alpha_{i,j,k}, \beta_{i,j,k}, \gamma_{i,j,k}$ are given scalar constants, are called **bilinear algorithms**. Since a bilinear algorithm does not use the commutativity of multiplication, it is also called **non-commutative algorithm**.

An algorithm of the form

$$m_k = \left(\sum_{i,j=1}^{p} \alpha_{i,j,k} a_{ij} + \sum_{i,j=1}^{p} \beta'_{i,j,k} b_{ij}\right)\left(\sum_{i,j=1}^{p} \alpha'_{i,j,k} a_{ij} + \sum_{i,j=1}^{p} \beta_{i,j,k} b_{ij}\right), \quad k = 1, \dots t,$$

$$c_{ij} = \sum_{k=1}^{t} \gamma_{i,j,k} m_k,$$

where $\alpha_{i,j,k}, \beta_{i,j,k}, \alpha'_{i,j,k}, \beta'_{i,j,k}, \gamma_{i,j,k}$ are given scalar constants, is said to be a **quadratic algorithm**. A quadratic algorithm where $\alpha'_{i,j,k}$ and $\beta'_{i,jk}$ are not identically zero relies on the commutative property of multiplication. For this reason, a quadratic algorithm is also called a **commutative**

algorithm. Each m_k is given in terms of a multiplication where the two factors are a linear combination of the entries a_{ij} and b_{ij}. A multiplication of this kind is called **nonscalar multiplication**, while the multiplication of an entry of A or of B by a constant is called **scalar multiplication** [BCS97].

The entries of the matrix C are bilinear functions of the entries of the matrices A and B. Given constants $\alpha_{i,j,k} \in \mathbb{F}$, $i = 1, \ldots, m$, $j = 1, \ldots, n$, $k = 1, \ldots, p$, and vectors of indeterminates $x = (x_i)_{i=1,m}$, $y = (y_j)_{j=1,n}$, the map

$$(x, y) \to z = (z_k), \quad z_k = \sum_{i=1}^{m} \sum_{j=1}^{n} \alpha_{i,j,k} x_i y_j, \ k = 1, \ldots, p$$

is said to be a **bilinear map**. Given constants $\beta_{i,j,k} \in \mathbb{F}$, $i, j = 1, \ldots, m + n$, $k = 1, \ldots, p$, and set $w^T = (x^T, y^T)$, the map

$$w \to z = (z_k), \quad z_k = \sum_{i,j=1}^{m+n} \beta_{k,i,j} w_i w_j, \ k = 1, \ldots, p$$

is said to be a **quadratic map**.

In general, bilinear algorithms compute bilinear maps, and quadratic algorithms compute quadratic maps. A bilinear map is a special case of a quadratic map.

Facts:

1. [Win69] *Winograd's commutative algorithm.* For moderately large values of n, it is possible to compute the product of $n \times n$ matrices with less than $2n^3 - n^2$ arithmetic operations by means of the following simple identities where $n = 2m$ is even:

$$\begin{aligned} u_i &= \sum_{k=1}^{m} a_{i,2k-1} a_{i,2k}, \quad v_i = \sum_{k=1}^{m} b_{2k-1,j} b_{2k,j}, && i = 1, n, \\ w_{i,j} &= \sum_{k=1}^{m} (a_{i,2k-1} + b_{2k,j})(a_{i,2k} + b_{2k-1,j}), && i, j = 1, n, \\ c_{ij} &= w_{i,j} - u_i - b_j, && i, j = 1, n. \end{aligned}$$

2. The number of arithmetic operations required is $n^3 + 4n^2 - 2n$, which is less than $2n^3 - n^2$ already for $n \geq 8$. This formula, which for large values of n is faster by a factor of about 2 with respect to the conventional algorithm, relies on the commutative property of multiplication. It can be extended to the case where n is odd.
3. [Str69] *Strassen's formula.* It is possible to multiply 2×2 matrices with only 7 multiplications instead of 8, but with a higher number of additions by means of the following identities:

$$\begin{aligned} m_1 &= (a_{12} - a_{22})(b_{21} + b_{22}), & m_5 &= a_{11}(b_{12} - b_{22}), \\ m_2 &= (a_{11} + a_{22})(b_{11} + b_{22}), & m_6 &= a_{22}(b_{21} - b_{11}), \\ m_3 &= (a_{11} - a_{21})(b_{11} + b_{12}), & m_7 &= (a_{21} + a_{22})b_{11}, \\ m_4 &= (a_{11} + a_{12})b_{22}, \\ c_{11} &= m_1 + m_2 - m_4 + m_6, & c_{12} &= m_4 + m_5, \\ c_{21} &= m_6 + m_7, & c_{22} &= m_2 - m_3 + m_5 - m_7. \end{aligned}$$

4. The overall number of arithmetic operations required by the Strassen formula is higher than the number of arithmetic operations required by the conventional matrix multiplication described in Algorithm 61.1.1. However, the decrease from 8 to 7 of the number of multiplications provides important consequences.

5. The identities of Fact 3 do not exploit the commutative property of multiplication like the identities of Fact 1; therefore, they are still valid if the scalar factors are replaced by matrices.
6. Strassen's formula provides a bilinear algorithm for 2×2 matrix multiplication where the constants $\alpha_{i,j,k}$, $\beta_{i,j,k}$, $\gamma_{i,j,k}$ are in the set $\{-1, 0, 1\}$. The Winograd identities of Fact 1 provide a quadratic algorithm for $n \times n$ matrix multiplication where the constants are in the set $\{-1, 0, 1\}$.
7. If n is even, say $n = 2m$, then A, B, and C can be partitioned into four $m \times m$ blocks, that is,

   $$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}, \quad B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix}, \quad A = \begin{bmatrix} C_{11} & C_{12} \\ C_{21} & C_{22} \end{bmatrix},$$

   where $A_{ij}, B_{ij}, C_{ij} \in \mathbb{F}^{m \times m}$, $i, j = 1, 2$, so that an $n \times n$ matrix product can be viewed as a 2×2 block matrix product. More specifically it holds that

   $$\begin{aligned} C_{11} &= A_{11}B_{11} + A_{12}B_{21}, \quad & C_{12} &= A_{11}B_{12} + A_{12}B_{22}, \\ C_{21} &= A_{21}B_{11} + A_{22}B_{21}, \quad & C_{22} &= A_{21}B_{12} + A_{22}B_{22}. \end{aligned}$$

8. If $n = 2m$, the four blocks C_{ij} of Fact 7 can be computed by means of Strassen's formula with 7 $m \times m$ matrix multiplications and 18 $m \times m$ matrix additions, i.e., with $7(2m^3 - m^2) + 18m^2$ arithmetic operations. The arithmetic cost of matrix multiplication is reduced roughly by a factor of 7/8.
9. [Str69] *Strassen's algorithm.* Furthermore, if m is even then the seven $m \times m$ matrix products of Fact 8 can be computed once again by means of Strassen's formula. If $n = 2^k$, k a positive integer, Strassen's formula can be repeated recursively until the size of the blocks is 1. Algorithm 2 synthesizes this computation.
10. The number $M(k)$ of arithmetic operations required by Algorithm 2 to multiply $2^k \times 2^k$ matrices is such that $M(k) = 7M(k-1) + 18\left(2^{k-1}\right)^2$, $M(0) = 1$, which provides $M(k) = 7 \cdot 7^k - 6 \cdot 4^k = 7n^{\log_2 7} - 6n^2$, where $n = 2^k$ and $\log_2 7 = 2.8073\ldots < 3$. This yields the bound $\omega \leq \log_2 7$ on the exponent ω of matrix multiplication complexity.
11. In practice it is not convenient to carry out Strassen's algorithm up to matrices of size 1. In fact, for 2×2 matrices Strassen's formula requires much more operations than the conventional multiplication formula (see Fact 61.1.5). Therefore, in the actual implementation the recursive iteration of Strassen's algorithm is stopped at size $p = 2^r$, where p is the largest value such that the conventional method applied to $p \times p$ matrices is faster than Strassen's method.
12. Strassen's algorithm can be carried out even though n is not an integer power of 2. Assume that $2^{k-1} < n < 2^k$, set $p = 2^k - n$, and embed the matrices A, B, C into matrices $\widehat{A}$, $\widehat{B}$, $\widehat{C}$ of size 2^k in the following way:

   $$\widehat{A} = \begin{bmatrix} A & \mathbf{0}_{n \times p} \\ \mathbf{0}_{p \times n} & \mathbf{0}_{p \times p} \end{bmatrix}, \ \widehat{B} = \begin{bmatrix} B & \mathbf{0}_{n \times p} \\ \mathbf{0}_{p \times n} & \mathbf{0}_{p \times p} \end{bmatrix}, \ \widehat{C} = \begin{bmatrix} C & \mathbf{0}_{n \times p} \\ \mathbf{0}_{p \times n} & \mathbf{0}_{p \times p} \end{bmatrix}.$$

   Then one has $\widehat{C} = \widehat{A}\widehat{B}$ so that Strassen's algorithm can be applied to $\widehat{A}$ and $\widehat{B}$ in order to compute C. Even in this case the cost of Strassen's algorithm is still $O(n^{\log_2 7})$.

```
Algorithm 2. Strassen's algorithm
Procedure Strassen($k$,$A$,$B$)
Input: the elements $a_{ij}$ and $b_{ij}$ of the $2^k \times 2^k$ matrices $A$ and $B$;
Output: the elements $c_{ij}$ of the $2^k \times 2^k$ matrix $C = AB$;
if $k = 0$ then
    output $c_{11} = a_{11}b_{11}$;
else
    partition $A$, $B$, and $C$ into $2^{k-1} \times 2^{k-1}$ blocks $A_{ij}, B_{ij}, C_{ij}$, respectively,
    where $i, j = 1, 2$;
    compute
      $P_1 = A_{12} - A_{22}$,  $Q_1 = B_{21} + B_{22}$,  $P_5 = A_{11}$,            $Q_5 = B_{12} - B_{22}$,
      $P_2 = A_{11} + A_{22}$,  $Q_2 = B_{11} + B_{22}$,  $P_6 = A_{22}$,            $Q_6 = B_{21} - B_{11}$,
      $P_3 = A_{11} - A_{21}$,  $Q_3 = B_{11} + B_{12}$,  $P_7 = A_{21} + A_{22}$,  $Q_7 = B_{11}$,
      $P_4 = A_{11} + A_{12}$,  $Q_4 = B_{22}$,
    for $i = 1$ to $7$ do
      $M_i = \text{Strassen}\,(k-1, P_i, Q_i)$;
    end for
    compute
    $C_{11} = M_1 + M_2 - M_4 + M_6$,   $C_{12} = M_4 + M_5$,
    $C_{21} = M_6 + M_7$,               $C_{22} = M_2 - M_3 + M_5 - M_7$.
end if
```

13. [Hig02, p. 440] *Numerical stability of Strassen's algorithm.* Let $\widetilde{C}$ be the $n \times n$ matrix obtained by performing Strassen's algorithm in floating point arithmetic with machine precision ϵ where $n = 2^k$. Then the following bound holds: $\max_{i,j} |\widetilde{c}_{ij} - c_{ij}| \leq \gamma_n \epsilon \max_{i,j} |a_{ij}| \max_{i,j} |b_{ij}| + O(\epsilon^2)$, where $\gamma_n = 6n^{\log_2 12}$ and $\log_2 12 \approx 3.585$. Thus, Strassen's algorithm has slightly less favorable stability properties than the conventional algorithm: the error bound does not hold component-wise but only norm-wise, and the multiplicative factor $6n^{\log_2 12}$ is larger than the factor n^2 of the bound given in Fact 61.1.4.
14. [BCS97] Let t and r be the minimum number of nonscalar multiplications for computing a bilinear map, say $n \times n$ matrix multiplication, by means of a bilinear algorithm and by means of a quadratic algorithm, respectively. Then $r \leq t \leq 2r$. Therefore, in order to evaluate the exponent of matrix multiplication it is not loss of generality to restrict the attention to bilinear algorithms.

Examples:

1. For $n = 16$, applying the basic Strassen algorithm to the 2×2 block matrices with blocks of size 8 and computing the seven products with the conventional algorithm requires $7 * (2 * 8^3 - 8^2) + 18 * 8^2 = 7872$ arithmetic operations. Using the conventional algorithm requires $2 * 16^3 - 16^2 = 7936$ arithmetic operations. Thus, it is convenient to stop the recursion of Algorithm 2 when $n = 16$. A similar analysis can be performed if the Winograd commutative formula of Fact 1 is used.

61.3 Other Algorithms

Facts:

1. [Win71] *Winograd's formula.* The following identities enable one to compute the prod-

uct of 2×2 matrices with 7 multiplications and with 15 additions; this is the minimum number of additions among bilinear algorithms for multiplying 2×2 matrices with 7 multiplications:

$$\begin{array}{llll}
s_1 = a_{21} + a_{22}, & s_2 = s_1 - a_{11}, & s_3 = a_{11} - a_{21}, & s_4 = a_{12} - s_2, \\
t_1 = b_{12} - b_{11}, & t_2 = b_{22} - t_1, & t_3 = b_{22} - b_{12}, & t_4 = t_2 - b_{21}, \\
m_1 = a_{11}b_{11}, & m_2 = a_{12}b_{21}, & m_3 = s_4 b_{22}, & m_4 = a_{22}t_4, \\
m_5 = s_1 t_1, & m_6 = s_2 t_2, & m_7 = s_3 t_3, & \\
u_1 = m_1 + m_6, & u_2 = u_1 + m_7, & u_3 = u_1 + m_5, & \\
c_{11} = m_1 + m_2, & c_{12} = u_3 + m_3, & & \\
c_{21} = u_2 - m_4, & c_{22} = u_2 + m_5. & &
\end{array}$$

The numerical stability of the recursive version of Winograd's formula is slightly inferior since the error bound of Fact 61.2.13 holds with $\gamma_n = 12n^{\log_2 18}$, $\log_2 18 \approx 4.17$.

2. [Win71], [BD78], [AS81] No algorithm exists for multiplying 2×2 matrices with less than 7 multiplications. The number of nonscalar multiplications needed for multiplying $n \times n$ matrices is at least $2n^2 - 1$.
3. If $n = 3^k$, the matrices A, B, and C can be partitioned into 9 blocks of size $n/3$ so that $n \times n$ matrix multiplication is reduced to computing the product of 3×3 block matrices. Formulas for 3×3 matrix multiplication that do not use the commutative property, i.e., bilinear algorithms, can be recursively used for general $n \times n$ matrix multiplication.
4. In general, if there exists a bilinear formula for computing the product of $q \times q$ matrices with t nonscalar multiplications, then matrices of size $n = q^k$ can be multiplied with the cost of $O(q^t) = O(n^{\log_q t})$ arithmetic operations.
5. There exist bilinear algorithms for multiplying 3×3 matrices that require 25 multiplications [Gas71], 24 multiplications [Fid72], and 23 multiplications [Lad76]. None of these algorithms beats Strassen's algorithm since $\log_3 21 < \log_2 7 < \log_3 22$. No bilinear algorithm is known for multiplying 3×3 matrices with less than 23 nonscalar multiplications.
6. [HM73] *Rectangular matrix multiplication and the duality property.* If there exists a bilinear algorithm for multiplying two (rectangular) matrices of size $n_1 \times n_2$ and $n_2 \times n_3$, respectively, with t nonscalar multiplications, then there exist bilinear algorithms for multiplying matrices of size $n_{\sigma_1} \times n_{\sigma_2}$ and $n_{\sigma_2} \times n_{\sigma_3}$ with t nonscalar multiplications for any permutation $\sigma = (\sigma_1, \sigma_2, \sigma_3)$.
7. If there exists a bilinear algorithm for multiplying $n_1 \times n_2$ and $n_2 \times n_3$ matrices with t nonscalar multiplications, then square matrices of size $q = n_1 n_2 n_3$ can be multiplied with t^3 multiplications.
8. From Fact 7 and Fact 4 it follows that if there exists a bilinear algorithm for multiplying $n_1 \times n_2$ and $n_2 \times n_3$ matrices with t nonscalar multiplications, then $n \times n$ matrices can be multiplied with $O(n^w)$ arithmetic operations, where $w = \log_{n_1 n_2 n_3} t^3$.
9. [HK71] There exist bilinear algorithms for multiplying matrices of size 2×2 and 2×3 with 11 multiplications; there exist bilinear algorithms for multiplying matrices of size 2×3 and 3×3 with 15 multiplications.
10. There are several implementations of fast algorithms for matrix multiplication based on Strassen's formula and on Winograd's formula. In 1970, Brent implemented Strassen's algorithm on an IBM 360/67 (see [Hig02, p. 436]). This implementation was faster than the conventional algorithm already for $n \geq 110$. In 1988, Bailey provided a Fortran implementation for the Cray-2. Fortran codes, based on the Winograd variant have been provided since the late 1980s. For detailed comments and for more bibliography in this regard, we refer the reader to [Hig02, Sect. 23.3]. Effective parallel implementations of fast algorithms for matrix multiplication designed to minimize the communication cost are given in [BDH12].

61.4 Approximation Algorithms

Matrices can be multiplied faster if we allow that the matrix product can be affected by some arbitrarily small nonzero error. For the sake of simplicity, throughout this section the underlying field $\mathbb{F}$ is $\mathbb{R}$ or $\mathbb{C}$. However, almost all the results that we report hold over arbitrary fields. Here, we introduce a parameter $\lambda \in \mathbb{F}$ that represents a nonzero number with small modulus. Multiplication by λ and λ^{-1} is negligible in the complexity estimate for two reasons: first, by choosing λ equal to a power of 2, multiplication by λ can be accomplished by shifting the exponent in the base-two representation of floating point numbers. This operation has a cost lower than the cost of multiplication. Second, in the block application of matrix multiplication algorithms, multiplication by λ corresponds to multiplying an $m \times m$ matrix by the scalar λ. This operation costs only m^2 arithmetic operations like matrix addition.

Definitions:

Algorithms for multiplying the $p \times p$ matrices A and B of the form

$$\begin{aligned} m_k &= \left(\sum_{i,j=1}^{p} \alpha_{i,j,k} a_{i,j} \right) \left(\sum_{i,j=1}^{p} \beta_{i,j,k} a_{i,j} \right), \quad k = 1, \ldots t, \\ c_{i,j} &= \sum_{k=1}^{t} \gamma_{i,j,k} m_k + \lambda p_{i,j}(\lambda), \end{aligned}$$

where $\alpha_{i,j,k}, \beta_{i,j,k}, \gamma_{i,j,k}$ are given rational functions of λ and $p_{i,j}(\lambda)$ are bilinear forms in the entries of A and B, respectively, with coefficients that are polynomials in λ, are called bilinear **arbitrary precision approximating (APA) algorithms** [Bin80], [BCL79]. A quadratic APA algorithm is defined similarly. Without loss of generality one may assume that $\alpha_{i,j,k}$, $\beta_{i,j,k}$ are polynomials and that the rational functions $\gamma_{i,j,k}$ have denominators powers of λ.

Facts:

1. [BLR80] The matrix-vector product

$$\begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = \begin{bmatrix} a & b \\ 0 & a \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} ax + by \\ ay \end{bmatrix}$$

cannot be computed with less than three multiplications. However, the following bilinear APA algorithm approximates f_1 and f_2 with two nonscalar multiplications:

$$\begin{aligned} &m_1 = (a + \lambda b)(x + \lambda^{-1} y), \quad m_2 = ay, \\ &f_1 \approx f_1 + \lambda bx = m_1 - \lambda^{-1} m_2, \\ &f_2 = m_2. \end{aligned}$$

The algorithm is not defined for $\lambda = 0$, but for $\lambda \to 0$ the output of the algorithm converges to the exact solution if performed in exact arithmetic.

2. [BCL79] Consider the 2×2 matrix product $C = AB$ where $a_{12} = 0$, i.e.,

$$\begin{bmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{bmatrix} = \begin{bmatrix} a_{11} & 0 \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{bmatrix}.$$

The elements c_{ij} can be approximated with 5 nonscalar multiplications by means of the following noncommutative identities:

$$\begin{aligned}
&m_1 = (a_{11} + a_{22})(b_{12} + \lambda b_{21}), \quad m_2 = a_{11}(b_{11} + \lambda b_{21}), \quad m_3 = a_{22}(b_{12} + \lambda b_{22}),\\
&m_4 = (a_{11} + \lambda a_{21})(b_{11} - b_{12}), \quad m_5 = (\lambda a_{21} - a_{22})b_{12},\\
&c_{11} = m_2 - \lambda a_{11}b_{21}, \qquad\qquad\quad c_{12} = m_1 - m_3 - \lambda(a_{11}b_{21} + a_{22}b_{21} - a_{22}b_{22}),\\
&c_{21} = \lambda^{-1}(m_1 - m_2 + m_4 + m_5), \quad c_{22} = \lambda^{-1}(m_3 + m_5).
\end{aligned}$$

3. Formulas of Fact 2 can be suitably adjusted to the case where only the element a_{21} of the matrix A is zero.
4. The product of a 3×2 matrix and a 2×2 matrix can be approximated with 10 nonscalar multiplications by simply combining the formulas of Fact 2 and of Fact 3 in the following way:

$$\begin{bmatrix} \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \end{bmatrix} = \left(\begin{bmatrix} \# & \# \\ 0 & \# \\ 0 & 0 \end{bmatrix} + \begin{bmatrix} 0 & 0 \\ \star & 0 \\ \star & \star \end{bmatrix} \right) \begin{bmatrix} \cdot & \cdot \\ \cdot & \cdot \end{bmatrix}.$$

5. Facts 61.3.4, 61.3.7, and 61.3.8 are still valid for APA algorithms. By Fact 61.3.7 it follows that 1000 nonscalar multiplications are sufficient to approximate the product of 12×12 matrices.
6. By Fact 61.3.8 it follows that $O(n^{\log_{12} 1000})$ arithmetic operations are sufficient to approximate the product of $n \times n$ matrices, where $\log_{12} 1000 = 2.7798\ldots < \log_2 7$.
7. [BLR80] A rounding error analysis of an APA algorithm shows that the relative error in the output is bounded by $\alpha\lambda^h + \epsilon\beta\lambda^{-k}$, where α and β are positive constants depending on the input values, h and k are positive constants depending on the algorithm, and ϵ is the machine precision. This bound grows to infinity as λ converges to zero. However, setting $\lambda = \epsilon^{\frac{1}{h+k}}$, one obtains the bound $\gamma\epsilon^{\frac{h}{h+k}}$, for a constant γ. This bound is asymptotically optimal for $\epsilon \to 0$.
8. [Bin80] *From approximate to exact computations.* Given a bilinear APA algorithm for approximating a $k \times k$ matrix product with t nonscalar multiplications, there exists a bilinear algorithm for $n \times n$ *exact* matrix multiplication requiring $O(n^w \log n)$ arithmetic operations where $w = \log_k t$. In particular, by Fact 5 an $O(n^w \log n)$ algorithm exists for exact matrix multiplication with $w = \log_{12} 1000$. This provides the bound $\omega \leq \log_{12} 1000$ for the exponent ω of matrix multiplication defined in Section 61.2.
9. The exact algorithm is obtained from the approximate algorithm by applying the approximate algorithm with $O(\log n)$ different values (not necessarily small) of λ and then taking a suitable linear combination of the $O(\log n)$ different values obtained in this way in order to get the exact product. More details on this approach, which is valid for any APA algorithm that does not use the commutative property of multiplication, can be found in [Bin80]; see also the book [BCS97]. As an example of this property, the algorithm of Fact 1 computes $f_1(\lambda) = f_1 + \lambda bx$ that is close to f_1 for a small lambda. On the other hand, one has $f_1 = (f_1(1)+f_1(-1))/2$; i.e., a linear combination of the values computed by the APA algorithm with $\lambda = 1$ and with $\lambda = -1$ provides exactly f_1.
10. [Bin84] The product $y = Ax$ of the $n \times 2$ matrix A by the vector y of length 2 can be computed with $n+1$ nonscalar multiplications by using the following quadratic APA algorithm:

$$\begin{aligned}
&m_1 = x_1x_2\epsilon^{-1}\\
&m_i = (a_{i1} + x_2\epsilon^{-1})(x_1 + a_{i2}\epsilon), \quad i = 1, \ldots, n,\\
&y_i = m_i - m_1 + a_{i1}a_{i2}\epsilon, \qquad\quad\;\; i = 1, \ldots, n.
\end{aligned}$$

In particular the product of a 2×2 matrix and a vector can be approximated with 3 nonscalar multiplications.

11. [Bin84] It follows that the product $C = AB$ of 2×2 matrices can be approximated with 6 multiplications by means of the following quadratic algorithm:

$$\begin{aligned}
m_1 &= b_{11}b_{21}\epsilon^{-1}, & m_2 &= b_{12}b_{22}\epsilon^{-1} \\
m_3 &= (a_{11} + b_{21}\epsilon^{-1})(b_{11} + a_{12}\epsilon), & m_4 &= (a_{21} + b_{21}\epsilon^{-1})(b_{11} + a_{22}\epsilon), \\
m_5 &= (a_{11} + b_{22}\epsilon^{-1})(b_{12} + a_{12}\epsilon), & m_6 &= (a_{21} + b_{22}\epsilon^{-1})(b_{12} + a_{22}\epsilon), \\
c_{11} &= m_3 - m_1 + a_{11}a_{12}\epsilon, & c_{21} &= m_4 - m_1 + a_{21}a_{22}\epsilon \\
c_{12} &= m_5 - m_2 + a_{11}a_{12}\epsilon, & c_{22} &= m_6 - m_1 + a_{21}a_{22}\epsilon
\end{aligned}$$

12. Similarly, relying on Fact 10, the product of 3×3 matrices can be approximated by a quadratic algorithm in 21 multiplications. The product of 4×4 matrices can be approximated by a quadratic APA algorithm in 40 multiplications.
13. The product of 3×3 matrices can be approximated with 21 multiplications by means of a bilinear APA algorithm [Sch81].

61.5 The Tensor of Matrix Multiplication

The complexity of matrix multiplication, and more generally the complexity of bilinear maps, can be analyzed in terms of the rank of the associated tensor. For a large part of the results of this section, we refer the reader to the book [BCS97].

Facts:

1. *Complexity and tensor rank.* Given two $n \times n$ matrices A and B, the elements c_{ij} of the matrix product $C = AB$ are bilinear forms of the entries a_{ij} and b_{ij}. That is, C is a bilinear map. More specifically, denoting by a and b the vectors obtained, say, by stacking the columns of A and the rows of B, respectively, one finds that the entries c_{ij} can be written as $c_{ij} = a^T H^{(i,j)} b$, where $H^{(i,j)}$ for $i, j = 1, \dots, n$ are suitable $n^2 \times n^2$ matrices with entries in $\{0, 1\}$. For instance, if $n = 2$, then

$$a^T = (a_{11}, a_{21}, a_{12}, a_{22}), \quad b^T = (b_{11}, b_{12}, b_{21}, b_{22})$$

and

$$H^{(1,1)} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, H^{(2,1)} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix},$$

$$H^{(1,2)} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix}, H^{(2,2)} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

The three-way array of size $n^2 \times n^2 \times n^2$ whose slices are the matrices $H^{(i,j)}$, $i, j = 1, \dots, n$ is said **tensor of** $n \times n$ **matrix multiplication**. The entries of this tensor define the constants $\alpha_{i,j,k}$ introduced in the definition of bilinear map given in Section 61.2.

2. The tensor of $n \times n$ matrix multiplication has slices given by $H^{(i,j)} = I_n \otimes (e_i e_j^T)$, $i, j = 1, \dots, n$, where e_i, $i = 1, \dots, n$ are the vectors of the standard basis of $\mathcal{F}^n$, and $\otimes$ is the Kronecker product. The tensor associated with the multiplication of an $m \times p$

matrix and a $p \times n$ matrix has slices $H^{(i,j)} = I_p \otimes (e'_i \otimes e''_j)$ where e'_i, $i = 1, \ldots, m$ and e''_j, $j = 1, \ldots, n$ are the vectors of the standard bases of $\mathcal{F}^m$ and $\mathcal{F}^n$, respectively. This tensor is denoted by $\langle m, p, n \rangle$, its size is $(pm) \times (pn) \times (mn)$.

3. The tensor $\langle m, p, n \rangle$ can be viewed as the Kronecker product of three tensors of size $p \times p \times 1$, $m \times 1 \times m$, $1 \times n \times n$, formed by an identity matrix of size p, m, and n, respectively.
4. Any set $f_k(x, y) = x^T H^{(k)} y$, $k = 1, \ldots, p$ of bilinear forms, where x, y are vectors of indeterminates of length m and n, respectively, and $H^{(k)} = (h_{i,j,k})$ for $k = 1, \ldots, p$ are $m \times n$ matrices, provides a bilinear map associated with the $m \times n \times p$ tensor $\mathcal{H} = (h_{i,j,k})$.
5. An $m \times n \times p$ tensor $\mathcal{T}$ has rank one if there are vectors $u = (u_i), v = (v_j)$ and $w = (w_k)$ of length m, n, and p, respectively, such that $\mathcal{T} = (u_i v_j w_k)$. The bilinear forms associated with a rank-1 tensor are given by $w_k(\sum_i x_i a_i)(\sum_j b_j y_j)$, $k = 1, \ldots, p$, and can be computed with one nonscalar multiplication by a bilinear algorithm.
6. The rank $R(\mathcal{H})$ of an $m \times n \times p$ tensor $\mathcal{H}$ is defined as the minimum number t such that $\mathcal{H} = \sum_{s=1}^{t} \mathcal{T}_s$, where $\mathcal{T}_s = (u_{i,s} v_{j,s} w_{k,s})$, $s = 1, \ldots, R(\mathcal{H})$ are rank-one tensors; see Chapters 14 and 15.
7. Given an $m \times n \times p$ tensor $\mathcal{H}$ with slices $H^{(k)}$, $k = 1, \ldots, p$ and an additive decomposition $\mathcal{H} = \sum_{s=1}^{t} \mathcal{T}_s$ in terms of rank one tensors $\mathcal{T}_s = (u_{i,s} v_{j,s} w_{k,s})$, the bilinear forms $f_k(x, y) = x^T H^{(k)} y$, $k = 1, \ldots, p$, associated with $\mathcal{H}$ can be computed with t nonscalar multiplications by the following bilinear algorithm:

$$\begin{array}{ll} m_s = (\sum_{i=1}^{m} u_{i,s} x_i)(\sum_{j=1}^{n} v_{j,s} y_j), & s = 1, \ldots, t \\ f_k(x, y) = \sum_{s=1}^{t} w_{k,s} m_s, & k = 1, \ldots, p. \end{array}$$

8. [BCS97] The rank of $\mathcal{H}$ coincides with the minimum number of nonscalar multiplications sufficient to compute with a bilinear algorithm the bilinear forms associated with $\mathcal{H}$.
9. All the bilinear algorithms for matrix multiplication can be associated with an additive decomposition of the tensor $\langle m, p, n \rangle$ in terms of rank-one tensors.
10. *Approximate decomposition.* A decomposition of the kind

$$\mathcal{H} = \sum_{s=1}^{t} \mathcal{T}_s(\lambda) + \lambda \mathcal{K}(\lambda)$$

where $\mathcal{T}_s(\lambda)$ are rank one tensors whose entries are rational functions of λ and $\mathcal{K}(\lambda)$ is a tensor whose entries are polynomials in λ is called *approximate decomposition* of length t of $\mathcal{H}$. Without loss of generality one can assume that the entries of $\mathcal{T}_s(\lambda)$ are polynomials divided by a positive integer power of λ. If λ is small in modulus, then the above equation provides an approximation of $\mathcal{H}$ by means of the tensor $\sum_{s=1}^{t} \mathcal{T}_s(\lambda)$ of rank at most t.

11. [BLR80] *Approximate complexity and border rank.* There are tensors which, under a nonzero but arbitrarily small perturbation, decrease their rank. For instance, the $2 \times 2 \times 2$ tensor with slices $\left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$ and $\left[\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right]$ has rank three, while, for any $\lambda \neq 0$ the tensor with slices $\left[\begin{smallmatrix} 1 & 0 \\ 0 & 1 \end{smallmatrix}\right]$ and $\left[\begin{smallmatrix} 0 & 1 \\ \lambda & 0 \end{smallmatrix}\right]$ has rank two. Given the tensor $\mathcal{H}$ of rank t, the minimum $\underline{t}$ of the set of integers q for which there exists an approximate decomposition of $\mathcal{H}$ of length q is called the *border rank* of $\mathcal{H}$ and is denoted by $\underline{R}(\mathcal{H})$. The above example shows that there are tensors $\mathcal{H}$ such that $\underline{R}(\mathcal{H}) < R(\mathcal{H})$. The definition of border rank has been given in [BLR80] and refined in [Sch81]. Properties of border rank have been analyzed in many papers; for more details we refer the reader to Chapter 15 of the book [BCS97], and to Chapter 15 of this Handbook.

12. The minimum number of nonscalar multiplications sufficient to compute a bilinear map by a bilinear APA algorithm coincides with the border rank of the associate tensor [BLR80], [BCS97].
13. The approximate algorithms for matrix multiplication are associated with approximate decompositions of the tensor $\langle m, p, n\rangle$.
14. Border rank is not additive with respect to the direct sum of tensors. This fact has been pointed out by Scönhage in [Sch81], but an example of this fact was also implicitly given in a previous paper by Pan [Pan79]. Given two tensors $\mathcal{H}_1$ and $\mathcal{H}_2$ of size $m_1 \times n_1 \times p_1$ and $m_2 \times n_2 \times p_2$, respectively, their direct sum $\mathcal{H}_1 \oplus \mathcal{H}_2$ is the tensor of size $(m_1 + m_2) \times (n_1 + n_2) \times (p_1 + p_2)$, which coincides with $\mathcal{H}_1$ for $(i, j, k) \in \{1, \ldots, m_1\} \times \{1, \ldots, n_1\} \times \{1, \ldots, p_1\}$, coincides with $\mathcal{H}_2$ for $(i, j, k) \in \{m_1 + 1, \ldots, m_1 + m_2\} \times \{n_1 + 1, \ldots, n_1 + n_2\} \times \{p_1 + 1, \ldots, p_1 + p_2\}$, and is zero elsewhere.

    The example provided by Schönhage shows that

    $$\underline{R}(\langle m, 1, n\rangle \oplus \langle 1, (m-1)(n-1), 1\rangle = mn + 1$$

    while

    $$\underline{R}(\langle m, 1, n\rangle) = mn, \quad \underline{R}(\langle 1, (m-1)(n-1), 1\rangle = (m-1)(n-1).$$

61.6 Advanced Techniques

More advanced techniques have been introduced for designing fast algorithms for $n \times n$ matrix multiplication. The asymptotically fastest algorithm currently known requires $O(n^{2.373})$ arithmetic operations, but it is faster than the conventional algorithm only for huge values of n. Finding the infimum ω of the numbers w for which there exist $O(n^w)$ complexity algorithms is still an open problem. In this section, we provide a list of the main techniques used for designing asymptotically fast algorithms for $n \times n$ matrix multiplication.

Facts:

1. [Pan78] *Trilinear aggregating technique.* Different schemes for (approximate) matrix multiplication are based on the technique of trilinear aggregating by Pan. The technique relies on the fact that computing the trace of the product of three $n \times n$ matrices is equivalent to the problem of multiplying $n \times n$ matrices. Trilinear aggregating is very versatile: Different algorithms based on this technique have been designed for fast matrix multiplication of several sizes [Pan84]; in particular, an algorithm for multiplying 70×70 matrices with 143,640 multiplications which leads to the bound $\omega < 2.7952$.
2. [Sch81] *Partial matrix multiplication.* In the expression

    $$c_{ij} = \sum_{r=1}^{m} a_{ij} b_{ij}, \quad i, j = 1, \ldots, m,$$

    there are m^3 terms which are summed up. A *partial matrix multiplication* is encountered if some a_{ij} or some b_{ij} are zero, or if not all the elements c_{ij} are computed so that in the above expression there are less than m^3 terms, say, $k < m^3$. Schönhage [Sch81] has proved that if there exists a bilinear (APA) algorithm for computing (approximating) partial $m \times m$ matrix multiplication with k terms that uses t nonscalar multiplications, then $\omega \leq 3 \log_k t$. This result applied to the formula of Fact 61.4.2, which indeed is a partial matrix multiplication, provides the bound $\omega \leq 3 \log_6 5 < 2.695$.

3. [Sch81] *Disjoint matrix multiplication* Fact 61.5.14 shows that it is possible to approximate two disjoint matrix products with less multiplications than the number of multiplications needed for computing separately these products. In particular, from the approximate decomposition provided by Schönhage of the tensor $\langle m,1,n\rangle \oplus \langle 1,(m-1)(n-1),1\rangle$ it follows a bilinear APA algorithm for simultaneously multiplying an $m\times 1$ matrix by a $1\times n$ matrix and a $1\times(m-1)(n-1)$ matrix by an $(m-1)(n-1)\times 1$ matrix with only $mn+1$ nonscalar multiplications. Observe that mn multiplications are *needed* for the former product and $(m-1)(n-1)$ multiplications are *needed* for the latter.
4. [Sch81] *The τ-theorem.* Schönhage has proven the τ-theorem. Namely, if the set of disjoint matrix products of size $m_i \times n_i$ times $n_i \times p_i$, for $i=1,\ldots,k$ can be approximated with t nonscalar multiplications by a bilinear APA algorithm, then $\omega \le 3\tau$, where τ solves the equation $\sum_{i=1}^{k}(m_i n_i p_i)^\tau = t$. From the disjoint matrix multiplication of Fact 3 with $m=n=4$ it follows the equation $16^\tau + 9^\tau = 17$, which yields $\omega \le 3\tau = 2.5479\ldots$. In the same paper, combining his work with ideas by Pan, Schönhage arrived at the bound $\omega < 2.522$.
5. [CW82] Relying on the τ-theorem, Coppersmith and Winograd arrived at the bound $\omega < 2.496$.
6. [Str87] *The laser method.* In 1987, Strassen introduced a powerful and sophisticated method, which, by taking tensor powers of a set of bilinear forms that apparently are not related to matrix multiplication, provides some scheme for fast matrix multiplication. The name *laser method* was motivated from the fact that by tensor powering a set of "incoherent" bilinear forms it is possible to obtain a "coherent" set of bilinear forms.
7. [CW90] Coppersmith and Winograd combined the laser technique with a novel form of analysis based on large sets avoiding arithmetic progressions and relying on the Salem Spencer theorem [SS42]. By taking the second power of a suitable tensor, they arrived at the bound $\omega < 2.376$, which has remained unchanged for more than 20 years.
8. [CU03] Cohn and Umans introduced a new, group-theoretic framework for designing and analyzing matrix multiplication algorithms. In [CKS05], together with Kleinberg and Szegedy, they introduced several novel matrix multiplication algorithms relying on the new theoretical context, but they were not able to improve the record exponent. In the group-theoretic framework, they provided new conjectures which, if true, would imply that $\omega = 2$.
9. [Sto10] Stothers, in his Ph.D. thesis, has elaborated the method of Coppersmith and Winograd of Fact 7 and shown that by taking the fourth power of the tensor of Coppersmith and Winograd the exponent of matrix multiplication can be bounded by $\omega < 2.3737$.
10. [Wi11] Williams has independently obtained the slightly better bound $\omega < 2.3727$ by elaborating the eighth power of the tensor of Coppersmith and Winograd.
11. *Lower bounds.* At least $2n^2-1$ multiplications are needed for multiplying $n\times n$ matrices by means of noncommutative algorithms [BD78]. At least $(m+p)n+p-n-1$ multiplications are needed for multiplying an $m\times p$ matrix by an $p\times n$ matrix [LW78]. If $n,m \ge 3$, then $2mn+2n-m-2$ multiplications are needed for multiplying an $n\times m$ matrix by an $m\times n$ matrix [Bla03]. For $m=n\ge 3$ one gets the lower bound $2n^2+n-2$ for $n\times n$ matrix multiplication, in particular, computing the product of 3×3 matrices requires at least 19 multiplications. The lower bound $\frac{5}{2}n^2-3n$ has been proved in [Bla01]. This lower bound has been asymptotically improved by [Lan12] to $3n^2-4n^{3/2}+n$ and, if $n=4m^2$, to $3n^2-4n^{3/2}+3n$. The further slight improvement $3n^2-2\sqrt{2}n^3/2-3n$ has been provided by [MR12].

The nonlinear asymptotic lower bound $n^2 \log n$ has been proved in [Raz03]. This bound is proved in the bounded coefficient model in which scalar multiplication is restricted to scalars of bounded absolute value.

At least $n^2 + 2n - 2$ multiplications are needed for approximating the product of $n \times n$ matrices by means of a bilinear APA algorithm [Bin84]. The lower bound turns to $n^2 + \frac{3}{2}n - 2$ multiplications if commutativity is allowed. Seven multiplications are needed for approximating 2×2 matrix product by means of bilinear APA algorithms [Lan06]. If $n \geq 3$, at least $\frac{3}{2}n^2 + \frac{1}{2}n - 1$ multiplications are needed to approximate $n \times n$ matrix product by means of a bilinear algorithm [Lic84]. In [LO12] the lower bound has been improved to $2n^2 - n$.

12. *History of matrix multiplication complexity.* After the 1969 paper by Strassen [Str69], where it was shown that $O(n^{\log_2 7})$ operations were sufficient for $n \times n$ matrix multiplication and inversion, the exponent ω of matrix multiplication complexity remained stuck at 2.807 for almost 10 years until Pan, relying on the technique of trilinear aggregating, provided a bilinear algorithm for 70×70 matrix multiplication using 143,640 products. This led to the upper bound $\omega \leq \log_{70} 143640 \approx 2.795$. A few months later, Bini, Capovani, Lotti, and Romani [BCL79] introduced the concept of APA algorithms, and presented a scheme for approximating a 12×12 matrix product with 1000 products. In [Bin80] Bini showed that from any APA algorithm for matrix multiplication it is possible to obtain an exact algorithm with almost the same asymptotic complexity. This led to the bound $\omega \leq \log_{12} 1000 \approx 2.7798$.

    In the paper [BLR80] the concept of border rank was introduced and related to the approximate complexity of bilinear forms. The technique of partial matrix multiplication was introduced by Schönhage [Sch81] in 1981 together with the τ-theorem, yielding the bound $\omega \leq 2.55$, a great improvement with respect to the previous estimates. This bound relies on the tools of trilinear aggregating and of approximate algorithms. Based on the techniques thus far developed, Pan obtained the bound $\omega < 2.53$ in [Pan80] and one year later, Romani obtained the bound $\omega < 2.52$ in [Rom82]. The landmark bound $\omega < 2.5$ was obtained by Coppersmith and Winograd [CW82] in 1982 by means of a refinement of the τ-theorem. In [Str87] Strassen introduced the powerful *laser method* and proved the bound $\omega < 2.48$. The laser method has been perfected by Coppersmith and Winograd [CW90], who proved the best estimate known until 2010, i.e., $\omega < 2.38$. In [Sto10] Stothers has obtained the bound $\omega < 2.3737$ by analyzing the fourth tensor power of the Coppersmith-Winograd tensor. Independently in 2011, Williams [Wi11] has obtained the currently best bound $\omega < 2.3727$, by manipulating the eighth power of the Coppersmith-Winograd tensor. Table 61.1 synthesizes this picture together with the main concepts used.

61.7 Applications

Some of the main applications of matrix multiplication are outlined in this section. For more details the reader is referred to [Pan84].

Definitions:

A square matrix A is **strongly nonsingular** if all its principal submatrices are nonsingular.

Facts:

1. *Classic matrix inversion.* Given a nonsingular $n \times n$ matrix A, the elements of A^{-1} can be computed by means of Gaussian elimination in $O(n^3)$ arithmetic operations.
2. *Inversion formula.* Let $n = 2m$ and partition the $n \times n$ nonsingular matrix A into four square blocks of size m as
$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}.$$
Assume that A_{11} is nonsingular. Denote $S = A_{22} - A_{21}A_{11}^{-1}A_{12}$ the Schur complement of A_{11} in A and $R = A_{11}^{-1}$. Then S is nonsingular and the inverse of A can be written as
$$A^{-1} = \begin{bmatrix} R + RA_{12}S^{-1}A_{21}R & -RA_{12}S^{-1} \\ -S^{-1}A_{21}R & S^{-1} \end{bmatrix}.$$
Moreover, $\det A = \det S \det A_{11}$.
3. *Fast matrix inversion.* Let $n = 2^k$, with k positive integer and assume that A is strongly nonsingular. Then also A_{11} and the Schur complement S are strongly nonsingular and the inversion formula of Fact 2 can be applied again to S by partitioning S into four square blocks of size $n/4$, recursively repeating this procedure until the size of the blocks is 1. The algorithm obtained in this way is described in Algorithm 3. Denoting by $\mathcal{I}(n)$ the complexity of this algorithm for inverting a strongly nonsingular $n \times n$ matrix and denoting by $\mathcal{M}(n)$ the complexity of the algorithm used for $n \times n$ matrix multiplication, we obtain the expression
$$\begin{aligned} &\mathcal{I}(n) = 2\mathcal{I}(n/2) + 6\mathcal{M}(n/2) + n^2/2, \\ &\mathcal{I}(1) = 1. \end{aligned}$$
If $\mathcal{M}(n) = O(n^w)$ with $w \geq 2$, then one deduces that $\mathcal{I}(n) = O(n^w)$. That is, the complexity of matrix inversion is not asymptotically larger than the complexity of matrix multiplication.
4. The complexity of matrix multiplication is not asymptotically greater than the complexity of matrix inversion. This property follows from the simple identity
$$\begin{bmatrix} I & A & 0 \\ 0 & I & B \\ 0 & 0 & I \end{bmatrix}^{-1} = \begin{bmatrix} I & -A & AB \\ 0 & I & -B \\ 0 & 0 & I \end{bmatrix}.$$

5. Combining Facts 3 and 4, we deduce that matrix multiplication and matrix inversion have the same asymptotical complexity.

```
Algorithm 3: Fast matrix inversion
Procedure Fast_Inversion($k, A$)
Input: the elements $a_{ij}$ of the $2^k \times 2^k$ strongly nonsingular matrix $A$;
Output: the elements $b_{ij}$ of $B = A^{-1}$.
If $k = 0$, then
    output $b_{11} = a_{11}^{-1}$;
else
    partition $A$, into $2^{k-1} \times 2^{k-1}$ blocks $A_{ij}, i, j = 1, 2$;
    set $R =$ Fast_Inversion($k - 1, A_{11}$);
    compute $S = A_{22} - A_{21}RA_{12}$ and $V =$ Fast_Inversion($k - 1, S$)
    output
    $\begin{bmatrix} R + RA_{12}VA_{21}R & -RA_{12}V \\ -VA_{21}R & V \end{bmatrix}$
```

6. The property of strong singularity for A is not a great restriction if $\mathbb{F} = \mathbb{R}$ or $\mathbb{F} = \mathbb{C}$. In fact, if A is nonsingular, then $A^{-1} = (A^*A)^{-1}A^*$ and the matrix A^*A is strongly nonsingular.
7. *Computing the determinant.* Let A be strongly nonsingular. From Fact 2, $\det A = \det S \det A_{11}$. Therefore, an algorithm for computing $\det A$ can be recursively designed by computing S and then by applying recursively this algorithm to S and to A_{11} until the size of the blocks is 1. Denoting by $\mathcal{D}(n)$ the complexity of this algorithm one has

$$\mathcal{D}(n) = 2\mathcal{D}(n/2) + \mathcal{I}(n/2) + 2\mathcal{M}(n/2) + n^2/4,$$

   hence, if $\mathcal{M}(n) = O(n^w)$ with $w \geq 2$, then $\mathcal{D}(n) = O(n^w)$. In [BS83] it is shown that $\mathcal{M}(n) = O(\mathcal{D}(n))$
8. *Computing the characteristic polynomial.* The coefficients of the characteristic polynomial $p(x) = \det(A - xI)$ of the matrix A can be computed with the same asymptotic complexity of matrix multiplication.
9. *Combinatorial problems.* The complexity of some combinatorial problems is related to matrix multiplication, in particular, the complexity of the *all pair shortest distance problem* of finding the shortest distances $d(i, k)$ from i to k for all pairs (i, k) of vertices of a given digraph. We refer the reader to Section 18 of [Pan84] for more details. The problem of Boolean matrix multiplication can be reduced to that of general matrix multiplication.

A structured matrix is an $m \times n$ matrix with elements that can be determined from substantially fewer than mn parameters. This is a broad definition that includes sparse matrices, matrices with displacement structure, matrices with rank structure, and numerous types of matrices with specialized structure. Many common matrix operations can be performed using fast algorithms that exploit matrix structure to achieve asymptotic speed-up relative to conventional algorithms. For matrices with either displacement structure or rank structure, there are fast algorithms for the solution of linear systems, inversion, QR factorization, and matrix-vector multiplication. Fast algorithms typically achieve a factor of n speed-up over their conventional counterparts. Algorithms that do better than this are sometimes referred to as superfast.

This chapter focuses on methods for dense matrices with structure. The emphasis is on direct methods, with some limited coverage of the use of fast matrix-vector multiplication in iterative methods and the choice of preconditioners for structured systems. Displacement structure is used as a unifying context for the presentation of many of the fast algorithms. Toeplitz, Vandermonde, and Cauchy matrices are covered in detail. A notable omission is the topic of fast algorithms for matrices with rank structure.

Unless otherwise noted, all matrices are assumed to be complex.

62.1 Classes of Structured Matrices

Displacement equations were introduced to derive factorization algorithms and inversion formulas for matrices with an almost Toeplitz structure [FMK79]. Since then the concept has been generalized and has served as a unifying concept in the study of algorithms for a wide range of structured matrices. This approach allows uniform derivation of fast algorithms for LU, QR, and Cholesky factorization of Toeplitz, Vandermonde, Cauchy, Hankel, and related matrices.

Definitions:

Let $A \in \mathbb{C}^{m\times n}$, $E \in \mathbb{C}^{m\times m}$, $G \in \mathbb{C}^{m\times m}$, $F \in \mathbb{C}^{n\times n}$ and $H \in \mathbb{C}^{n\times n}$.

Let the vector $\mathbf{v}_n(\alpha)$ be given by

$$\mathbf{v}_n(\alpha) = \begin{bmatrix} 1 & \alpha & \alpha^2 & \cdots & \alpha^{n-1} \end{bmatrix}^{\mathrm{T}}$$

and $\mathbf{p}_n(\alpha)$ by

$$\mathbf{p}_n(\alpha) = \begin{bmatrix} p_0(\alpha) & p_1(\alpha) & \cdots & p_{n-1}(\alpha) \end{bmatrix}^{\mathrm{T}},$$

where each $p_k(\alpha)$ is a polynomial of degree k and $\alpha \in \mathbb{C}$.

Given a vector $\boldsymbol{v} \in \mathbb{C}^n$, $D_{\boldsymbol{v}}$ is the $n \times n$ diagonal matrix with diagonal elements taken in order from the elements of $\boldsymbol{v}$.

The matrix $Z_n = [z_{jk}]$ is the $n \times n$ downshift matrix given by $z_{jk} = 1$ for $j = k+1$ and $z_{jk} = 0$ otherwise.

The matrix $Z_{\delta,n}$ denotes $Z_n + \delta \mathbf{e}_1 \mathbf{e}_n^*$.

The matrix $\Sigma_{p,q}$ is the signature matrix $\Sigma_{p,q} = I_p \oplus -I_q$.

A matrix $T = [t_{jk}] \in \mathbb{C}^{m\times n}$ is **Toeplitz** if $t_{jk} = t_{j-k}$, that is if its elements are constant along diagonals.

A Toeplitz matrix $S = [s_{jk}] \in \mathbb{C}^{n\times n}$ is **circulant** if $s_{jk} = s_{(j-k) \bmod n}$.

A matrix $H = [h_{jk}] \in \mathbb{C}^{m\times n}$ is **Hankel** if $h_{jk} = h_{j+k}$; that is, if its elements are constant along cross diagonals.

A matrix $V \in \mathbb{C}^{m\times n}$ is **Vandermonde** if

$$V = \begin{bmatrix} \mathbf{v}_n(\alpha_1)^{\mathrm{T}} \\ \mathbf{v}_n(\alpha_2)^{\mathrm{T}} \\ \vdots \\ \mathbf{v}_n(\alpha_m)^{\mathrm{T}} \end{bmatrix}$$

for some set of distinct complex nodes $\{\alpha_1, \alpha_2, \ldots, \alpha_n\}$. Some authors use the transpose of V as the definition of a Vandermonde matrix.

Given a set of p distinct complex nodes $\{\alpha_1, \alpha_2, \ldots, \alpha_p\}$ and a multiset of size n formed from the α_k by including n_k repetitions of α_k, where $\sum_{k=1}^{p} n_k = n$, a matrix $V \in \mathbb{C}^{m\times n}$ is **confluent Vandermonde** if

$$V = \begin{bmatrix} V_1(\alpha_1) \\ V_2(\alpha_2) \\ \vdots \\ V_p(\alpha_p) \end{bmatrix},$$

where

$$V_k(\alpha) = \begin{bmatrix} \mathbf{v}_n(\alpha)^{\mathrm{T}} \\ \mathbf{v}_n'(\alpha)^{\mathrm{T}} \\ \vdots \\ \mathbf{v}_n^{(n_k-1)}(\alpha)^{\mathrm{T}} \end{bmatrix}.$$

A matrix $V \in \mathbb{C}^{m\times n}$ is **polynomial Vandermonde** if

$$V = \begin{bmatrix} \mathbf{p}_n(\alpha_1)^{\mathrm{T}} \\ \mathbf{p}_n(\alpha_2)^{\mathrm{T}} \\ \vdots \\ \mathbf{p}_n(\alpha_m)^{\mathrm{T}} \end{bmatrix}$$

for some set of distinct complex nodes $\{\alpha_1, \alpha_2, \ldots, \alpha_n\}$.

A matrix $C = [c_{jk}] \in \mathbb{C}^{m\times n}$ is **Cauchy** if $c_{jk} = 1/(\alpha_j - \beta_k)$ for $\alpha_j \neq \beta_k$, $j = 1, \ldots, m$ and $k = 1, \ldots, n$.

An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form

$$\Delta(A) = A - GAH^*$$

is a **Stein type displacement operator**.

An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form

$$\Delta(A) = EA - AH^*$$

is a **Sylvester type displacement operator**.

An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form

$$\Delta(A) = EAF^* - GAH^*$$

is a **general displacement operator**.

The **displacement rank** of a matrix A with respect to a given displacement operator Δ is the rank of $\Delta(A)$.

An equation of the form

$$\Delta(A) = A - GAH^* = XY^*, \tag{62.1}$$

where $A \in \mathbb{C}^{m\times n}$, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \text{rank}(\Delta(A))$ is a **Stein type displacement equation**.

An equation of the form

$$\Delta(A) = EA - AH^* = XY^*, \tag{62.2}$$

where $A \in \mathbb{C}^{m\times n}$, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \text{rank}(\Delta(A))$ is a **Sylvester type displacement equation**.

An equation of the form

$$EAF^* - GAH^* = XY^*, \tag{62.3}$$

where $A \in \mathbb{C}^{m\times n}$, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \text{rank}(\Delta(A))$ is a **general displacement equation**.

Given a displacement equation $\Delta(A) = XY^*$, the matrices X and Y are **generators** of A.

A matrix $T \in \mathbb{C}^{m\times n}$ is **Toeplitz-like** with displacement rank r if T satisfies a displacement equation of the form

$$T - Z_m T Z_n^* = XY^* \tag{62.4}$$

or

$$Z_{1,m}^* T - T Z_{\delta,n}^* = XY^*, \tag{62.5}$$

where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$.

A matrix $H \in \mathbb{C}^{m\times n}$ is **Hankel-like** with displacement rank r if H satisfies a displacement equation of the form

$$Z_m H - H Z_n^* = XY^*,$$

where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$.

A matrix $V \in \mathbb{C}^{m\times n}$ is **Vandermonde-like** with displacement rank r if V satisfies a displacement equation of the form

$$D_{\mathbf{v}} V - V Z_{\delta,n} = XY^*, \tag{62.6}$$

where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$.

A matrix $C \in \mathbb{C}^{m\times n}$ is **Cauchy-like** with displacement rank r if C satisfies a displacement equation of the form

$$D_{\mathbf{v}} C - C D_{\mathbf{w}} = XY^*, \tag{62.7}$$

where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$.

Facts:

1. Fast algorithms often exploit the fact that a matrix has low displacement rank with respect to a particular displacement operator. However, as seen in Eq. (62.5) and Eq. (62.4), the choice of displacement equation used to define a specific class of structured matrices can vary. Different displacement equations yield different algorithms. What is important algorithmically is that the displacement rank should not vary greatly with the particular choice of displacement operator.
2. [Dav79] A circulant matrix $S \in \mathbb{C}^{n\times n}$ commutes with the cyclic shift matrix and therefore satisfies the displacement equation

   $$Z_{1,n}^* S - S Z_{1,n}^* = 0.$$

   If $\mathbf{s}_j^*$ denotes row j of S, then this displacement equation is equivalent to $\mathbf{s}_{j+1}^* = \mathbf{s}_j^* Z_{1,n}^*$ so that the rows of a circulant are generated by repeated cyclic shifting of the first row.
3. A Toeplitz matrix $T \in \mathbb{C}^{m\times n}$ has displacement rank at most two with respect to the displacement equations

   $$T - Z_m T Z_n^* = \begin{bmatrix} t_0 & 0 \\ t_{-1} & t_{-1} \\ \vdots & \vdots \\ t_{-m+1} & t_{-m+1} \end{bmatrix} \begin{bmatrix} 1 & t_1/t_0 & \cdots & t_{n-1}/t_0 \\ 0 & -t_1/t_0 & \cdots & -t_{n-1}/t_0 \end{bmatrix} \qquad (62.8)$$

   and

   $$Z_{1,m}^* T - T Z_{\delta,n}^* = \begin{bmatrix} t_{-1} - \delta t_{n-1} & 0 \\ \vdots & \vdots \\ t_{-m+1} - \delta t_{-m+n+1} & 0 \\ t_0 - \delta t_{-m+n} & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & \cdots & 0 \\ 0 & t_1 - t_{-m+1} & \cdots & t_{n-1} - t_{-m+n-1} \end{bmatrix}. \qquad (62.9)$$

4. A Hermitian Toeplitz matrix $T \in \mathbb{C}^{n\times n}$ with $t_0 > 0$ satisfies

   $$T - Z_n T Z_n^* = X \Sigma_{1,1} X^*,$$

   where

   $$X^* = \begin{bmatrix} \sqrt{t_0} & t_1/\sqrt{t_0} & \cdots & t_{n-1}/\sqrt{t_0} \\ 0 & t_1/\sqrt{t_0} & \cdots & t_{n-1}/\sqrt{t_0} \end{bmatrix}. \qquad (62.10)$$

5. A Hankel matrix $H \in \mathbb{C}^{m\times n}$ has displacement rank two with respect to the displacement equation $\Delta(H) = Z_m H - H Z_n^{\mathrm{T}} = XY^*$.
6. A Vandermonde matrix $V \in \mathbb{C}^{m\times n}$ with nodes $\alpha_1, \ldots, \alpha_m$ has displacement rank one with respect to the displacement equation

   $$D_{\mathbf{v}} V - V Z_{\delta,n} = \begin{bmatrix} \alpha_1^n - \delta \\ \vdots \\ \alpha_m^n - \delta \end{bmatrix} \begin{bmatrix} 0 & \cdots & 0 & 1 \end{bmatrix}, \qquad (62.11)$$

   where $\mathbf{v} = [\alpha_j]_{j=1}^m \in \mathbb{C}^m$.

7. A Cauchy matrix $C \in \mathbb{C}^{m\times n}$ has displacement rank 1 with respect to
$$D_{\mathbf{v}}C - CD_{\mathbf{w}} = \begin{bmatrix}1\\1\\\vdots\\1\end{bmatrix}\begin{bmatrix}1 & 1 & \cdots & 1\end{bmatrix},$$
where $\mathbf{v} = [\alpha_j]_{j=1}^m \in \mathbb{C}^m$ and $\mathbf{w} = [\beta_j]_{j=1}^n \in \mathbb{C}^n$.
8. [SK95] A displacement operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ is a linear transformation. If Δ is invertible, then it is possible to fully reconstruct A from $\Delta(A)$. A general displacement operator with lower triangular $E = [e_{jk}]_{j,k=1}^m$, $F = [f_{jk}]_{j,k=1}^n$, $G = [g_{jk}]_{j,k=1}^m$, and $H = [h_{jk}]_{j,k=1}^n$ is invertible if and only if
$$e_{jj}\overline{f}_{kk} - g_{jj}\overline{h}_{kk} \neq 0$$
for all choices of j and k. This fact can be specialized. A Sylvester type displacement operator is invertible if and only if $e_{jj} - \overline{h}_{kk}$ is always nonzero. A Stein type displacement operator is invertible if and only if $1 - g_{jj}\overline{h}_{kk}$ is always nonzero. Related conditions can be stated in terms of the generalized eigenvalues of the matrix pencils $E - \lambda G$ and $F - \lambda H$, in which case the assumption of triangularity of E, F, G, and H can be dropped. The triangular case covers all displacement operators associated with the algorithms considered in this chapter.
9. Several displacement equations allow simple reconstruction of A from $\Delta(A) = XY^*$. If $G^k = 0$ or $H^k = 0$ and if A satisfies the Stein type displacement equation (62.1), then
$$A = \sum_{j=0}^{k-1}(G)^j XY^*(H^*)^j.$$
If A satisfies an invertible Sylvester type displacement equation with $E = D_{\mathbf{e}}$, then row j of A, denoted by $\mathbf{a}_j^*$, can be obtained by solving
$$\mathbf{a}_j^*(e_jI - H^*) = \mathbf{x}_j^*Y^*,$$
where $\mathbf{x}_j^*$ is row j of X. If A satisfies an invertible Sylvester type displacement equation with $E = D_{\mathbf{e}}$ and $H = D_{\mathbf{h}}$, then individual elements of A can be computed from the formula
$$a_{jk} = \frac{\mathbf{x}_j^*\mathbf{y}_k}{e_j - \overline{h}_k},$$
where $\mathbf{y}_k^*$ is row k of Y.

Examples:

1. Given the multiset of nodes $\{\alpha_1, \alpha_1, \alpha_1, \alpha_2, \alpha_2\}$, a 5×5 confluent Vandermonde matrix formed from these nodes is
$$V = \begin{bmatrix}1 & \alpha_1 & \alpha_1^2 & \alpha_1^3 & \alpha_1^4\\ 0 & 1 & 2\alpha_1 & 3\alpha_1^2 & 4\alpha_1^3\\ 0 & 0 & 2 & 6\alpha_1 & 12\alpha_1^2\\ 1 & \alpha_2 & \alpha_2^2 & \alpha_2^3 & \alpha_2^4\\ 0 & 1 & 2\alpha_2 & 3\alpha_2^2 & 4\alpha_2^3\end{bmatrix}.$$

2. The Toeplitz matrix

$$T = \begin{bmatrix} 4 & 2 & 1 \\ 2 & 4 & 2 \\ 1 & 2 & 4 \end{bmatrix}$$

has displacement rank two with respect to the Stein type displacement equation

$$T - Z_3 T Z_3^* = \begin{bmatrix} 4 & 2 & 1 \\ 2 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix} = \begin{bmatrix} 2 & 0 \\ 1 & 1 \\ 1/2 & 1/2 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} 2 & 1 & 1/2 \\ 0 & 1 & 1/2 \end{bmatrix}.$$

This example illustrates Eq. (62.4).

62.2 Transformations of Structured Matrices

A structured matrix satisfying a displacement equation in which E, F, G, and H are all either diagonal matrices or shifts can be transformed to a Cauchy-like matrix using the discrete Fourier transform [Hei94, GKO95]. Such transformations are of great numerical significance. Most matrix structures are not preserved by the pivoting schemes typically used to stabilize Gaussian elimination. Cauchy-like structure is the exception; permuting the rows or columns of a Cauchy-like matrix results in another Cauchy-like matrix. Consequently, various pivoting schemes can be incorporated into fast solvers for Cauchy-like systems, making such solvers numerically robust even on indefinite and non-Hermitian systems. By first transforming a structured matrix to a Cauchy-like matrix, numerically robust solvers for Cauchy-like systems can be applied to Toeplitz, Hankel, Vandermonde, and other matrices with related displacement structures.

Definitions:

Let the $n \times n$ matrix $F_n = [f_{jk}] = \frac{1}{\sqrt{n}}[\omega_n^{(j-1)(k-1)}]$, where $\omega_n = e^{i2\pi/n}$, denote the unitary $n \times n$ discrete Fourier transform matrix.

Facts:

Let δ denote a positive real number and $\delta^{1/n}$ its positive nth root.

1. [Dav79]An $n \times n$ circulant matrix S with first row equal to

$$\mathbf{s}^T = \begin{bmatrix} s_0 & s_1 & \cdots & s_{n-1} \end{bmatrix}$$

has eigenvalue decomposition

$$S = F_n D_{\mathbf{v}} F_n^* \qquad (62.12)$$

where $\mathbf{v} = \sqrt{n} F_n \mathbf{s}$.

2. [Hei94, HB97] The shift matrices $Z_{1,n}$, $Z_{-1,n}$, and $Z_{\delta,n}$ satisfy

$$F_n^* Z_{1,n}^* F_n = D_{\mathbf{v}_n(\omega_n)},$$

$$F_n^* D_{\mathbf{v}_n(\omega_{2n})}^* Z_{-1,n}^* D_{\mathbf{v}_n(\omega_{2n})} F_n = \omega_{2n} D_{\mathbf{v}_n(\omega_n)},$$

and

$$F_n^* D_{\mathbf{v}_n(\delta^{1/n})}^{-1} Z_{\delta,n}^* D_{\mathbf{v}_n(\delta^{1/n})} F_n = \delta^{1/n} D_{\mathbf{v}_n(\omega_n)}.$$

3. [Hei94, HB97] If $T \in \mathbb{C}^{m\times n}$ is a Toeplitz-like matrix satisfying
$$Z_{1,m}^* T - T Z_{-1,n}^* = XY^*,$$
then $C = F_m^* T D_{\mathbf{v}_n(\omega_{2n})} F_n$ is a Cauchy-like matrix satisfying
$$D_{\mathbf{v}_m(\omega_m)} C - C(\omega_{2n} D_{\mathbf{v}_n(\omega_n)}) = F_m^* XY^* D_{\mathbf{v}_n(\omega_{2n})} F_n. \tag{62.13}$$
If $m = n$, then the sets of diagonal elements of $D_{\mathbf{v}_m(\omega_m)}$ and $\omega_{2n} D_{\mathbf{v}_n(\omega_n)}$ are disjoint and the matrix C satisfying Eq. (62.13) is uniquely determined.
4. [Gu98b] If $T \in \mathbb{C}^{m\times n}$ is a Toeplitz-like matrix satisfying
$$Z_{1,m}^* T - T Z_{\delta,n}^* = XY^*,$$
then $C = F_m^* T D_{\mathbf{v}_n(\delta^{1/n})} F_n$ is a Cauchy-like matrix satisfying
$$D_{\mathbf{v}_m(\omega_m)} C - C(\delta^{1/n} D_{\mathbf{v}_n(\omega_n)}) = F_m^* XY^* D_{\mathbf{v}_n(\delta^{1/n})} F_n. \tag{62.14}$$
If $\delta > 1$, then the sets of diagonal elements of $D_{\mathbf{v}_m(\omega_m)}$ and $\delta^{1/n} D_{\mathbf{v}_n(\omega_n)}$ are disjoint and the matrix C satisfying Eq. (62.14) is uniquely determined.
5. If $V \in \mathbb{C}^{m\times n}$ is a Vandermonde-like matrix satisfying Eq. (62.6) with $\delta > 0$, then $C = V D^{-1}_{v_n(\delta^{1/n})} F_n$ is a Cauchy-like matrix satisfying
$$D_{\mathbf{v}} C - C(\delta^{1/n} D^*_{\mathbf{v}_n(\omega_n)}) = XY^* D^{-1}_{\mathbf{v}_n(\delta^{1/n})} F_n. \tag{62.15}$$
If
$$\delta^{1/n} < \min_i |\alpha_i| \qquad \text{or} \qquad \delta^{1/n} > \max_i, |\alpha_i|$$
then the sets of diagonal elements of $\delta^{1/n} D_{\mathbf{v}_n(\omega_m)}$ and $D_{\mathbf{v}}$ are disjoint and the matrix C satisfying Eq. (62.15) is uniquely determined.
6. [HB97] Transformations of other structured matrices to Cauchy-like matrices can also be accomplished using real trigonometric transformations. Such transformations can be used to avoid the use of complex arithmetic.

Examples:

1. The Toeplitz matrix
$$T = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix}$$
satisfies the displacement equation
$$Z_{1,3}^* T - T Z_{-1,3}^* = \mathbf{x}\mathbf{y}^* = \begin{bmatrix} 2 \\ 2 \\ 2 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \end{bmatrix}$$
and can be transformed to the Cauchy-like matrix
$$C = F_3^* T D_{\mathbf{v}_3(\omega_6)} F_3 = \begin{bmatrix} 1 + \omega_6 + \omega_6^2 & 1 & 1 - \omega_6 - \omega_6^2 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix},$$
which satisfies the displacement equation
$$D_{\mathbf{v}_3(\omega_3)} C - \omega_6 C D_{\mathbf{v}_3(\omega_3)} = \begin{bmatrix} 2\sqrt{3} \\ 0 \\ 0 \end{bmatrix} \begin{bmatrix} \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} & \frac{1}{\sqrt{3}} \end{bmatrix} = (F_3^* \mathbf{x})(\mathbf{y}^* D_{\mathbf{v}_3(\omega_6)} F_3).$$
This example illustrates Fact 3.

62.3 Generalized Schur Algorithms

It is a remarkable fact that under very general conditions the displacement structure of a matrix is inherited by its Schur complement. In particular, if E, F, G, and H are lower triangular, and if $A = [A_{jk}]$ with $a_{11} \neq 0$ has displacement rank r with respect to Eq. (62.3), then the Schur complement of a_{11} in A has displacement rank r with respect to a related displacement equation. The generators of the Schur complement can be computed from those of A using simple recurrences. Gaussian elimination can be interpreted as recursive Schur complementation so that an LU factorization of A, when it exists, can be computed using operations acting solely on the generators of A. This describes in outline the common features of the large class of fast generalized Schur algorithms for structured matrix factorization.

Instead of describing a Schur algorithm for the most general type of displacement structure, we focus on two specific equations that allow for particularly simple generator updates. The first equation is the Sylvester type displacement equation in which E and H are lower triangular. The second is the Stein type displacement equation in which G and H are strictly lower triangular.

Definitions:

Generators X and Y of a matrix satisfying a displacement equation are in **proper form** if

$$X = \begin{bmatrix} x_{11} & 0 \\ \mathbf{x}_{21} & X_{22} \end{bmatrix}, \qquad \text{and} \qquad Y = \begin{bmatrix} y_{11} & 0 \\ \mathbf{y}_{21} & Y_{22} \end{bmatrix}. \tag{62.16}$$

Facts:

Partition the $m \times n$ matrix A as

$$A = \begin{bmatrix} a_{11} & \mathbf{a}_{12}^* \\ \mathbf{a}_{21} & A_{22} \end{bmatrix}$$

and assume $a_{11} \neq 0$. Let $A_S = A/[a_{11}] = A_{22} - \frac{1}{a_{11}}\mathbf{a}_{21}\mathbf{a}_{12}^*$ be the Schur complement of a_{11} in A. The recurrences given here for computing generators of Schur complements have appeared in many papers in either more specialized or more general forms. They can be viewed in specialized forms of the general recurrences in [SK95].

The pseudocode presentation of each of the Schur algorithm variants uses recursion with the recursive function applied to structured Schur complements of decreasing size. No explicit termination criterion is given. The functions being defined compute triangular factors or generators of a matrix inverse. In actual implementation, the recursion would terminate when the function is called on a Schur complement that is small enough that a conventional factorization or inversion algorithm can be applied.

1. If A satisfies the Stein type displacement equation (62.1) with strictly lower triangular G and H partitioned as

   $$G = \begin{bmatrix} 0 & 0 \\ \mathbf{g}_{21} & G_{22} \end{bmatrix}, \qquad \text{and} \qquad H = \begin{bmatrix} 0 & 0 \\ \mathbf{h}_{21} & H_{22} \end{bmatrix},$$

   and generators X and Y in proper form (62.16), then A_S satisfies the displacement equation

   $$A_S - G_{22}A_S H_{22}^* = X_S Y_S^*$$

   where

$$\begin{aligned} X_S &= \begin{bmatrix} G_{22}\mathbf{x}_{21} + \mathbf{g}_{21}x_{11} & X_{22} \end{bmatrix}, \\ Y_S &= \begin{bmatrix} H_{22}\mathbf{y}_{21} + \mathbf{h}_{21}y_{11} & Y_{22} \end{bmatrix}. \end{aligned} \tag{62.17}$$

The first column and row of A can be computed from the generators X and Y by using

$$\begin{bmatrix} a_{11} & \mathbf{a}_{12}^* \end{bmatrix} = x_{11} \begin{bmatrix} \overline{y}_{11} & \mathbf{y}_{21}^* \end{bmatrix}, \qquad \text{and} \qquad a_{21} = \mathbf{x}_{21}\overline{y}_{11}. \tag{62.18}$$

Given generators X and Y for A that are not in proper form, when $a_{11} \neq 0$ it is possible to compute an invertible square matrix V such that XV and YV^{-*} are proper form generators for A. The construction of such a transformation when A is positive definite and $Y = X\Sigma_{p,q}$ is described in Section 62.4. The transformation of the generators to proper form can be accomplished using $O((m+n)r)$ operations. If the complexity of matrix-vector multiplication with G and H is $O(m+n)$, then the generators of A_S can be computed using $O((m+n)r)$ operations.

2. If A satisfies a Sylvester type displacement equation (62.2) with lower triangular E and H partitioned as

$$E = \begin{bmatrix} e_{11} & 0 \\ \mathbf{e}_{21} & E_{22} \end{bmatrix} \qquad \text{and} \qquad H = \begin{bmatrix} h_{11} & 0 \\ \mathbf{h}_{21} & H_{22} \end{bmatrix},$$

and generators X and Y partitioned as

$$\begin{bmatrix} \mathbf{x}_1^* \\ X_2 \end{bmatrix} \qquad \text{and} \qquad \begin{bmatrix} \mathbf{y}_1^* \\ Y_2 \end{bmatrix},$$

then A_S satisfies the displacement equation

$$E_{22}A_S - A_S H_{22}^* = X_S Y_S^*$$

where

$$\begin{aligned} X_S &= X_2 - \tfrac{1}{a_{11}}\mathbf{a}_{21}\mathbf{x}_1^*, \\ Y_S &= Y_2 - \tfrac{1}{a_{11}}\mathbf{a}_{12}\mathbf{y}_1^*. \end{aligned} \tag{62.19}$$

The first column and row of A can be obtained by solving

$$\begin{aligned} (E - \overline{h}_{11}I) \begin{bmatrix} a_{11} \\ \mathbf{a}_{21} \end{bmatrix} &= \begin{bmatrix} \mathbf{x}_1^* \\ X_2 \end{bmatrix} \mathbf{y}_1, \\ \begin{bmatrix} a_{11} & \mathbf{a}_{12}^* \end{bmatrix} (e_{11}I - H^*) &= \mathbf{x}_1^* \begin{bmatrix} \mathbf{y}_1 & Y_2^* \end{bmatrix}. \end{aligned} \tag{62.20}$$

If E and H are banded with bandwidth that does not depend on n, then the systems can be solved using $O(m+n)$ operations and the generators of A_S can be computed using $O((m+n)r)$ operations.

3. If all leading principal minors of A are nonzero and if A satisfies either a Stein type displacement equation with strictly lower triangular G and H or a Sylvester displacement equation with lower triangular E and H, then repeated Schur complementation using the generator recurrences can be used to compute an LU factorization. The result is Algorithm 62.1. If $m > n$ and if the displacement equations are such that generator updates require $O((m+n)r)$ operations, then the complexity of LU factorization is $O(rmn)$.

Algorithm 62.1 (Generalized Schur Algorithm)

Let A be an $m \times n$ matrix with nonzero leading principal minors and satisfying Eq. (62.1) (or Eq. (62.2)). The function $(L, U) = \text{GSchur}(X, Y, E, F, G, H)$ computes an LU factorization of A. For the Stein equation it is assumed that $E = I$ and $F = I$. For the Sylvester equation it is assumed that $F = I$ and $G = I$.

```
function $(L, U) = \text{GSchur}(X, Y, E, F, G, H)$
    If       the displacement is of Stein type
      Then   Transform $G$ and $H$ to proper form.
    Let      $\begin{bmatrix} u_{11} & \mathbf{u}_{12}^* \end{bmatrix} = \begin{bmatrix} a_{11} & \mathbf{a}_{12}^* \end{bmatrix}$ using Eq. (62.18) (or Eq. (62.20)).
             $\mathbf{l}_{21} = \frac{1}{a_{11}} \mathbf{a}_{21}$ using Eq. (62.18) (or Eq. (62.20)).
    Compute  $X_S$ and $Y_S$ using Eq. (62.17) (or Eq. (62.19)).
    Let      $L = \begin{bmatrix} 1 & 0 \\ \mathbf{l}_{21} & L_{22} \end{bmatrix}, \quad U = \begin{bmatrix} u_{11} & \mathbf{u}_{12}^* \\ 0 & U_{22} \end{bmatrix}$
                 where $(L_{22}, U_{22}) = \text{GSchur}(X_S, Y_S, E_{22}, F_{22}, G_{22}, H_{22})$.
```

4. [KC94] Given an $n \times n$ invertible structured matrix, the generalized Schur algorithm can be applied to the augmented matrix

$$M = \begin{bmatrix} A & I \\ I & 0 \end{bmatrix}$$

to compute a generator representation of the inverse of a structured matrix. The Schur complement of A in M is $-A^{-1}$. If A satisfies the displacement equation $E_1 A - A H_1^* = X_{11} Y_{11}^*$ and if lower triangular E_2 and H_2 can be chosen so that $E_2 - H_1^* = X_{21} Y_{21}^*$ and $E_1 - H_2^* = X_{12} Y_{12}^*$ both have low rank, then M has low displacement rank with respect to

$$(E_1 \oplus E_2)M - M(H_1 \oplus H_2)^* = \begin{bmatrix} X_{11} & X_{12} & 0 \\ 0 & 0 & X_{21} \end{bmatrix} \begin{bmatrix} Y_{11}^* & 0 \\ 0 & Y_{12}^* \\ Y_{21}^* & 0 \end{bmatrix}.$$

Using this displacement representation of M, n steps of the Sylvester form of Algorithm 62.1 can be applied to the generators of M to compute generators of $-A^{-1}$. If A satisfies the Stein type equation $A - G_1 A H_1^* = X_{11} Y_{11}^*$ and it is possible to choose strictly lower triangular G_2 and H_2 so that $I - G_2 H_1^* = X_{21} Y_{21}^*$ and $I - G_1 H_2^* = X_{12} Y_{12}^*$ both have low rank, then M has low displacement rank with respect to

$$M - (G_1 \oplus G_2)M(H_1 \oplus H_2)^* = \begin{bmatrix} X_{11} & X_{12} & 0 \\ 0 & 0 & X_{21} \end{bmatrix} \begin{bmatrix} Y_{11}^* & 0 \\ 0 & Y_{12}^* \\ Y_{21}^* & 0 \end{bmatrix},$$

so that the Stein form of Algorithm 62.1 can be used to compute generators of $-A^{-1}$. This approach is applicable to Toeplitz matrices, in which case G_1 and H_1 are shift matrices and G_2 and H_2 can also be chosen to be shift matrices. Other augmented matrices can be used to achieve other ends, including QR factorization and the solution of a linear system.

62.4 Schur Algorithms for Positive Definite Matrices

The Stein variant of the generalized Schur algorithm can be adapted to compute the Cholesky factorization of a Hermitian positive definite structured matrix. In the case of a positive definite Toeplitz matrix, the algorithm has been widely used; see Section 62.6. The approach can be applied to any $n \times n$ positive definite matrix A satisfying a displacement equation of the form $A - GAG^* = X\Sigma_{p,q}X^*$ where G is strictly lower triangular. The algorithm is simply the Stein variant of Algorithm 62.1 with a transformation to proper form accomplished using $\Sigma_{p,q}$-unitary transformations.

Definitions:

For a given signature matrix $\Sigma_{p,q}$, a matrix S satisfying $S^*\Sigma_{p,q}S = \Sigma_{p,q}$ is **Σ-unitary** with respect to the signature $\Sigma_{p,q}$.

A matrix

$$S = \frac{1}{\sqrt{1-|\rho|^2}} \begin{bmatrix} 1 & \bar{\rho} \\ \rho & 1 \end{bmatrix},$$

where $|\rho| < 1$, is a **hyperbolic rotation**.

Facts:

1. If A is symmetric and if the displacement $A - GAG^*$ has p positive and q negative eigenvalues, then there is always a factorization of the displacement $A - GAG^* = X\Sigma_{p,q}X^*$. Such generators can be obtained using a variety of standard matrix decompositions applied to the displacement, including truncated LDL^* factorization. However, in considering such a factorization, it is important to note that Bunch-Parlett pivoting [GV96] is more reliable than Bunch-Kaufman pivoting in revealing rank deficiency in the displacement [SV97]. In most cases, generators are obtained using a more direct formula, or even an explicit formula in terms of the matrix elements as in Eq. (62.10).
2. A hyperbolic rotation can be computed and applied to introduce zeros into a column or row vector. If $|x| > |y|$ and $\rho = -y/x$, then

$$\frac{1}{\sqrt{1-|\rho|^2}} \begin{bmatrix} 1 & \bar{\rho} \\ \rho & 1 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} \frac{x}{|x|}\sqrt{|x|^2 - |y|^2} \\ 0 \end{bmatrix}$$

   and

$$\frac{1}{\sqrt{1-|\rho|^2}} \begin{bmatrix} x & y \end{bmatrix} \begin{bmatrix} 1 & \rho \\ \bar{\rho} & 1 \end{bmatrix} = \begin{bmatrix} \frac{x}{|x|}\sqrt{|x|^2 - |y|^2} & 0 \end{bmatrix}.$$

3. A hyperbolic rotation is Σ-unitary with respect to the signature $\Sigma_{1,1}$. A $(p+q)\times(p+q)$ hyperbolic rotation

$$S = I_{j-1} \oplus \begin{bmatrix} \frac{1}{\sqrt{1-|\rho|^2}} & 0 & \frac{\bar{\rho}}{\sqrt{1-|\rho|^2}} \\ 0 & I_{k-j-1} & 0 \\ \frac{\rho}{\sqrt{1-|\rho|^2}} & 0 & \frac{1}{\sqrt{1-|\rho|^2}} \end{bmatrix} \oplus I_{p+q-k}$$

   acting in rows (or columns) j and k where $j \le p$ and $k > p$ is Σ-unitary with respect to $\Sigma_{p,q}$.
4. A hyperbolic rotation has triangular factorizations

$$\frac{1}{\sqrt{1-|\rho|^2}} \begin{bmatrix} 1 & \bar{\rho} \\ \rho & 1 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ \rho & \sqrt{1-|\rho|^2} \end{bmatrix} \begin{bmatrix} \frac{1}{\sqrt{1-|\rho|^2}} & \frac{\bar{\rho}}{\sqrt{1-|\rho|^2}} \\ 0 & 1 \end{bmatrix}$$

   and

$$\frac{1}{\sqrt{1-|\rho|^2}} \begin{bmatrix} 1 & \rho \\ \bar{\rho} & 1 \end{bmatrix} = \begin{bmatrix} \frac{1}{\sqrt{1-|\rho|^2}} & 0 \\ \frac{\bar{\rho}}{\sqrt{1-|\rho|^2}} & 1 \end{bmatrix} \begin{bmatrix} 1 & \rho \\ 0 & \sqrt{1-|\rho|^2} \end{bmatrix}.$$

For numerical stability, it is necessary to multiply by hyperbolic rotations in factored form, that is by multiplying by the triangular factors in sequence [BBV87]. For a hyperbolic rotation S, the first formula is stable for products of the form SX and the second is stable for products of the form XS.

5. For a symmetric positive-definite matrix A satisfying $A - GAG^* = X\Sigma_{p,q}X^*$, the Stein type generalized Schur can be arranged to compute a Cholesky factorization $A = C^*C$. The result is Algorithm 62.2. It can be shown that the matrix A is positive definite if and only if $|\hat{x}_{11}| > |\hat{x}_{13}|$ in each recursive application of Algorithm 62.2.

Algorithm 62.2 (Positive Definite Generalized Schur Algorithm)

Given an $n \times n$ positive definite matrix A satisfying $A - GAG^* = X\Sigma_{p,q}X^*$ for strictly lower triangular G, the function PDGSchur(X, G) computes the Cholesky factorization $A = C^*C$.

```
function $C = \text{PDGSchur}(X, G)$
    Let $X \begin{bmatrix} U & 0 \\ 0 & V \end{bmatrix} = \left[\begin{array}{cc|cc} x_{11} & 0 & x_{13} & 0 \\ \mathbf{x}_{21} & X_{22} & \mathbf{x}_{23} & X_{24} \end{array}\right]$
        where $U$ and $V$ are $p \times p$ and $q \times q$ Householder transformations.
    $X \begin{bmatrix} U & 0 \\ 0 & V \end{bmatrix} S = \left[\begin{array}{cc|cc} \hat{x}_{11} & 0 & 0 & 0 \\ \hat{\mathbf{x}}_{21} & X_{22} & \hat{\mathbf{x}}_{23} & X_{24} \end{array}\right]$
        where $S$ is a hyperbolic rotation acting in columns 1 and $p+1$
        with $\rho = -\overline{x}_{13}/\overline{x}_{11}$.
    $X_S = \left[\begin{array}{cc|cc} \mathbf{e}_{21}\hat{x}_{11} + E_{22}\hat{\mathbf{x}}_{21} & X_{22} & \hat{\mathbf{x}}_{23} & X_{24} \end{array}\right]$
    $C = \begin{bmatrix} \overline{\hat{x}}_{11} & \hat{\mathbf{x}}_{21}^* \\ 0 & C_{22} \end{bmatrix}$, where $C_{22} = \text{PDGSchur}(X_S, G_{22})$.
```

62.5 Fast Algorithms for Cauchy-like Systems

Row and column permutations destroy most types of displacement structure. Consequently it is not generally possible to introduce pivoting for stability into most fast algorithms. Cauchy-like matrices, however, are an important exception. This advantage often motivates a preliminary transformation of matrices with other structures to Cauchy-like form prior to applying the generalized Schur algorithm.

Facts:

1. If P and Q are permutations and C is a Cauchy-like matrix satisfying Eq. (62.7), then the matrix PCQ satisfies

$$\hat{D}_{\mathbf{v}}PCQ - PCQ\hat{D}_{\mathbf{w}} = PXY^*Q,$$

where $\hat{D}_{\mathbf{v}} = PD_{\mathbf{v}}P^*$ and $\hat{D}_{\mathbf{w}} = Q^*D_{\mathbf{w}}Q$. Thus, PCQ is also a Cauchy-like matrix and pivoting schemes can be incorporated into fast solvers for Cauchy-like systems. The paper [Hei94] introduced the idea of transforming other structured matrices to Cauchy-like form in order to exploit pivoting and thereby improve the stability of fast algorithms, particularly algorithms applied to indefinite or nonsymmetric matrices. The paper presented a number of $O(n^2)$ and $O(n\log^3(n))$ methods.

2. The use of the Sylvester variant of Algorithm 62.1, in combination with partial pivoting, was investigated in [GKO95], where experiments were presented to illustrate

the numerical reliability of the method. However, the algorithm is not stable in all cases. A source of numerical instability was described and analyzed in [SB95].
3. [Gu98a] The basic approach of applying Algorithm 62.1 with pivoting can be made provably stable by using a stronger pivoting method, somewhat analogous to a structured form of complete pivoting, and by introducing a refactorization of the generators that is intended to limit growth of generator elements. The same approach can be extended to solve structured least squares problems [Gu98b].

62.6 Fast Algorithms for Toeplitz-like Systems

A broad range of direct fast algorithms have been proposed over many years for the solution of Toeplitz systems of equations. Iterative methods that exploit fast matrix-vector multiplication and effective, fast preconditioners have also been widely used.

Definitions:

The **Strang type preconditioner** for a $2m \times 2m$ Hermitian Toeplitz matrix $T = [t_{j-k}]$ is the circulant matrix S with first row given by

$$\mathbf{s}_0^* = \begin{bmatrix} t_0 & t_{-1} & \cdots & t_{-m} & t_{-m+1} & \cdots & t_{-1} \end{bmatrix}.$$

The **Chan type preconditioner** for an $n \times n$ Toeplitz matrix T is the circulant matrix S with first row given by

$$\mathbf{s}_0^* = \frac{1}{n} \begin{bmatrix} nt_0 & t_{-n+1} + (n-1)t_1 & 2t_{-n+2} + (n-2)t_2 & \cdots & (n-1)t_{-1} + t_{n-1} \end{bmatrix}.$$

A **multilevel Toeplitz matrix** is a matrix $T = [t_{\mathbf{j},\mathbf{k}}]$ with $t_{\mathbf{j},\mathbf{k}} = t_{\mathbf{j}-\mathbf{k}}$ and with rows and columns arranged by lexicographic ordering of index vectors

$$\mathbf{j} = (j_1, j_2, \ldots, j_p) \qquad \text{and} \qquad \mathbf{k} = (k_1, k_2, \ldots, k_p).$$

For $\mathbf{x} \in \mathbb{C}^n$, let $L(\mathbf{x})$ denote the $n \times n$ lower triangular Toeplitz matrix with $\mathbf{x}$ as its first column.

Facts:

1. Given an $n \times n$ positive definite Toeplitz matrix T satisfying

$$T - Z_n T Z_n^* = X \Sigma_{1,1} X^*,$$

Algorithm 62.2 can be applied to factor T by setting $G = Z_n$. Only hyperbolic rotations, and not Householder transformations, are required. This algorithm was first described in this form in [Bar69]. It was later noted that the algorithm can be interpreted as a reformulation in matrix terms of the classical Schur algorithm for testing whether a power series is bounded in the interior of the unit circle [KS95]. The algorithm is numerically stable [BBH95].
2. Given an $n \times n$ positive definite Toeplitz T, the Levinson algorithm [Lev47] solves a linear system using $O(n^2)$ operations. The algorithm can also be interpreted as computing a triangular factorization of T^{-1}.
3. The algorithms of [Hei94, GKO95, Gu98a, Gu98b] can all be applied to solve Toeplitz systems by transforming a Toeplitz matrix to a Cauchy-like matrix using Eq. (62.13). The algorithms of [Gu98a, Gu98b] give the highest guarantee of numerical stability when the matrix is indefinite or non-Hermitian.

4. [KC94] If T is Toeplitz, then $A = T^*T$ has displacement rank at most four with respect to $\Delta(A) = A - Z_nAZ_n^*$. Block Toeplitz-like matrices can be used to compute QR factorizations of Toeplitz matrices. By applying n steps of the positive definite generalized Schur algorithm to

$$A = \begin{bmatrix} T^*T & T^* \\ T & 0 \end{bmatrix} = \begin{bmatrix} R^* \\ Q \end{bmatrix} \begin{bmatrix} R & Q^* \end{bmatrix} - \begin{bmatrix} 0 & 0 \\ 0 & -QQ^* \end{bmatrix}$$

with $E = Z_n \oplus Z_n$, it is possible to determine the rows of R and Q^* from the triangular factors of A.
5. There are many other methods for fast QR factorization of Toeplitz and Toeplitz-like matrices. Although the presentation is based on Cholesky downdating, the algorithms of [Swe84, BBH86] are computationally similar to the generalized Schur algorithm [KC94]. Factorization algorithms of this type can be shown to provide weakly stable methods for the solution of Toeplitz least squares problems [SV97]. The methods of [Cyb80, Nag93] involve an inverse QR factorization, which computes R^{-1} instead of R. The method of [Ste07] generalizes the isometric Arnoldi algorithm of [Gra93] so that it can be used to orthogonalize the columns of a Toeplitz-like matrix.
6. Toeplitz matrices allow fast matrix-vector multiplication. Using Eq. (62.12), multiplication of a vector by an $n \times n$ circulant can be performed using $O(n \log(n))$ operations. An arbitrary $m \times n$ Toeplitz matrix T can be embedded as the leading principal submatrix of an $(m + n - 1) \times (m + n - 1)$ circulant as in the following:

$$S = \left[\begin{array}{c|c} T & S_{12} \\ \hline S_{21} & S_{22} \end{array}\right] = \left[\begin{array}{ccc|ccc} t_0 & t_1 & t_2 & t_{-3} & t_{-2} & t_{-1} \\ t_{-1} & t_0 & t_1 & t_2 & t_{-3} & t_{-2} \\ t_{-2} & t_{-1} & t_0 & t_1 & t_2 & t_{-3} \\ t_{-3} & t_{-2} & t_{-1} & t_0 & t_1 & t_2 \\ \hline t_2 & t_{-3} & t_{-2} & t_{-1} & t_0 & t_1 \\ t_1 & t_2 & t_{-3} & t_{-2} & t_{-1} & t_0 \end{array}\right].$$

A matrix-vector product $\mathbf{y} = T\mathbf{x}$ involving an $m \times n$ Toeplitz matrix T can be computed using $O((m+n)\log(m+n))$ operations by embedding T in a circulant and computing the product

$$\begin{bmatrix} T & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ 0 \end{bmatrix} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}$$

using the fast Fourier transform and Eq. (62.12).
7. [GF74, HR84] For an $n \times n$ nonsingular, Hermitian Toeplitz matrix T, the Gohberg-Semencul formula represents T^{-1} as the difference of products of lower triangular Toeplitz matrices

$$T^{-1} = L(\mathbf{x})L(\mathbf{x})^* - L(\mathbf{y})L(\mathbf{y})^*. \tag{62.21}$$

The formula is also implicit in the Toeplitz inversion algorithm of [Tre64] and is equivalent to

$$T^{-1} - Z_nT^{-1}Z_n^* = \begin{bmatrix} \mathbf{x} & \mathbf{y} \end{bmatrix} \Sigma_{1,1} \begin{bmatrix} \mathbf{x}^* \\ \mathbf{y}^* \end{bmatrix}$$

so that $\mathbf{x}$ and $\mathbf{y}$ are columns of a generator matrix for T^{-1}. These vectors can be obtained in a variety of ways. See Section 62.8 for an $O(n\log^2(n))$ divide-and-conquer algorithm. If $\mathbf{x}$ and $\mathbf{y}$ have been computed, Eq. (62.21) can be combined with circulant embeddings of $L(\mathbf{x})$ and $L(\mathbf{y})$ and Eq. (62.12) to multiply a vector by T^{-1} using $O(n\log(n))$ operations.

8. [Cha88] The Chan type preconditioner is the closest circulant approximation to T in the Frobenius norm.
9. [CS89, Cha89] Consider a family of Hermitian positive definite Toeplitz matrices T_n that are generated from a positive function $f(\theta) > 0$ defined on $[0, 2\pi)$. In particular, let the Fourier series of $f(\theta)$ be

$$f(\theta) = \sum_{j=-\infty}^{\infty} t_j e^{-ij\theta}$$

with $t_{-j} = \bar{t}_j$ and assume that $\{t_j\}_{j=-\infty}^{\infty} \in l_1$. Let T be the infinite Toeplitz matrix $T = [t_{j-k}]_{j,k=0}^{\infty}$ and let T_n be the $n \times n$ leading principal submatrix of T. Then T_n is positive definite. If S_n is the Strang or Chan preconditioner for T_n then $S_n^{-1}T_n$ has eigenvalues clustered around 1 in the sense that for any $\epsilon > 0$ there exist N and $M > 0$ such that for all $n > N$, at most M eigenvalues of $S_n^{-1}T_n - I$ have absolute value larger than ϵ. This is sufficient to show superlinear convergence of the preconditioned conjugate gradient algorithm [GV96] applied to a system $T_n\mathbf{x} = \mathbf{b}$. If matrix-vector multiplication by T_n and inversion of S_n are performed using Eq. (62.12) and the fast Fourier transform, the complete algorithm requires $O(n\log(n))$ operations.
10. Multilevel circulant matrices have been widely used and studied as preconditioners for multilevel Toeplitz systems. Such systems have diverse applications, including problems in image processing [HNO06]. This class of methods often works well in practice. However, the clustering results are weaker than for ordinary Toeplitz systems and it is not possible in general to guarantee superlinear convergence [CT99].

62.7 Fast Algorithms for Vandermonde Systems

Systems involving Vandermonde matrices, confluent Vandermonde matrices, and polynomial Vandermonde matrices arise in polynomial interpolation, computation of quadrature weights, and various problems in approximation. In addition to algorithms based on displacement structure, there are several more specialized algorithms.

Facts:

1. General displacement techniques can be applied to factor an $n \times n$ Vandermonde system using $O(n^2)$ operations. In particular, with $\delta = 0$, the Sylvester form of Algorithm 62.1 can be directly applied to the displacement equation (62.6) to compute an LU factorization of V. If the corresponding rows of X and diagonal of $D_{\mathbf{v}}$ are reordered correspondingly, partial pivoting can be used. In [KO97], this approach is developed more generally, in a form applicable to polynomial Vandermonde matrices in which the polynomials satisfy a three-term recurrence.
2. The transformation (62.15) can be used to transform a Vandermonde-like matrix into a Cauchy-like matrix. The algorithm of [Gu98a] or [Gu98b] can then be used to solve the corresponding Vandermonde linear system or least squares problem. This approach is backward stable.

Algorithm 62.3 (Primal Björck-Pereyra Algorithm)

Let V be an $n \times n$ Vandermonde matrix with distinct nodes $\{\alpha_1, \ldots, \alpha_n\}$. The following function computes the solution to the primal system $V\mathbf{a} = \mathbf{f}$.

```
function $\mathbf{a} = \mathrm{primalBP}(\alpha_1, \ldots, \alpha_n, \mathbf{f})$
    $\mathbf{a} := \mathbf{f}$
    for $k = 1, \ldots, n$
        for $j = n, n-1, \ldots, k+1$
            $a_j := (a_j - a_{j-1})/(\alpha_j - \alpha_{j-k})$
    for $k = n-1, \ldots, 1$
        for $j = k, k+1, \ldots, n-1$
            $a_j := a_j - \alpha_k a_{j+1}$
```

3. The Björck-Pereyra algorithm [BP70] exploits the fact that a Vandermonde system $V\mathbf{a} = \mathbf{f}$ is equivalent to a polynomial interpolation problem with interpolation points (α_k, f_k). Such a problem can be solved using Newton interpolation and a nested product recurrence for computing the coefficients of the interpolating polynomial. Interpreted in matrix terms, the process can be represented as

$$\mathbf{a} = V^{-1}\mathbf{f} = U_0 \cdots U_{n-1} L_{n-1} \cdots L_0 \mathbf{f},$$

where the U_k are upper triangular and bidiagonal and the L_k are lower triangular and bidiagonal. Multiplication by the L_k corresponds to computing the Newton form of the interpolating polynomial. Multiplication by the U_k corresponds to multiplying out the Newton interpolating polynomial to get the coefficients of the powers of α. Given this factorization of V^{-1}, transposition can be used to derive recurrences for the dual Vandermonde system $V^*\mathbf{x} = \mathbf{b}$. Algorithm 62.3 solves a primal Vandermonde system. Algorithm 62.4 solves a dual Vandermonde system. Both algorithms require $O(n^2)$ operations to solve an $n \times n$ system. The algorithms naturally extend to the case of confluent Vandermonde systems [BE73], and also to polynomial Vandermonde systems for which the polynomials satisfy a three-term recurrence [Hig88]. The algorithm of [RO91] applies when the polynomials are Chebyshev polynomials. The algorithm of [BEG07] applies in the case of Szëgo polynomials.

Algorithm 62.4 (Dual Björck-Pereyra Algorithm)

Let V be an $n \times n$ Vandermonde matrix with distinct nodes $\{\alpha_1, \ldots, \alpha_n\}$. The following function computes the solution to the dual system $V^*\mathbf{x} = \mathbf{b}$.

```
function $\mathbf{x} = \mathrm{dualBP}(\alpha_1, \ldots, \alpha_n, \mathbf{b})$
    $\mathbf{x} := \mathbf{b}$
    for $k = 1, \ldots, n$
        for $j = n, n-1, \ldots, k+1$
            $x_j := x_j - \overline{\alpha}_k x_{j-1}$
    for $k = n-1, \ldots, 1$
        for $j = k+1, \ldots, n$
            $x_j := x_j/(\overline{\alpha}_j - \overline{\alpha}_{j-k})$
        for $j = k, \ldots, n-1$
            $x_j := x_j - x_{j+1}$
```

4. The stability properties of the Björk-Pereyra algorithm are striking. Real Vandermonde matrices are known to be ill-conditioned. In fact, it is shown in [Tyr94] that an arbitrary real $n \times n$ Vandermonde matrix V satisfies $\kappa_2(V) \geq 2^{n-2}/\sqrt{n^{1/2}}$. Nevertheless, as originally noted in [BP70], the solution of specific Vandermonde systems using the Björck-Pereyra algorithms with real nodes is often surprisingly accurate. This behavior is in part explained by an error analysis in [Hig87], which shows that if $0 \leq \alpha_1 < \alpha_2 < \cdots < \alpha_n$ and if the vectors $\mathbf{f}$ and $\mathbf{b}$ have components with alternating signs, then the error in the computed solutions is small independent of the condition number of V.
5. There are also $O(n^2)$ algorithms for the inversion of Vandermonde and related matrices. Traub [Tra66] describes such an algorithm and gives a summary, with citations, of the repeated discovery of the method by many authors.

62.8 Superfast Algorithms

Most fast algorithms solve an $n \times n$ linear system using $O(n^2)$ operations. When implemented with aid of the fast Fourier transform, various doubling procedures can sometimes be applied to reduce the number of operations to $O(n \log^2(n))$ or $O(n \log^3(n))$. The Toeplitz case is the most extensively studied, but such techniques can be applied broadly to matrices with other displacement structures.

Algorithm 62.5 (Generic Superfast Divide-and-Conquer Inversion)

The is the recursive definition of a function $A^{-1} = \text{inverse}(A)$. In all references to matrices passed to or returned by the function, it is assumed that a structured representation of the matrix is used.

```
function $A^{-1} = \text{inverse}(A)$
    Let $n$ = number of rows of $A$
        $\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} = A$, where $A_{11}$ is $n/2 \times n/2$.
        $A_{11}^{-1} = \text{inverse}(A_{11})$.
        $A_S = A_{22} - A_{21}A_{11}^{-1}A_{12}$
        $A_S^{-1} = \text{inverse}(A_S)$
        $A^{-1}$ be as in Eq. (62.22) with products computed using fast multiplication.
```

Facts:

For a given degree k polynomial $p(z)$, let $\overline{p}(z)$ denote the polynomial obtained by conjugating the coefficients of $p(z)$ and let $\tilde{p}(z) = z^k \overline{p}(1/z)$.

1. Given an $n \times n$ nonsingular matrix A with displacement structure and with nonzero leading principal minor A_{11}, the block inversion

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}^{-1} = \begin{bmatrix} A_{11}^{-1} + A_{11}^{-1}A_{12}A_S^{-1}A_{21}A_{11}^{-1} & -A_{11}^{-1}A_{12}A_S^{-1} \\ -A_S^{-1}A_{21}A_{11}^{-1} & A_S^{-1} \end{bmatrix}, \qquad (62.22)$$

where $A_S = A_{22} - A_{21}A_{11}^{-1}A_{12}$, can be arranged to exploit the fact that A_{21}, A_{12}, A_{11}^{-1}, and A_S^{-1} all inherit displacement structure from A. The products required to form the blocks of the inverse can then be formed using a fast multiplication algorithm, typically using $O(n\log(n))$ operations. The details vary with the structure of the matrix A, but many algorithms follow the outline of Algorithm 62.5. The recursive formulation assumes that all leading principal submatrices of A are nonsingular. This approach was applied to Toeplitz matrices in [BA80] and to Cauchy-like matrices in [Hei94]. A general formulation is given in [Pan01]. If the multiplication steps use $O(n\log(n))$ operations, then the structured inversion algorithm requires $O(n\log^2(n))$ operations. However, the constants hidden by this complexity estimate are typically large.

2. [Hoo87, AG86, AG88] Consider an $n \times n$ positive definite Toeplitz matrix T satisfying

$$T - Z_n T Z_n^* = \begin{bmatrix} u_0 & v_0 \\ \vdots & \vdots \\ u_{n-1} & v_{n-1} \end{bmatrix} \Sigma_{1,1} \begin{bmatrix} \overline{u}_0 & \cdots & \overline{u}_{n-1} \\ \overline{v}_0 & \cdots & \overline{v}_{n-1} \end{bmatrix}.$$

The generators of T can be represented by polynomials, instead of a matrix, by defining

$$u_0(z) = u_0 + u_1 z + \cdots + u_{n-1} z^{n-1} \qquad \text{and} \qquad v_0(z) = v_0 + v_1 z + \cdots + v_{n-1} z^{n-1}.$$

The Schur algorithm, applied for k steps to the generator polynomials, takes the form

$$\begin{bmatrix} u_k(z) & v_k(z) \end{bmatrix} = \begin{bmatrix} u_0(z) & v_0(z) \end{bmatrix} \begin{bmatrix} a_k^{(0)}(z) & b_k^{(0)}(z) \\ \tilde{b}_k^{(0)}(z) & \tilde{a}_k^{(0)}(z) \end{bmatrix},$$

where $u_k(z)$ and $v_k(z)$ are the generator polynomials for the zero bordered Schur complement of the leading $k \times k$ principal submatrix of T and

$$\begin{bmatrix} a_k^{(l)}(z) & b_k^{(l)}(z) \\ \tilde{b}_k^{(l)}(z) & \tilde{a}_k^{(l)}(z) \end{bmatrix} = \prod_{j=l}^{k-1} \frac{1}{\sqrt{1-|\rho_j|^2}} \begin{bmatrix} 1 & \overline{\rho}_j \\ \rho_j & 1 \end{bmatrix} \begin{bmatrix} z & 0 \\ 0 & 1 \end{bmatrix}.$$

represents an accumulation of the generator transformations. If

$$\phi(z) = \frac{1}{t_0}(\tilde{a}_n^{(0)}(z) + b_n^{(0)}(z)) = \phi_0 + \phi_1 z + \cdots + \phi_{n-1} z^{n-1},$$

then

$$T^{-1} - Z_n T^{-1} Z_n^* = \begin{bmatrix} \phi_0 & 0 \\ \phi_1 & \phi_{n-1} \\ \vdots & \vdots \\ \phi_{n-1} & \phi_1 \end{bmatrix} \Sigma_{1,1} \begin{bmatrix} \overline{\phi}_0 & \overline{\phi}_1 & \cdots & \overline{\phi}_{n-1} \\ 0 & \overline{\phi}_{n-1} & \cdots & \overline{\phi}_1 \end{bmatrix}.$$

Thus, the polynomials give generators for T^{-1}. Multiplication of a vector by T^{-1} can then be implemented using $O(n\log(n))$ operations by embedding T^{-1} in a circulant and using the fast Fourier transform. If all polynomial multiplications are implemented using the fast Fourier transform, the polynomials $a_n^{(0)}(z)$ and $b_n^{(0)}(z)$ can be computed with $O(n\log^2(n))$ operations using the doubling procedure shown in Algorithm 62.6.

Algorithm 62.6 (Superfast Positive Definite Toeplitz Inversion)

Given a Schur complement of a Toeplitz matrix in the form of the polynomials $u_l(z)$ and $v_l(z)$ the following function performs k steps of the Schur algorithm. To perform a complete inversion the function should be called with $\text{SFSschur}(u_0(z), v_0(z), n)$.

```
function $(u_{l+k}(z), v_{l+k}(z), a_k^{(l)}(z), b_k^{(l)}(z)) = \text{SFSchur}(u_l(z), v_l(z), k)$
    Let $m = k/2$.
        $(u_{l+m}(z), v_{l+m}(z), a_m^{(l)}(z), b_m^{(l)}(z)) = \text{SFSchur}(u_l(z), v_l(z), m)$
        $\begin{bmatrix} u_{l+m}(z) & v_{l+m}(z) \end{bmatrix} = \begin{bmatrix} u_l(z) & v_l(z) \end{bmatrix} \begin{bmatrix} a_m^{(l)}(z) & b_m^{(l)}(z) \\ \tilde{b}_m^{(l)}(z) & \tilde{a}_m^{(l)}(z) \end{bmatrix}.$
        $(u_{l+k}(z), v_{l+k}(z), a_m^{(l+m)}(z), b_m^{(l+m)}(z)) = \text{SFSchur}(u_{l+m}(z), v_{l+m}(z), m)$
        $\begin{bmatrix} u_{l+k}(z) & v_{l+k}(z) \end{bmatrix} = \begin{bmatrix} u_{l+m}(z) & v_{l+m}(z) \end{bmatrix} \begin{bmatrix} a_m^{(l+m)}(z) & b_m^{(l+m)}(z) \\ \tilde{b}_m^{(l+m)}(z) & \tilde{a}_m^{(l+m)}(z) \end{bmatrix}.$
        $\begin{bmatrix} a_k^{(l)}(z) & b_k^{(l)}(z) \\ \tilde{b}_k^{(l)}(z) & \tilde{a}_k^{(l)}(z) \end{bmatrix} = \begin{bmatrix} a_m^{(l)}(z) & b_m^{(l)}(z) \\ \tilde{b}_m^{(l)}(z) & \tilde{a}_m^{(l)}(z) \end{bmatrix} \begin{bmatrix} a_m^{(l+m)}(z) & b_m^{(l+m)}(z) \\ \tilde{b}_m^{(l+m)}(z) & \tilde{a}_m^{(l+m)}(z) \end{bmatrix}$
```

3. Using a transformation of a nonsymmetric Toeplitz matrix to a Cauchy form and an associated interpolation problem, the algorithm of [VHK01] solves a nonsymmetric Toeplitz system with complexity $O(n \log^2(n))$.
4. The algorithm of [Ste03] adapts the approach of [Hoo87, AG86] so as to solve a Toeplitz system by using a divide-and-conquer form of back-substitution instead of by structured multiplication by the inverse.
5. The algorithm of [CGS07] exploits the presence of approximate low-rank blocks in a Cauchy-like matrix obtained from a transformation of a nonsymmetric Toeplitz matrix. The resulting algorithm gives an approximation to a solution to a system using $O(n \log(n))$ operations.

Heike Faßbender
Technische Universität Braunschweig

Many eigenvalue problems arising in practice are structured due to (physical) properties induced by the original problem. Structure can also be introduced by discretization and linearization techniques. Preserving this structure can help preserve physically relevant symmetries in the eigenvalues of the matrix and may improve the accuracy and efficiency of an eigenvalue computation. This is well known for symmetric matrices $A = A^T \in \mathbb{R}^{n \times n}$. Every eigenvalue is real and every right eigenvector is also a left eigenvector belonging to the same eigenvalue. Many numerical methods, such as QR, Arnoldi, and Jacobi-Davidson automatically preserve symmetric matrices (and hence compute only real eigenvalues), so unavoidable round-off errors cannot result in the computation of complex-valued eigenvalues. Algorithms tailored to symmetric matrices (e.g., divide and conquer or Lanczos methods) take much less computational effort and sometimes achieve high relative accuracy in the eigenvalues and — having the right representation of A at hand — even in the eigenvectors.

Another example is matrices for which the complex eigenvalues with nonzero real part theoretically appear in a pairing $\lambda, \overline{\lambda}, \lambda^{-1}, \overline{\lambda^{-1}}$. Using a general eigenvalue algorithm such as QR or Arnoldi results here in computed eigenvalues which in general do not display this eigenvalue pairing any longer. This is due to the fact that each eigenvalue is subject to unstructured rounding errors, so that each eigenvalue is altered in a slightly different way (see left picture in Figure 63.1). When using a structure-preserving algorithm this effect can be avoided, as the eigenvalue pairing is enforced so that all four eigenvalues are subject to the same rounding errors (see right picture in Figure 63.1).

This chapter focuses on two related classes of structured eigenproblems (symmetric/Hermitian and orthogonal/unitary; Hamiltonian and symplectic), structure-preserving algorithms, and structured error analysis (such as structured condition numbers and backward errors) for these classes. It is based on [FK06].

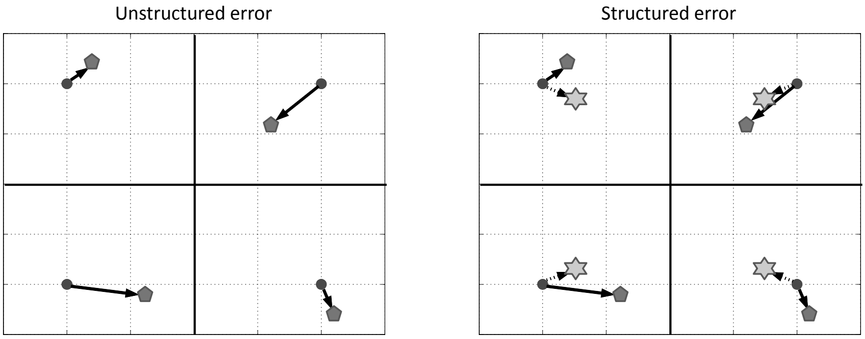

FIGURE 63.1 Effect of unstructured and structured rounding errors, round = original eigenvalue, pentagon = unstructured perturbation, star = structured perturbation.

63.1 Types of Matrices

A well-known example for structured eigenvalue problems are symmetric eigenvalue problems. They are probably the best understood and examined eigenvalue problems; closely connected are orthogonal/unitary problems. A different set of closely connected eigenproblems are Hamiltonian and symplectic eigenproblems, which are also fairly well understood. The relation between the Hamiltonian and symplectic eigenproblems is best described by comparing it with the relation between symmetric and orthogonal eigenproblems or the Hermitian and unitary eigenproblems. In all these cases, the underlying algebraic structures are an algebra and a group acting on this algebra. For the algebra (Hamiltonian, symmetric/Hermitian matrices), the structure is explicit, i.e., can be read off the matrix by viewing it. In contrast, the structure of a matrix contained in a group (symplectic, orthogonal/unitary matrices) is given only implicitly. It is very difficult to make this structure explicit. Common to all considered structured matrix classes is that the matrices in these classes can be represented by just a few parameters. This can be used to develop structure-preserving algorithms, which are usually faster and more accurate than standard solver.

Definitions:

Let $\mathrm{J} = \begin{bmatrix} 0 & I \\ -I & 0 \end{bmatrix} \in \mathbb{R}^{2n \times 2n}$ where $I \in \mathbb{R}^{n \times n}$ is the identity.

A matrix $S \in \mathbb{R}^{n \times n}$ is called **symmetric** if and only if $A = A^T$.

A matrix $G \in \mathbb{C}^{n \times n}$ is called **Hermitian** if and only if $G = G^*$.

A matrix $Q \in \mathbb{R}^{n \times n}$ is called **orthogonal** if and only if $QQ^T = Q^TQ = I$.

A matrix $U \in \mathbb{C}^{n \times n}$ is called **unitary** if and only if $UU^* = U^*U = I$.

A matrix $H \in \mathbb{R}^{2n \times 2n}$ is called **Hamiltonian** if and only if $H\mathrm{J} = (H\mathrm{J})^T$.

A matrix $M \in \mathbb{R}^{2n \times 2n}$ is called **symplectic** if and only if $M\mathrm{J}M^T = \mathrm{J}$, or equivalently, $M^T\mathrm{J}M = \mathrm{J}$.

A matrix $T =$  $\in \mathbb{R}^{n \times n}$ is called **tridiagonal** if $t_{ij} = 0$ for $i > j + 1$ and $i < j - 1, j = 1, \ldots, n$.

A matrix T is called **unreduced tridiagonal** if T is a tridiagonal matrix with $t_{i,i-1} \neq 0, i = 2, \ldots, n$ and $t_{i,i+1} \neq 0, i = 1, \ldots, n - 1$.

A matrix $A =$  $\in \mathbb{R}^{n \times n}$ is called **upper Hessenberg** if $a_{ij} = 0$ for $i > j+1, i, j = 1, \ldots, n$.

A matrix A is called **unreduced upper Hessenberg** if A is an upper Hessenberg matrix with $a_{i,i-1} \neq 0, i = 2, \dots, n$.

A matrix $B =$  $\in \mathbb{R}^{n \times n}$ is called **upper triangular** if $b_{ij} = 0$ for $i > j, i, j = 1, \dots, n$.

A matrix $B =$  is called **strict upper triangular** if B is an upper triangular matrix with $b_{jj} = 0, j = 1, \dots, n$.

A matrix $A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \in \mathbb{R}^{2n \times 2n}, A_{ij} \in \mathbb{R}^{n \times n}$, is called J–**Hessenberg** if A_{11}, A_{21}, A_{22} are upper triangular matrices and A_{12} is an upper Hessenberg matrix, that is

$A =$  .

A matrix A is called **unreduced** J–**Hessenberg** if A is a J–Hessenberg matrix, A_{21}^{-1} exists, and A_{12} is an unreduced upper Hessenberg matrix.

A Hamiltonian matrix $H = \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \in \mathbb{R}^{2n \times 2n}, H_{ij} \in \mathbb{R}^{n \times n}$, is called **Hamiltonian J-Hessenberg** if $H_{11} = -H_{22}, H_{21}$ are diagonal matrices and H_{12} is a symmetric tridiagonal matrix, that is

$H =$  .

A Hamiltonian matrix $H = \begin{bmatrix} T & R \\ 0 & -T^T \end{bmatrix}$ is called a **real Hamiltonian Schur matrix** if R is an $n \times n$ symmetric and T is an $n \times n$ quasi upper triangular matrix.

A matrix $R = \begin{bmatrix} R_{11} & R_{12} \\ R_{21} & R_{22} \end{bmatrix} \in \mathbb{R}^{2n \times 2n}, R_{ij} \in \mathbb{R}^{n \times n}$, is called **J-triangular** if the submatrices R_{ij} are all upper triangular, and R_{21} is strictly upper triangular, that is

$R =$  .

A symplectic matrix $B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix} \in \mathbb{R}^{2n \times 2n}, B_{ij} \in \mathbb{R}^{n \times n}$, is called **symplectic butterfly** if B_{11} and B_{21} are diagonal matrices and B_{12} and B_{22} are tridiagonal matrices, that is

$B =$  .

The **QR factorization** of $A \in \mathbb{K}^{n \times n}$ is given by $A = QR$ where $Q \in \mathbb{R}^{n \times n}$ is orthogonal and $R \in \mathbb{R}^{n \times n}$ is upper triangular if $\mathbb{K} = \mathbb{R}$. If $\mathbb{K} = \mathbb{C}$, then $Q \in \mathbb{C}^{n \times n}$ is unitary and $R \in \mathbb{C}^{n \times n}$ is upper triangular.

The **SR factorization** of a matrix $A \in \mathbb{R}^{2n \times 2n}$ is given by $A = SR$ where $S \in \mathbb{R}^{2n \times 2n}$ is symplectic and $R \in \mathbb{R}^{2n \times 2n}$ is J-triangular.

A **trivial matrix** is both symplectic and J-triangular and has the form $\begin{bmatrix} C^{-1} & F \\ 0 & C \end{bmatrix}$, where $C, F \in \mathbb{R}^{n \times n}$ are diagonal matrices.

A **Cayley transformation** of a square matrix A is given by $C = (I - A)^{-1}(I + A)$. The inverse transformation is $A = (C - I)(C + I)^{-1}$.

The matrix $G_k = G(k, c, s)$

$$G_k = \left[\begin{array}{ccc|ccc} I^{k-1,k-1} & & & & & \\ & c & & & s & \\ & & I^{n-k,n-k} & & & \\ \hline & & & I^{k-1,k-1} & & \\ & -s & & & c & \\ & & & & & I^{n-k,n-k} \end{array}\right],$$

where $c^2 + s^2 = 1,\ c, s \in \mathbb{R}$ is called a **symplectic Givens transformation**.

The matrix $H_k = H(k, \mathbf{v})$

$$H_k = \left[\begin{array}{cc|cc} I^{k-1,k-1} & & & \\ & P & & \\ \hline & & I^{k-1,k-1} & \\ & & & P \end{array}\right],$$

where $P = I^{n-k+1,n-k+1} - 2\frac{\mathbf{v}\mathbf{v}^T}{\mathbf{v}^T\mathbf{v}},\ \mathbf{v} \in \mathbb{R}^{n-k+1}$ is called a **symplectic Householder transformation**.

The matrix $L_k = L(k, c, d)$

$$L_k = \left[\begin{array}{cccc|cccc} I^{k-2,k-2} & & & & & & & \\ & c & & & & & d & \\ & & c & & & d & & \\ & & & I^{n-k,n-k} & & & & \\ \hline & & & & I^{k-2,k-2} & & & \\ & & & & & c^{-1} & & \\ & & & & & & c^{-1} & \\ & & & & & & & I^{n-k,n-k} \end{array}\right],$$

where $c, d \in \mathbb{R}$ is called a **symplectic Gauss transformation (type I)**.

The matrix $\widetilde{L}_k = \widetilde{L}(k, c, d)$

$$\widetilde{L}_k = \left[\begin{array}{ccc|ccc} I^{k-1,k-1} & & & & & \\ & c & & & d & \\ & & I^{n-k,n-k} & & & \\ \hline & & & I^{k-1,k-1} & & \\ & & & & c^{-1} & \\ & & & & & I^{n-k,n-k} \end{array}\right],$$

where $c, d \in \mathbb{R}$ is called a **symplectic Gauss transformation (type II)**.

Facts: Let $G_k = G_k(\gamma_k) = \operatorname{diag}(I_{k-1}, \begin{bmatrix} -\gamma_k & \sigma_k \\ \sigma_k & \overline{\gamma_k} \end{bmatrix}, I_{n-k-1})$ with $\gamma_k \in \mathbb{C}, \sigma_k \in \mathbb{R}^+$ and $|\gamma_k|^2 + \sigma_k^2 = 1$, and $G_n(\gamma_n) = \operatorname{diag}(I_{n-1}, -\gamma_n)$ with $\gamma_n \in \mathbb{C}, |\gamma_n| = 1$.

Let $P = [\mathbf{e}_1\ \mathbf{e}_3\ \cdots\ \mathbf{e}_{2n-1}\ \mathbf{e}_2\ \mathbf{e}_4\ \cdots\ \mathbf{e}_{2n}] \in \mathbb{R}^{2n\times 2n}$ where $\mathbf{e}_j$ is the jth standard basis vector on $\mathbb{R}^{2n}$.

1. [Wat07, Chap. 1.3] The matrix multiplication PAP^T performs a perfect shuffle of the rows and columns of $A \in \mathbb{R}^{2n\times 2n}$. If one performs a perfect shuffle of the rows and columns of a J-triangular matrix, one gets an upper triangular matrix. The product of J-triangular matrices is J-triangular. The nonsingular J-triangular matrices form a group.

2. [PL81, BMW89] The symplectic Givens and Householder transformations are orthogonal, while the symplectic Gauss transformations are nonorthogonal. It is crucial that the simple structure of these elementary symplectic transformations is exploited when computing matrix products of the form $G_kA, AG_k, H_kA, AH_k, L_kA, AL_k, \widetilde{L}_kA$, and $A\widetilde{L}_k$. Failure to recognize this and to treat the elementary symplectic transformations as general matrices increases work by an order of magnitude. The updates never entail the explicit formation of the transformation matrix, only the relevant parameters are computed. Algorithms to compute these parameters of the above-mentioned transformations are given in [PL81, BMW89].
3. [GV96, Chap. 5] The QR decomposition always exists. It is unique up to diagonal factors if and only if the first $n-1$ columns of A are linearly independent, that is, e.g., if for such $A \in \mathbb{R}^{n\times n}$ the QR decompositions $A = Q_1R_1 = Q_2R_2$ exist, then there exists a unitary diagonal matrix D such that $Q_1 = Q_2D, R_1 = D^{-1}R_2$. In case the decomposed matrix $A = QR$ is nonsingular, R may be chosen so that all its diagonal entries are positive. In this case, Q and R are unique.
4. [Els79, Bun86] The SR decomposition does not always exist, but the set of matrices which can be factorized in this way is dense in $\mathbb{R}^{2n\times 2n}$. More precisely, let $A \in \mathbb{R}^{2n\times 2n}$ be nonsingular. There exists a symplectic matrix S and a J-triangular matrix R such that $A = SR$ if and only if all leading principal minors of even dimension of PA^TJAP^T are nonzero. The SR decomposition is unique up to trivial factors, that is, if for $A \in \mathbb{R}^{2n\times 2n}$ the SR decompositions $A = S_1R_1 = S_2R_2$ exist, then there exists a trivial matrix D such that $S_1 = S_2D, R_1 = D^{-1}R_2$.
5. [Bun86] While the QR decomposition is usually considered for matrices in $\mathbb{R}$ and $\mathbb{C}$, the SR decomposition is usually not considered for complex matrices $A \in \mathbb{C}^{2n\times 2n}$. This is due to the fact that the set of matrices $A \in \mathbb{C}^{2n\times 2n}$ which have an SR decomposition $A = SR$, where $S^*JS = J$ or $S^*JS = -J$, is not dense in $\mathbb{C}^{2n\times 2n}$. Moreover, for complex matrices $A \in \mathbb{C}^{2n\times 2n}$, the definition of being symplectic depends on the scalar product chosen. One can say either A is complex symplectic if $AJA^T = J$ or A is conjugate symplectic if $AJA^* = J$ (see [MMT03]). In order to keep the presentation in this chapter simple, it is restricted to the real case (as far as possible).
6. [McC04, Chap. 0] The symmetric/Hermitian matrices form a Jordan algebra (see Section 86.5 for information about Jordan algebras).
7. [Wey97, Chap. 5] Any orthogonal/unitary matrix is nonsingular ($Q^{-1} = Q^T, U^{-1} = U^*$). Moreover, orthogonal/unitary matrices are normal. The orthogonal/unitary matrices form a multiplicative group.
8. [BK89, Chap. 1] The Hamiltonian matrices form a Lie algebra (see Chapter 87 for information about Lie algebras).
9. [Wey97, Chap. 6] Symplectic matrices are nonsingular ($M^{-1} = \mathrm{J}M^T\mathrm{J}^T$). The symplectic matrices form a multiplicative group (even more, a Lie group).
10. [Meh91] A $2n \times 2n$ matrix H is Hamiltonian if and only if it can be written in the form $H = \begin{bmatrix} A & G \\ Q & -A^T \end{bmatrix}, A, G, Q \in \mathbb{R}^{n\times n}, G = G^T, Q = Q^T$.
11. [DJ09] No such explicit form exists for symplectic matrices.
12. [Wil65, Chap. 1],[GV96, Chap. 8.1] The eigenvalues of symmetric/Hermitian matrices are real. Every right eigenvector is also a left eigenvector belonging to the same eigenvalue. Symmetric/Hermitian matrices are orthogonally/unitarily diagonalizable.
13. [GV96] (or see Section 8.2) The eigenvalues of orthogonal/unitary matrices have absolute modulus 1. Every right eigenvector is also a left eigenvector belonging to the same eigenvalue. Orthogonal/unitary matrices are diagonalizable.
14. [Dat04, Chap. 13],[Meh91] The eigenvalues of Hamiltonian matrices occur in quadruples $\{\lambda, -\lambda, \bar{\lambda}, -\bar{\lambda}\}$ for complex eigenvalues with nonzero real part and in pairs

$\{\lambda, -\lambda\}$ for real and purely imaginary eigenvalues; that is, the spectrum of any Hamiltonian matrix is symmetric with respect to the real and and imaginary axes.

15. [Dat04, Chap. 13],[Meh91] The eigenvalues of symplectic matrices occur in reciprocal pairs: If λ is an eigenvalue of M with right eigenvector $\mathbf{x}$, then λ^{-1} is an eigenvalue of M with left eigenvector $(\mathrm{J}\mathbf{x})^T$. Further, if $\lambda \in \mathbb{C}$ is an eigenvalue of M, then so are $\overline{\lambda}, \lambda^{-1}, \overline{\lambda^{-1}}$. The spectrum of a symplectic matrix is symmetric with respect to the unit circle.
16. [Meh96] A Cayley transform turns a symplectic matrix into a Hamiltonian one and vice versa.
17. [GV96, Chap. 7.4] Any matrix can be reduced to upper Hessenberg form by a backward stable algorithm using unitary similarity transformations in finitely many steps.
18. [GV96, Chap. 8.3] Any symmetric matrix can be reduced to symmetric tridiagonal form by a backward stable algorithm using an orthogonal similarity transformation (e.g., involving $n-1$ Householder transformations with $\mathbf{v}_j\mathbb{R}^j, j = 2, \ldots, n-1$ (see Chapter 51)). Hence any symmetric matrix can be represented by $2n-1$ real parameters plus the $n^2/2$ parameters needed to represent the orthogonal similarity transformation.
19. [Gra86] The product $H = H(\gamma_1, \gamma_2, ..., \gamma_n) := G_1(\gamma_1)G_2(\gamma_2)\cdots G_n(\gamma_n) =$

$$= \begin{bmatrix} -\gamma_1 & -\sigma_1\gamma_2 & \cdots & \cdots & -\sigma_1 ... \sigma_{k-1}\gamma_k & \cdots & -\sigma_1 ... \sigma_{n-1}\gamma_n \\ \sigma_1 & -\overline{\gamma_1}\gamma_2 & \cdots & \cdots & -\overline{\gamma_1}\sigma_2 ... \sigma_{k-1}\gamma_k & \cdots & -\overline{\gamma_1}\sigma_2 ... \sigma_{n-1}\gamma_n \\ & \sigma_2 & -\overline{\gamma_2}\gamma_3 & \cdots & \vdots & \cdots & -\overline{\gamma_2}\sigma_3 ... \sigma_{n-1}\gamma_n \\ & & \ddots & \ddots & & & \vdots \\ & & & \sigma_{k-1} & -\overline{\gamma_{k-1}}\gamma_k & \cdots & -\overline{\gamma_{k-1}}\sigma_k ... \sigma_{n-1}\gamma_n \\ & & & & \ddots & \ddots & \vdots \\ & & & & & \sigma_{n-1} & -\overline{\gamma_{n-1}}\gamma_n \end{bmatrix}$$

is a unitary upper Hessenberg matrix with positive subdiagonal elements. Conversely, if $H \in \mathbb{C}^{n\times n}$ is a unitary upper Hessenberg matrix with positive subdiagonal elements, then one can determine matrices $G_1, G_2, ..., G_n$ such that $G_n^* ... G_2^* G_1^* H = I$. Since H as a unitary matrix has a unique inverse, this has to be $G_n^* ... G_2^* G_1^*$. Thus, H has a unique factorization of the form $H = H(\gamma_1, \gamma_2, ..., \gamma_n) = G_1(\gamma_1)G_2(\gamma_2)\cdots G_n(\gamma_n)$. The Schur parameters $\{\gamma_k\}_{k=1}^n$ and the complementary Schur parameters $\{\sigma_k\}_{k=1}^n$ can be computed from the elements of H by a stable $O(n^2)$ algorithm.

Algorithm 1: Computing the Schur parameters of an unreduced unitary Hessenberg matrix
Input: an unreduced unitary upper Hessenbergmatrix $H = [h_{ij}]$
Output: its Schur parameters γ_j and its complementary Schur parameters σ_j

```
for $j = 1 \to n$ do
  $h'_{1j} = h_{1j}$
end for
for $k = 1 \to n-1$ do
  $\gamma_k = -h'_{kk}, \sigma_k = h_{k+1,k}$
  for $j = k+1 \to n$ do
    $h'_{k+1,j} = \sigma_k h'_{kj} + \gamma_k h_{k+1,j}$
  end for
end for
$\gamma_n = -h'_{nn}, \sigma_n = 0$
```

In statistics the Schur parameters are referred to as partial correlation coefficients and in signal processing as reflection coefficients [AGR87, Cyb84, DGK82, Mak75, RA90]. Hence, any unitary matrix can be represented by n complex parameters plus the $n^2/2$ parameters needed to represent the unitary similarity transformation to Hessenberg form. For numerical stability, it is essential to retain the complementary Schur parameters as well.

20. [Gra86] In the notation of Fact 17, if $\sigma_k = 0$, then $|\gamma_k| = 1$, and H can be decomposed into the direct sum $H = H(\gamma_1, ..., \gamma_k) \oplus H(\overline{\gamma}_k\gamma_{k+1}, ..., \overline{\gamma}_k\gamma_n)$.
21. [GV96, Chap. 7.4] If λ is an eigenvalue of an unreduced Hessenberg matrix, then its geometric multiplicity is one. Since symmetric/Hermitian and orthogonal/unitary matrices are diagonalizable, no eigenvalue of an unreduced symmetric/Hermitian/orthogonal/unitary upper Hessenberg matrix is defective; that is, the eigenvalues of an unreduced symmetric/Hermitian/orthogonal/unitary upper Hessenberg matrix are distinct. Note that in the symmetric/Hermitian case, an upper Hessenberg matrix is tridiagonal.
22. [AGR87] $H = G_1(\gamma_1)...G_n(\gamma_n)$ is transformed by a unitary similarity transformation with $U = F_{2\lfloor(n+1)/2\rfloor-1}...F_7F_5F_3$ into $UHU^* = G_oG_e^*$, where $F_k = \prod_{j=k}^{n} G_j(\gamma_j)$, and

$$\begin{aligned} G_o = G_1(\gamma_1)G_3(\gamma_3)...G_{2\lfloor(n+1)/2\rfloor-1}(\gamma_{2\lfloor(n+1)/2\rfloor-1}) = \\ = \begin{bmatrix} -\gamma_1 & \sigma_1 & & & \\ \sigma_1 & \overline{\gamma}_1 & & & \\ & & -\gamma_3 & \sigma_3 & \\ & & \sigma_3 & \overline{\gamma}_3 & \\ & & & & \ddots \end{bmatrix} \end{aligned}$$

is the product of all odd numbered elementary reflectors and

$$G_e^* = G_2(\gamma_2)G_4(\gamma_4)...G_{2\lfloor n/2\rfloor}(\gamma_{2\lfloor n/2\rfloor}) = \begin{bmatrix} 1 & & & \\ & -\gamma_2 & \sigma_2 & \\ & \sigma_2 & \overline{\gamma}_2 & \\ & & & \ddots \end{bmatrix}$$

is the product of all even numbered elementary reflectors. G_o, G_e are block diagonal matrices with block size at most two. The nontrivial entries are the Schur parameters and the complementary Schur parameters. Therefore, the matrix pencil $G_o - \lambda G_e$ is called Schur parameter pencil.

23. [LMX99, LM74] There exist Hamiltonian and symplectic canonical forms (e.g., Jordan or Kronecker canonical forms) as well as symplectic or Hamiltonian Schur forms.
24. [LH90, LMX99, PL81] For a Hamiltonian matrix H there exists a real orthogonal and symplectic matrix Z such that Z^THZ is in real Hamiltonian Schur form, if and only if every purely imaginary eigenvalue λ of H has even algebraic multiplicity, say $2k$, and any basis $X_k \in \mathbb{C}^{2n\times 2k}$ of the maximal invariant subspace for H corresponding to λ satisfies that $X_k^HJX_k$ is congruent to $J^{2k,2k}$. Moreover, Z can be chosen such that T_1 has only eigenvalues in the open left half-plane. A perturbation analysis for the Hamiltonian Schur form can be found in [KMP02]. Unfortunately, the numerical computation of the Hamiltonian Schur form via strongly backward stable $\mathcal{O}(n^3)$ method has been an open problem since its introduction. It proved difficult to solve, however, so much so that it came to be known as *Van Loan's curse* (see [MSW09] and Section 63.3).

25. [BM86] Any Hamiltonian matrix can be reduced in finitely many steps to Hamiltonian J-Hessenberg form. This reduction is achieved by a series of similarity transformations involving symplectic $n^2 - n$ Givens transformations and two symplectic Householder transformations with $\mathbf{v}_j \in \mathbb{R}^j, j = 2, \ldots, n-1$ (see Chapter 51) as well as $n-1$ non-orthogonal symplectic Gauss transformations. The symplectic Gauss transformations needed can be chosen so that among all possible transformations of that form, the one with the minimal condition number is chosen. Due to the Hamiltonian structure, the $(1,1)$ and the $(2,2)$ block in the Hamiltonian J-Hessenberg form are identical, while the $(1,2)$ block is symmetric. A Hamiltonian J-Hessenberg matrix can be represented by $4n-1$ real parameters. Hence, any Hamiltonian matrix can be represented by $4n-1$ real parameters plus the $2n^2$ parameters needed to represent the symplectic similarity transformation to Hamiltonian J-Hessenberg form.
26. [BB94] For every symplectic matrix M, there exist numerous symplectic matrices S such that $B = S^{-1}MS$ is a symplectic butterfly matrix.This reduction is achieved by a series of similarity transformations involving $n^2 - n$ symplectic Givens transformations and two symplectic Householder transformations with $\mathbf{v}_j \in \mathbb{R}^j, j = 2, \ldots, n-1$ (see Chapter 51) as well as $n-1$ non-orthogonal symplectic Gauss transformations. The Gauss transformations needed can be chosen such that among all possible transformations of that form, the one with the minimal condition number is chosen. The symplectic butterfly form contains at most $8n-4$ nonzero entries.
27. [Fas00a, Chap. 3.2] For simplicity, assume that B is an unreduced symplectic butterfly matrix; that is, that the submatrix B_{22} is unreduced (otherwise B can be easily decomposed into two or more smaller unreduced butterfly matrices). Any unreduced symplectic butterfly matrix can be factorized into two simpler symplectic matrices

$$B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix} = \begin{bmatrix} B_{21}^{-1} & B_{11} \\ 0 & B_{21} \end{bmatrix} \begin{bmatrix} 0 & -I \\ I & B_{21}^{-1}B_{22} \end{bmatrix}$$

where $T = B_{21}^{-1}B_{22}$ is an unreduced, symmetric, tridiagonal matrix and B_{11} and B_{21} are diagonal matrices. In this representation, the symplectic structure of the matrix is explicit: for any choice of diagonal matrices B_{11} and B_{21} and a tridiagonal matrix B_{22} such that T is an unreduced, symmetric, tridiagonal matrix the above matrix B is a symplectic matrix. Any symplectic butterfly matrix can be represented by $4n-1$ real parameters. Hence, any symplectic matrix can be represented by $4n-1$ real parameters plus the $2n^2$ parameters needed to represent the symplectic similarity transformation to symplectic butterfly form.

Examples:

1. The matrix

$$R = \left[\begin{array}{cc|cc} 4 & 4 & 2 & 4 \\ 0 & 2 & 0 & 2 \\ \hline 0 & 4 & 8 & 4 \\ 0 & 0 & 0 & 1 \end{array}\right]$$

is J-triangular. The perfect shuffle PRP^T yields an upper triangular matrix

$$PRP^T = \left[\begin{array}{cc|cc} 4 & 4 & 2 & 4 \\ 0 & 8 & 4 & 4 \\ \hline 0 & 0 & 2 & 2 \\ 0 & 0 & 0 & 1 \end{array}\right].$$

2. The matrices J and

$$H = \left[\begin{array}{cc|cc} 1 & 2 & 5 & 7 \\ 3 & 4 & 7 & 6 \\ \hline 8 & 10 & -1 & -3 \\ 10 & 9 & -2 & -4 \end{array}\right]$$

are Hamiltonian matrices.

3. The matrix

$$\left[\begin{array}{ccc|ccc} 6 & & & 1 & 2 & \\ & 7 & & 2 & 3 & 4 \\ & & 8 & & 4 & 5 \\ \hline 9 & & & -6 & & \\ & 10 & & & -7 & \\ & & 11 & & & -8 \end{array}\right]$$

is in Hamiltonian J-Hessenberg form.

4. The matrices J and

$$S = \begin{bmatrix} 0 & 1 & 0 & 2 \\ \frac{19}{4} & \frac{1}{2} & \frac{5}{4} & 1 \\ 8 & 1 & 2 & 3 \\ 3 & 2 & 1 & 4 \end{bmatrix}$$

are symplectic matrices.

5. For 4 × 4 matrices, the condition that the principal minors of even dimension of PA^TJAP^T need to be nonzero in order for the SR factorization to exist translate into the condition that for

$$A = \begin{bmatrix} A_1 & A_2 \\ A_3 & A_4 \end{bmatrix}$$

the determinants $\det A, \det A_1$, and $\det A_3$ need to be nonzero. Hence, for

$$\begin{bmatrix} 1 & 2 & 3 & 4 \\ 3 & 6 & 5 & 6 \\ 2 & 4 & 7 & 8 \\ 5 & 10 & 9 & 10 \end{bmatrix}$$

the SR factorization does not exist, while for

$$A = \begin{bmatrix} 0 & 2 & 0 & 4 \\ 19 & 25 & \frac{39}{2} & 26 \\ 32 & 42 & 32 & 45 \\ 12 & 20 & 14 & 24 \end{bmatrix}$$

the SR factorization exists and is given by

$$A = SR = \begin{bmatrix} 0 & 1 & 0 & 2 \\ \frac{19}{4} & \frac{1}{2} & \frac{5}{4} & 1 \\ 8 & 1 & 2 & 3 \\ 3 & 2 & 1 & 4 \end{bmatrix} \left[\begin{array}{cc|cc} 4 & 4 & 2 & 4 \\ 0 & 2 & 0 & 2 \\ \hline 0 & 4 & 8 & 4 \\ 0 & 0 & 0 & 1 \end{array}\right].$$

6. The matrix

$$B = \left[\begin{array}{ccc|ccc} 7 & 0 & 0 & 26 & 42 & 0 \\ 0 & 8 & 0 & 48 & 31 & 160 \\ 0 & 0 & 9 & 0 & 180 & 32 \\ \hline \frac{1}{2} & 0 & 0 & 2 & 3 & 0 \\ 0 & 1 & 0 & 6 & 4 & 20 \\ 0 & 0 & \frac{1}{4} & 0 & 5 & 1 \end{array}\right] = \left[\begin{array}{c|c} B_{11} & B_{12} \\ \hline B_{21} & B_{22} \end{array}\right]$$

is a symplectic butterfly matrix which can be further decomposed into the product

$$B = \left[\begin{array}{c|c} B_{21}^{-1} & B_{11} \\ \hline 0 & B_{21} \end{array}\right] \left[\begin{array}{c|c} 0 & -I \\ \hline I & B_{21}^{-1}B_{22} \end{array}\right] = \left[\begin{array}{ccc|ccc} 2 & 0 & 0 & 7 & 0 & 0 \\ 0 & 1 & 0 & 0 & 8 & 0 \\ 0 & 0 & 4 & 0 & 0 & 9 \\ \hline 0 & 0 & 0 & \frac{1}{2} & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{4} \end{array}\right] \left[\begin{array}{ccc|ccc} 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 0 & -1 \\ \hline 1 & 0 & 0 & 4 & 6 & 0 \\ 0 & 1 & 0 & 6 & 4 & 20 \\ 0 & 0 & 1 & 0 & 20 & 4 \end{array}\right].$$

Hence, the symplectic butterfly matrix B can be represented by just 11 parameters: the diagonal entries of B_{11} and B_{21} and the nonzero entries of the tridiagonal B_{22}.

63.2 (Structured) Backward Error and (Structured) Backward Stability

Any numerical eigensolver will not compute the exact eigenvalues λ_j and eigenvectors $\mathbf{x}_j$ of a matrix A ($A\mathbf{x}_j = \lambda_j \mathbf{x}_j$). The computation is affected by round-off errors due to the limitations of finite-precision. Already representing the entries of a matrix A in finite-precision causes a tiny error in the entries ("unit-roundoff", see, e.g., [Hig96]). Hence, any computed eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is not an eigenpair of A, but of a perturbed matrix $A + E$: $(A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}$. In case A is a structured matrix (e.g., symmetric, Hamiltonian, symplectic), then $A + E$ will in general be an unstructured matrix. This will happen when applying a standard eigensolver to a structured matrix, for example when using the QR- or Arnoldi-method for solving a Hamiltonian or symplectic eigenproblem. It implies that any eigenstructure of A can be lost in $A + E$. Hence, for structured problems, it is reasonable to require $A + E$ to be of the same structure as A in order to preserve the eigenstructure. In any case, only a small $||E||$ will give good approximate eigenpairs. The error E will generally differ for each eigenpair (a notable exception are the eigenpairs of a symmetric matrix computed by the QR algorithm). As shown in [Tis03], groups of eigenpairs can be combined, but the size of the resulting E may be larger than for the individual pairs. See Chapter 50 for more on standard backward error analysis.

Definitions:

Let $\mathcal{C}$ denote the set of matrices of interest (e.g., symmetric, Hamiltonian, symplectic) and $||\cdot||$ denotes any vector norm and its corresponding subordinate matrix norm.

The **normwise backward error** of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is given by $\eta(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{||E|| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}\}$.

The **componentwise backward error** of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is given by $\omega(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{\max_{i,j} |e_{ij}| : E = [e_{ij}], (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}\}$.

An eigensolver is called **backward stable** if instead of the exact eigenpair $(\lambda, \mathbf{x})$ an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is computed with a small backward error $\eta(\tilde{\lambda}, \tilde{\mathbf{x}})$, e.g., $\eta(\tilde{\lambda}, \tilde{\mathbf{x}})$ is less than a reasonable multiple of unit roundoff.

For $A \in \mathcal{C}$, the **structured normwise backward error** of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is given by $\eta^{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{||E|| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}, (A + E) \in \mathcal{C}\}$.

For $A \in \mathcal{C}$, the **structured componentwise backward error** of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is given by $\omega^{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{\max_{i,j} |e_{ij}| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}, (A + E) \in \mathcal{C}\}$.

For $A \in \mathcal{C}$, an eigensolver is called **strongly backward stable** if instead of the exact eigenpair $(\lambda, \mathbf{x})$ an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is computed with a small structured backward error $\eta_{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}})$; that is, it is backward stable and $(A + E) \in \mathcal{C}$.

Facts:

1. [Hig96] The componentwise backward error provides a more meaningful measure of the stability than the normwise error when the entries in A vary widely in magnitude.
2. [Dei89] For the 2-norm the normwise backward error is a scaled residual: $\eta(\tilde{\lambda}, \tilde{\mathbf{x}}) = ||A\tilde{\mathbf{x}} - \tilde{\lambda}\tilde{\mathbf{x}}||_2/||\tilde{\mathbf{x}}||_2$. Note that $||A\mathbf{x} - \lambda\mathbf{x}||_2$ is minimized when $\lambda = \mathbf{x}^*A\mathbf{x}/\mathbf{x}^*\mathbf{x}$.
3. [Geu82] $\omega(\tilde{\lambda}, \tilde{\mathbf{x}}) = \max_i |\mathbf{r}_i|/|\tilde{\mathbf{x}}_i|$ for $\mathbf{r} = (A - \tilde{\lambda}I)\tilde{\mathbf{x}}$.
4. [GV96, Chaps. 8.3 and 9], [Ste01a, Chaps. 3, 5, and 6] Methods known to be backward stable include the QR algorithm, most Jacobi-like methods, the power method, the Arnoldi method, IRA, and many of the better Newton-like methods.
5. [GV96, Chaps. 8.3 and 9], [Ste01a, Chaps. 3, 5, and 6] For symmetric matrices, the QR method, the Arnoldi method, and the Jacobi-Davidson method automatically preserve the symmetric structure and are strongly backward stable.
6. [BM86] The SR method is structure-preserving for Hamiltonian and symplectic matrices, but it is not backward stable due to the use of nonorthogonal symplectic transformation matrices. The condition number of the symplectic transformations can easily be monitored and kept at a reasonable size. An error analysis of the symplectic Lanczos method for the symplectic eigenproblem is given in [Fas00b].
7. [BMX98] A numerically backward stable method for computing the eigenvalues (but not the invariant subspaces) of real Hamiltonian matrices is known. An efficient strongly backward stable method for the Hamiltonian or the symplectic eigenproblem is not known thus far.
8. [Tis03] The structured backward error with respect to symmetric matrices is rather close to the standard backward error. This is not the case for all structures considered here. A chart of structured backward errors for approximate eigenpairs of structured eigenvalue problem such as symmetric, Hamiltonian, symplectic, and many others can be found in [Tis03].
9. While rounded symmetric/Hermitian and Hamiltonian matrices remain symmetric/Hermitian and Hamiltonian, orthogonal/unitary and symplectic matrices generally do not. This means that, strictly speaking, algorithms for the orthogonal/unitary, and symplectic eigenvalue problems cannot be strongly backward stable.

63.3 (Structured) Eigenvalue Methods

Algorithms for solving structured eigenvalue problems are often extensions or special cases of existing algorithms for solving the general, unstructured eigenvalue problem. For a discussion of standard eigenvalue algorithms see, e.g., Chapters 56 and 57 or [GV96, Ste01a, Wat07]. Generally, algorithms for solving structured eigenvalue problems preserve the structure of the problem in order to, e.g., preserve eigenvalue pairings in finite-precision arithmetic. Moreover, exploiting the structure often leads to reduced computational time. The Hamiltonian and the symplectic eigenvalue problem are of great importance in many applications in control theory and signal processing; see [AFI03, LR95, Meh91, Sim96, ZDG95].

Definitions:

A Hamiltonian matrix $H = \begin{bmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{bmatrix} \in \mathbb{R}^{2n\times 2n}$ is said to be in **Hamiltonian Hessenberg form** if H_{11} and H_{22}^T are upper Hessenberg matrices, H_{21} has a single nonzero entry at the position

(n, n), and H_{12} is a full matrix, that is

$$H = \begin{bmatrix} \diagdown & \square \\ * & \diagdown \end{bmatrix}.$$

A Hamiltonian matrix H is said to be in **Hamiltonian Schur form** if $H = \begin{bmatrix} T & R \\ 0 & -T^* \end{bmatrix}, T, R \in \mathbb{C}^{n\times n}$ where T is upper triangular and $R^* = R$. It is in **real Hamiltonian Schur form** if in addition T is quasi-upper triangular and $R^T = R$.

Any symplectic matrix S is said to be in **real symplectic Schur form** if $S = \begin{bmatrix} T & Z \\ 0 & T^{-T} \end{bmatrix}, T, R \in \mathbb{R}^{n\times n}$ where T is quasi-upper triangular.

The **SR algorithm** is a QR-like iterative algorithm that performs an SR decomposition at each iteration step (see [BM86]): If B_j is the current iterate, then a spectral transformation function q_j is chosen and the SR decomposition of $q_j(B_j)$ is formed, if possible: $q_j(B_j) = S_j R_j$. Then the symplectic factor S_j is used to perform a similarity transformation on B_j to yield the next iterate $B_{j+1} = S_j^{-1} B_j S_j$. The spectral transformation function may be chosen as simple as $q(B) = B - \mu I$ for a shift $\mu \in \mathbb{R}$ or any other rational polynomial in B.

Facts:

1. The well-known (structure-preserving) algorithms for symmetric eigenproblems are the QR algorithm, the Lanczos algorithm, and the Jacobi method, which are discussed in most basic books on numerical methods (see, e.g., [GV96, Wat91, Dem97, Par98, CW02] or Chapter 55). While the standard implicit QR method requires $\mathcal{O}(n^2)$ operations for each iteration step on an upper Hessenberg matrix, the symmetric QR method applied to a symmetric tridiagonal matrix requires only $\mathcal{O}(n)$ operations for each iteration step. It is structure-preserving as the symmetric tridiagonal form is retained in every iteration step. One of the fastest available methods for computing all eigenvalues and all eigenvectors of a symmetric tridiagonal is the divide-and-conquer algorithm [Cup81, GE95]. Bisection combined with inverse iteration can also be used [Dem97]. The method of Multiple Relatively Robust Representations solves symmetric tridiagonal eigenproblems such that the eigenvectors are orthogonal to working precision [Dhi98, DP03, DP04]. There is also a symmetric version of the Jacobi-Davidson algorithm [BDD00, SV96].
2. [Gra86] The QR algorithm automatically preserves orthogonal/unitary matrices. Making use of the Schur parameter representation of a unitary matrix, one step of the shifted QR algorithm can be implemented very efficiently in an $\mathcal{O}(n)$ process by working only on the parameters, not on the matrix itself; see Algorithm 2. As given here, the algorithm is numerically unstable. See [Ste01b, Ste06] for a discussion and modifications that lead to a provably stable algorithm. A careful choice of the shifts can lead to cubic convergence or even ensure global convergence [WG02, WG03]. Multishift QR steps can be implemented in a similar way working on the parameters only [Wat07].
3. Other structure-preserving or structure-exploiting eigensolvers for unitary (and orthogonal) eigenproblems have been developed. Krylov subspace methods are discussed in [BF97b, HKB05, JR92], while in [GR90] a divide-and-conquer approach was proposed.

Algorithm 2: Single shifted QR step

Input: Schur parameters γ_j and complementary Schur parameters σ_j of an unreduced unitary upper Hessenberg matrix $H = H(\gamma_1, \dots, \gamma_n)$, single shift τ

Output: modified Schur parameters γ_j^{new} and complementary Schur parameters σ_j^{new} of an unreduced unitary upper Hessenberg matrix $H^{new} = H(\gamma_1^{new}, \dots, \gamma_n^{new})$, such that $H = QR - \tau I, H^{new} = RQ + \tau I = Q^* HQ$

```
$\alpha_0 = \tilde{\alpha}_0 = \beta_0 = 1$
for $k = 1 \to n-1$ do
  $\rho_k = \sqrt{\sigma_k^2 + |\tau\alpha_{k-1} + \gamma_k\tilde{\alpha}_{k-1}|^2}$
  $\sigma_{k-1}^{new} = \beta_{k-1}\rho_k, \beta_k = \sigma_k/\rho_k$
  $\alpha_k = (\tau\alpha_{k-1} + \gamma_k\tilde{\alpha}_{k-1})/\rho_k$
  $\tilde{\alpha}_k = (\tilde{\alpha}_{k-1} + \gamma_k^*\tau\tilde{\alpha}_{k-1})/\rho_k$
  $\gamma_k^{new} = \alpha_k\tilde{\alpha}_k^* - \beta_k^2\gamma_{k+1}\tau^*$
end for
$\rho_n = |\tau\alpha_{n-1} + \gamma_n\tilde{\alpha}_{n-1}|, \sigma_{n-1}^{new} = \beta_{n-1}\rho_n$
if $\rho_n > 0$ then
  $\alpha_n = (\tau\alpha_{n-1} + \gamma_n\tilde{\alpha}_{n-1})/\rho_n$
else
  $\alpha_n$ is arbitrary with $|\alpha_n| = 1$
end if
$\tilde{\alpha}_n = \gamma_n^*\alpha_n, \gamma_n^{new} = \gamma_n$
```

4. [Fas00a] The eigenvalues and invariant subspaces of Hamiltonian or symplectic matrices may be computed by the QR algorithm. But the QR method cannot take advantage of the special structure; it will treat the structured matrix like any arbitrary $2n \times 2n$ matrix. The computed eigenvalues will in general not come in quadruples $\lambda, -\lambda, \overline{\lambda}, -\overline{\lambda}$ for Hamiltonian matrices or in pairs λ, λ^{-1} for symplectic matrices, although the exact eigenvalues have this property. Even worse, e.g., for Hamiltonian problems, small perturbations may cause eigenvalues close to the imaginary axis to cross the axis such that the number of true and computed eigenvalues in the right half-plane may differ. To preserve the Hamiltonian or symplectic structure, similarity transformations with symplectic matrices instead of the transformations with the usual unitary matrices in the QR algorithm have to be employed. Hence, in order to develop fast, efficient, reliable, and structure-preserving numerical methods for the Hamiltonian or symplectic eigenproblem one should make use of the rich mathematical structure of the problems. Different structure-preserving methods have been proposed. Most methods for the symplectic eigenproblems are modifications of algorithms for the Hamiltonian eigenproblem.
5. [BM86] The SR algorithm preserves the Hamiltonian J-Hessenberg form. A standard implementation of the SR algorithm for general, unstructured matrices will require $\mathcal{O}(n^3)$ flops in each iteration step. Using the $4n - 1$ parameters, one step of the SR algorithm for H can be carried out in $\mathcal{O}(n)$ flops [Fas07]. Moreover, the Hamiltonian structure, which will be destroyed in the numerical process due to roundoff errors when working with a Hamiltonian (J-Hessenberg) matrix, will be forced by working just with the parameters. The general convergence theory for GR methods developed in [WE91] implies that the SR algorithm for Hamiltonian matrices is typically cubically convergent. The Hamiltonian SR algorithm is currently the fastest structure-preserving algorithm for the Hamiltonian eigenproblem, but it is inherently not backward stable.

6. [Wat07, BFS11, BF97a, FLW97] Structure-preserving Krylov-subspace algorithms based on the SR algorithm have been developed for the Hamiltonian eigenproblem.
7. Jacobi-like methods for computing the Hamiltonian Schur form were proposed in [Bye90, BF97c]. In [FMM01] Jacobi-like algorithm for solving the complete eigenproblem for Hamiltonian (and skew-Hamiltonian) matrices that are also symmetric or skew-symmetric are developed. In addition to preserving structure, these algorithms are inherently parallelizable, and numerically strongly backward stable. The stability in particular of the latter algorithms has been investigated in [Tis01, Tis03].
8. [CLM07, Wat06, MSW09] Using the symplectic URV-decomposition an $\mathcal{O}(n^3)$ method for computing the Hamiltonian Schur form of a Hamiltonian matrix that has no purely imaginary eigenvalues has been developed and generalized to an algorithm which by now is the best available Hamiltonian eigensolver based on the Hamiltonian Schur form although it still does not entirely lift *Van Loan's curse.* This algorithm is based on ideas in [BMX97, BMX98, BMX99] where a numerically backward stable method is proposed to compute all eigenvalues and invariant subspaces of real Hamiltonian matrices using an approach via non-similarity transformations which exploits that one can compute the real skew-Hamiltonian matrix H^2 without forming the square and which makes use of a symplectic URV decomposition.
9. Other structure-preserving or structure-exploiting algorithms for the Hamiltonian eigenproblem have been proposed; see, e.g., the squared-reduced method [V84] or the multishift algorithm [ABM93]. See [BKM05] for a survey on the Hamiltonian eigenvalue problem. Implementations of the algorithms in [BMX98] and [BMX97] are freely available from the SLICOT package.[1] The ideas presented have been extended to Hamiltonian/skew-Hamiltonian, palindromic, and even eigenvalue problems; see, e.g., [KSW09, MP12].
10. [Fas00a, Fas01, BB94] The SR algorithm preserves the symplectic butterfly form. A standard implementation of the SR algorithm for general, unstructured matrices will require $\mathcal{O}(n^3)$ flops in each iteration step. Using the $4n-1$ parameters, one step of the SR algorithm for S can be carried out in $\mathcal{O}(n)$ flops. The method suffers from loss of the symplectic structure due to roundoff errors, but using the factors of the symplectic butterfly matrix B, one can easily and cheaply restore the symplectic structure of the iterates whenever necessary. The general convergence theory for GR methods developed in [WE91] implies that the SR algorithm for symplectic matrices is typically cubically convergent. The symplectic butterfly SR algorithm is currently the fastest structure-preserving algorithm for the Hamiltonian eigenproblem, but it is inherently not backward stable.
11. [Wat07, BF00, BF98] Structure-preserving Krylov-subspace algorithms based on the SR algorithm for symplectic butterfly matrices have been developed for the symplectic eigenproblem.
12. [BMX98, BMX97] Using a Cayley transformation the numerically backward stable, structure-preserving method for computing the eigenvalues and the stable invariant subspace of Hamiltonian eigenproblems can also be used for symplectic matrices. That is, via the Cayley transformation a symplectic matrix is transformed to a Hamiltonian problem. Eigenvalues and the stable invariant subspace are then computed with the method proposed. The eigenvalues of the original symplectic problem are obtained via the inverse Cayley transformation. As the Cayley transformation preserves invariant subspaces, the stable invariant subspace of the original symplectic problem

---

[1] See the SLICOT homepage www.slicot.org.

can be easily read off. This approach is rather expensive for solving a standard symplectic eigenproblem, as such a problem is converted into a generalized Hamiltonian eigenproblem.

13. Other structure-preserving or structure-exploiting algorithms for the symplectic eigenproblem have been proposed; see, e.g., the $S + S^{-1}$–transformation [Lin87] and algorithms based on this idea [LW97, Pat93a] and the multishift algorithm [Pat93b]. The numerical computation of the symplectic Schur form via strongly backward stable $\mathcal{O}(n^3)$ method is still an open problem; see [LMX99]. See [Fas00a] for a survey on the symplectic eigenproblem.

63.4 (Structured) Condition Numbers

A small (structured) backward error is not sufficient to allow conclusions on the accuracy of the eigenvalue. In general, a backward stable algorithm can be expected to accurately solve well-conditioned problems (see Chapter 50, or, e.g., [TB97]), where an eigenproblem is called well-conditioned when small changes in the matrix A result in small changes in the eigenvalues. That is, for $A\mathbf{x} = \lambda\mathbf{x}$ and $(A+E)\tilde{\mathbf{x}} = \hat{\lambda}\tilde{\mathbf{x}}$ a small E implies that λ and $\hat{\lambda}$ are close. In applications one is usually not interested in computing a single eigenvalue/eigenvector, but in computing a number of eigenvalues and the corresponding invariant subspace. Hence, it is not only important to analyze the influence of (structured) perturbations of A on eigenvalues, but also on invariant subspaces.

Bounds on the ratio between the structured and unstructured eigenvalue condition numbers for a number of structures related to Jordan algebras, Lie algebras, and automorphism groups have been established. There are classes of structured matrices for which this ratio is 1 or close to 1. For these structures, the usual unstructured perturbation analysis is sufficient.

Pseudospectra give even more detailed information on the behavior of eigenvalues under perturbations [TE05]. Structured pseudospectra have been considered, e.g., in [Kar03]. See Section 21.1 for more on standard matrix perturbation theory and Section 50.4 for more on conditioning and condition numbers.

Definitions:

Let $\mathcal{C}$ denote the set of matrices of interest (e.g., symmetric, Hamiltonian, symplectic) and $||\cdot||$ denotes a matrix norm. Let $A \in \mathcal{C}$ with an eigenvalue λ.

The **eigenvalue condition number** $\text{cond}(A, \lambda)$ is defined as

$$\text{cond}(A,\lambda) = \lim_{\epsilon\to 0} \sup_{||E||\leq\epsilon} \{\frac{|\tilde{\lambda} - \lambda|}{\epsilon} : \tilde{\lambda} \in \sigma(A+E), E \in \mathbb{C}^{n\times n}\},$$

where $\tilde{\lambda}$ is the eigenvalue of the perturbed matrix $A + E$ closest to λ.

If $\text{cond}(A, \lambda)$ is large, then λ is said to be **ill-conditioned**. If $\text{cond}(A, \lambda)$ is small, then λ is said to be **well-conditioned**. The meaning of "small" and "large" depends on the precision required for the problem to be solved; in general the condition numbers will be suitably scaled (see also Section 50.4).

The **structured eigenvalue condition number** $\text{cond}(A, \lambda, \mathcal{C})$ is formally defined as

$$\text{cond}^{\mathcal{C}}(A,\lambda) = \lim_{\epsilon\to 0} \sup_{||E||\leq\epsilon} \{\frac{|\tilde{\lambda} - \lambda|}{\epsilon} : \tilde{\lambda} \in \sigma(A+E), A+E \in \mathcal{C}\},$$

where $\sigma(A + E)$ denotes the spectrum of $A + E$.

The **condition number of a simple invariant subspace** $\mathcal{X}$ is defined as

$$c(\mathcal{X}) = \lim_{\epsilon \to 0} \sup_{||E||_F \leq \epsilon} \{\frac{||\Theta(\mathcal{X}, \hat{\mathcal{X}})||_F}{\epsilon} : E \in \mathbb{C}^{n\times n}, \hat{\mathcal{X}} \text{ is an invariant subspace of } A+E\}.$$

Here $\Theta(\mathcal{X}, \mathcal{Y}) = \operatorname{diag}(\theta_1((\mathcal{X}, \mathcal{Y}), \ldots, (\theta_k((\mathcal{X}, \mathcal{Y}))$ for invariant subspaces $\mathcal{X}$ and $\mathcal{Y}$ of A. The **canonical angles** between $\mathcal{X}$ and $\mathcal{Y}$ are given as $\theta_j(\mathcal{X}, \mathcal{Y}) = \arccos \sigma_j$ for $j = 1, \ldots, k$ where $\sigma_1 \leq \sigma_2 \leq \ldots \leq \sigma_k$ denote the singular values of X^*Y and the columns of X and Y form orthogonal bases for $\mathcal{X}$ and $\mathcal{Y}$.

The **structured condition number of an invariant subspace** $\mathcal{X}$ with respect to $\mathcal{C}$ is defined as

$$c^{\mathcal{C}}(\mathcal{X}) = \lim_{\epsilon \to 0} \sup_{||E||_F \leq \epsilon} \{\frac{||\Theta(\mathcal{X}, \hat{\mathcal{X}})||_F}{\epsilon} : A + E \in \mathcal{C}, \hat{\mathcal{X}} \text{ is an invariant subspace of } A+E\}.$$

A **stable invariant subspace** $\mathcal{X} \in \mathbb{R}^n$ of $A \in \mathbb{R}^{n\times n}$ is an invariant subspace $\mathcal{X}$ of A (that is, $A(\mathcal{X}) = \{A\mathbf{x} : \mathbf{x} \in \mathcal{X}\} \subseteq \mathcal{X}$ or, equivalently, let $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_k$ be any basis of $\mathcal{X}$, then $AX = XB$ for $X = [\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_k] \in \mathbb{R}^{n\times k}$ and a matrix $B \in \mathbb{R}^{k\times k}$), which corresponds to the eigenvalues in the left half-plane (that is, the eigenvalues of B are all in the left half-plane).

Facts: Facts requiring proof for which no specific reference is given can be found in [KKT06] or [BK06].

1. The definition of the (structured) eigenvalue condition number implies $|\tilde{\lambda} - \lambda| \lessapprox \operatorname{cond}(A, \lambda)||E||_2$ ($|\tilde{\lambda} - \lambda| \lessapprox \operatorname{cond}^{\mathcal{C}}(A, \lambda)||E||_2$). Hence, a backward stable method (that is, small $||E||$) attains high accuracy for a well-conditioned eigenvalue (that is, small $\operatorname{cond}(A, \lambda)$ or small $\operatorname{cond}^{\mathcal{C}}(A, \lambda)$).
2. Unstructured condition numbers are the same as the structured condition numbers for $\mathcal{C} = \mathbb{C}^{n\times n}$, that is $\operatorname{cond}(A, \lambda) = \operatorname{cond}^{\mathbb{C}^{n\times n}}(A, \lambda)$.
3. The structured eigenvalue condition number is always smaller than or equal to the unstructured one: $\operatorname{cond}^{\mathcal{C}}(A, \lambda) \leq \operatorname{cond}(A, \lambda)$. Restricting the admissable perturbations might have a positive effect on the sensitivity of an eigenvalue.
4. Consider $\operatorname{cond}(A, \lambda)$ and $\operatorname{cond}^{\mathcal{C}}(A, \lambda)$ for the matrix 2-norm or the Frobenius norm and a simple eigenvalue λ of A.
   (a) Let $\mathbf{x}$ and $\mathbf{y}$ denote the normalized right and left eigenvector corresponding to λ, i.e., $A\mathbf{x} = \lambda\mathbf{x}, \mathbf{y}^*A = \lambda\mathbf{y}^*, ||\mathbf{x}||_2 = ||\mathbf{y}||_2 = 1$, then $\operatorname{cond}(A, \lambda) = \frac{1}{|\mathbf{y}^*\mathbf{x}|}$.
   (b) $\operatorname{cond}(A, \lambda) \geq 1$, but $\operatorname{cond}^{\mathcal{C}}(A, \lambda)$ can be less than 1.
5. There is a matrix $\hat{X}$ such that the columns of $\hat{X}$ form a basis for an invariant subspace $\hat{\mathcal{X}}$ of the slightly perturbed matrix $A + E$ and $\|\hat{X} - X\|_F \lessapprox c(\mathcal{X})\|E\|_F$ for all $E \in \mathbb{C}^{n\times n}$. The same statement holds for the structured condition number $c^{\mathcal{C}}(\mathcal{X})$ of an invariant subspace.
6. $c(\mathcal{X}) = 1/\operatorname{sep}(A_{11}, A_{22})$ where $\operatorname{sep}(A_{11}, A_{22}) = \min_{R\neq 0} \frac{||A_{22}R - RA_{11}||_F}{||R||_F}$ and A_{11}, A_{22} are the diagonal block of the block Schur decomposition of A corresponding to $\mathcal{X}$. That is, let the columns of the matrix $X \in \mathbb{C}^{n\times k}$ form an orthonormal basis of $\mathcal{X}$ and the columns of $X_\perp \in \mathbb{C}^{n\times k}$ form an orthonormal basis for the orthogonal complement of $\mathcal{X}$, then the block Schur decomposition is given by $[X, X_\perp]^*A[X, X_\perp] = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix}$. See also [Ste73, SS90].
7. For symmetric matrices $A = A^T \in \mathbb{R}^{n\times n}$, the structured eigenvalue and invariant subspace condition numbers are equal to the corresponding unstructured condition numbers, i.e., $\operatorname{cond}^{\mathsf{symm}}(A, \lambda) = \operatorname{cond}(A, \lambda) = 1$ and $c^{\mathsf{symm}}(\mathcal{X}) = c(\mathcal{X}) =$

$\frac{1}{\min\{|\mu-\lambda|:\ \lambda\in\Lambda_1,\mu\in\Lambda_2\}}$, where $\mathcal{X}$ is a simple invariant subspace belonging to an eigenvalue subset $\Lambda_1 \subset \lambda(A)$, and $\Lambda_2 = \lambda(A)\backslash\Lambda_1$.

8. For skew-symmetric matrices $A = -A^T \in \mathbb{R}^{n\times n}$ the structured condition number for a nonzero eigenvalue always satisfies $\text{cond}^{\mathsf{skew}}(A,\lambda) = \text{cond}(A,\lambda) = 1$ while for a simple zero eigenvalue it holds that $\text{cond}^{\mathsf{skew}}(0) = 0$ but $\text{cond}(0) = 1$ [Rum06]. For an invariant subspace $\mathcal{X}$ the structured and the unstructured condition number are equal, $c^{\mathsf{skew}}(\mathcal{X}) = c(\mathcal{X})$.
9. For orthogonal matrices $A \in \mathbb{R}^{n\times n}$, the left and right eigenvector are identical: $A\mathbf{x} = \lambda\mathbf{x}, \mathbf{x}^*A = \lambda\mathbf{x}^*$ for $\mathbf{x} \in \mathbb{C}^n, \|\mathbf{x}\|_2 = 1$. The structured eigenvalue condition number always satisfies $\text{cond}^{\mathsf{orth}}(\lambda) = \sup\{|\mathbf{x}^*AH\mathbf{x}| : H \in \mathsf{skew}, \|AH\|_2 = 1\} = \sup\{|\mathbf{x}^*H\mathbf{x}| : H \in \mathsf{skew}, \|H\|_2 = 1\}$ where the set of skew-symmetric matrices is denoted by skew. (Note that the tangent space of the set of orthogonal matrices at A is given by $\{AH, H \in \mathsf{skew}\}$.) Hence, if $\lambda = \pm 1$ then $\mathbf{x}$ can be chosen to be real, which implies $\mathbf{x}^TH\mathbf{x} = 0$ for all $\mathbf{x}$ and consequently $\text{cond}^{\mathsf{orth}}(\lambda) = 0$, provided that λ is simple. Similarly, if λ is complex, it follows that $\text{cond}^{\mathsf{orth}}(\lambda) = \text{cond}(\lambda) = 1$ and hence $c_2^{\mathsf{orth}}(\lambda) = 1$. A more general perturbation analysis of orthogonal and unitary eigenvalue problems, based on the Cayley transform, can be found in [BBF00].
10. For Hamiltonian matrices $H \in \mathbb{R}^{2n\times 2n}$ there is no or little difference between $\text{cond}(H,\lambda)$ and $\text{cond}^{\mathsf{Hamil}}(H,\lambda)$, the (structured) eigenvalue condition numbers. $c(\mathcal{X})$ and $c^{\mathsf{Hamil}}(\mathcal{X})$ are equal for the important case that $\mathcal{X}$ is the invariant subspace belonging to all eigenvalues in the open left half-plane.
11. For the stable invariant subspace of a Hamiltonian matrix H the structured and the unstructured condition numbers are always the same. Here H does not have any purely imaginary eigenvalues, and the subspace corresponding to the n eigenvalues having negative real part is called the stable invariant subspace of H.
12. For symplectic matrices $S \in \mathbb{R}^{2n\times 2n}$ there is no difference between $\text{cond}(\lambda)$ and $\text{cond}(1/\lambda)$, the unstructured eigenvalue condition numbers, in case λ is a simple eigenvalue. The structured eigenvalue condition numbers differ.
13. For unstructured perturbations both condition numbers for invariant subspaces are the same; that is, if $\mathcal{C} = \mathbb{C}^{n\times n}$, then $c(\mathcal{X}) = c^{\mathbb{C}^{n\times n}}(\mathcal{X})$.
14. For the stable invariant subspace of an orthogonal matrix the structured and the unstructured condition numbers are always the same.

Examples:

1. For any normal matrix $N \in \mathbb{C}^{n\times n}$ (that is, $N^*N = NN^*$) there exists a unitary matrix Q such that $Q^*NQ = \text{diag}(\lambda_1,\ldots,\lambda_n)$ is diagonal. Hence, $N\mathbf{q}_j = \lambda_j\mathbf{q}_j$ and $\mathbf{q}_j^*N = \mathbf{q}_j^*\lambda_j$. Thus, every right eigenvector is also a left eigenvector belonging to the same eigenvalue and $\text{cond}(N,\lambda) = 1$ for all its eigenvalues. Hence, eigenvalues of normal matrices are well-conditioned.
2. [BK06] Let

$$A = \left[\begin{array}{cc|cc} 0 & -1-\alpha & 2 & 0 \\ 1+\alpha & 0 & 0 & 2 \\ \hline 0 & 0 & 0 & 1-\alpha \\ 0 & 0 & -1+\alpha & 0 \end{array}\right], \mathcal{X} = \left\{ \text{Span} \begin{bmatrix} 1 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \\ 0 \end{bmatrix} \right\},$$

where $\alpha \geq 0$ is considered to be tiny. $\mathcal{X}$ is an invariant subspace of A. While $c(\mathcal{X}) = \frac{1}{2\alpha}$, the structured condition number is given by $c(\mathcal{X},\mathcal{C}) = \frac{1}{2}$ if the set $\mathcal{C}$ of perturbations is restricted to matrices of the form $A + E = \begin{bmatrix} \tilde{A}_{11} & \tilde{A}_{12} \\ \tilde{A}_{21} & \tilde{A}_{22} \end{bmatrix}$ with $\tilde{A}_{ij} = \begin{bmatrix} \beta_{ij} & \gamma_{ij} \\ -\gamma_{ij} & \beta_{ij} \end{bmatrix}$ for some $\beta_{ij}, \gamma_{ij} \in \mathbb{R}$.

Computational problems, especially in science and engineering, often involve large matrices. Examples of such problems include large sparse systems of linear equations [FGN92], [Saa03], [vdV03], e.g., arising from discretizations of partial differential equations, eigenvalue problems for large matrices [BDD00], [LM05], linear time-invariant dynamical systems with large state-space dimensions [FF94], [FF95], [Fre03], and large-scale linear and nonlinear optimization problems [KR91], [Wri97], [NW99], [GMS05]. The large matrices in these problems exhibit special structures, such as sparsity, that can be exploited in computational procedures for their solution. Roughly speaking, computational problems involving matrices are called "large-scale" if they can be solved only by methods that exploit these special matrix structures.

In this chapter, as in Chapter 57, multiplication of a vector $\mathbf{v}$ by a scalar λ is denoted by $\mathbf{v}\lambda$ rather than $\lambda\mathbf{v}$.

64.1 Basic Concepts

Many of the most efficient algorithms for large-scale matrix computations are based on approximations of the given large matrix by small matrices obtained via Petrov–Galerkin projections onto suitably chosen small-dimensional subspaces. In this section, we present some basic concepts of such projections.

Definitions:

Let $C \in \mathbb{C}^{n\times n}$ and let $V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j] \in \mathbb{C}^{n\times j}$ be a matrix with orthonormal columns, i.e.,

$$\mathbf{v}_i^*\mathbf{v}_k = \begin{cases} 0 & \text{if } i \neq k, \\ 1 & \text{if } i = k, \end{cases} \quad \text{for all} \quad i, k = 1, 2, \ldots, j.$$

The matrix

$$C_j := V_j^* C V_j \in \mathbb{C}^{j \times j}$$

is called the **orthogonal Petrov–Galerkin projection** of C onto the subspace

$$S = \operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \}$$

of $\mathbb{C}^n$ spanned by the columns of V_j.

Let $C \in \mathbb{C}^{n \times n}$, and let $V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j] \in \mathbb{C}^{n \times j}$ and $W_j = [\mathbf{w}_1 \quad \mathbf{w}_2 \quad \cdots \quad \mathbf{w}_j] \in \mathbb{C}^{n \times j}$ be two matrices such that $W_j^T V_j$ is nonsingular. The matrix

$$C_j := \left(W_j^T V_j\right)^{-1} W_j^T C V_j \in \mathbb{C}^{j \times j}$$

is called the **oblique Petrov–Galerkin projection** of C onto the subspace

$$S = \operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \}$$

of $\mathbb{C}^n$ spanned by the columns of V_j and orthogonally to the subspace

$$T = \operatorname{span}\{\, \mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_j \}$$

of $\mathbb{C}^n$ spanned by the columns of W_j.

A **flop** is the work associated with carrying out any one of the elementary operations $a+b$, $a-b$, ab, or a/b, where a, $b \in \mathbb{C}$, in floating-point arithmetic.

Let $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ be a given matrix. Matrix-vector multiplications with A are said to be **fast** if for any $\mathbf{x} \in \mathbb{C}^n$, the computation of $\mathbf{y} = A\mathbf{x}$ requires significantly fewer than $2mn$ flops.

A matrix $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ is said to be **sparse** if only a small fraction of its entries a_{ik} are nonzero.

For a sparse matrix $A = [a_{ik}] \in \mathbb{C}^{m \times n}$, $nnz(A)$ denotes the number of nonzero entries of A.

A matrix $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ is said to be **dense** if most of its entries a_{ik} are nonzero.

Facts:

The following facts on sparse matrices can be found in [Saa03, Chap. 3] and the facts on computing Petrov–Galerkin projections of matrices in [Saa03, Chap. 6].

1. For a sparse matrix $A = [a_{ik}] \in \mathbb{C}^{m \times n}$, only its nonzero or potentially nonzero entries a_{ik}, together with their row and column indices i and k, need to be stored.
2. Matrix-vector multiplications with a sparse matrix $A = [a_{ik}] \in \mathbb{C}^{m \times n}$ are fast. More precisely, for any $\mathbf{x} \in \mathbb{C}^n$, $\mathbf{y} = A\mathbf{x}$ can be computed with at most $2nnz(A)$ flops.
3. If $C \in \mathbb{C}^{n \times n}$ and $j \ll n$, the computational cost for computing the orthogonal Petrov–Galerkin projection of C onto the j-dimensional subspace $S = \operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \}$ of $\mathbb{C}^n$ is dominated by the j matrix-vector products $\mathbf{y}_i = C\mathbf{v}_i$, $i = 1, 2, \ldots, j$.
4. If $C \in \mathbb{C}^{n \times n}$ and $j \ll n$, the computational cost for computing the oblique Petrov–Galerkin projection of C onto the j-dimensional subspace $S = \operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \}$ of $\mathbb{C}^n$ and orthogonally to the j-dimensional subspace $T = \operatorname{span}\{\, \mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_j \}$ of $\mathbb{C}^n$ is dominated by the j matrix-vector products $\mathbf{y}_i = C\mathbf{v}_i$, $i = 1, 2, \ldots, j$.
5. If matrix-vector products with a large matrix $C \in \mathbb{C}^{n \times n}$ are fast, then orthogonal and oblique Petrov–Galerkin projections C_j of C can be generated with low computational cost.

64.2 Sparse Matrix Factorizations

In this section, we present some basic concepts of sparse matrix factorizations. A more detailed description can be found in [DER89].

Definitions:

Let $A \in \mathbb{C}^{n\times n}$ be a sparse nonsingular matrix. A **sparse** LU **factorization** of A is a factorization of the form

$$A = PLUQ,$$

where P, $Q \in \mathbb{R}^{n\times n}$ are permutation matrices, $L \in \mathbb{C}^{n\times n}$ is a sparse unit lower triangular matrix, and $U \in \mathbb{C}^{n\times n}$ is a sparse nonsingular upper triangular matrix.

Fill-in of a sparse LU factorization $A = PLUQ$ is the set of nonzero entries of L and U that appear in positions (i,k) where $a_{ik} = 0$.

Let $A = A^* \in \mathbb{C}^{n\times n}$, $A \succ 0$, be a sparse Hermitian positive definite matrix. A **sparse Cholesky factorization** of A is a factorization of the form

$$A = PLL^*P^T,$$

where $P \in \mathbb{R}^{n\times n}$ is a permutation matrix and $L \in \mathbb{C}^{n\times n}$ is a sparse lower triangular matrix.

Fill-in of a sparse Cholesky factorization $A = PLL^*P^T$ is the set of nonzero entries of L that appear in positions (i,k) where $a_{ik} = 0$.

Let $T \in \mathbb{C}^{n\times n}$ be a sparse nonsingular (upper or lower) triangular matrix, and let $\mathbf{b} \in \mathbb{C}^n$. A **sparse triangular solve** is the solution of a linear system

$$T\mathbf{x} = \mathbf{b}$$

with a sparse triangular coefficient matrix T.

Facts:

The following facts can be found in [DER89].

1. The permutation matrices P and Q in a sparse LU factorization of A allow for reorderings of the rows and columns of A. These reorderings serve two purposes. First, they allow for pivoting for numerical stability in order to avoid division by the number 0 or by numbers close to 0, which would result in breakdowns or numerical instabilities in the procedure used for the computation of the factorization. Second, the reorderings allow for pivoting for sparsity, the goal of which is to minimize the amount of fill-in.
2. For Cholesky factorizations of matrices $A = A^* \succ 0$, the positive definiteness of A implies that pivoting for numerical stability is not needed. Therefore, the permutation matrix P in a sparse Cholesky factorization serves the single purpose of pivoting for sparsity.
3. For both sparse LU and sparse Cholesky factorizations, the problem of “optimal” pivoting for sparsity, i.e., finding reorderings that minimize the amount of fill-in, is NP-complete. This means that for practical purposes, minimizing the amount of fill-in of factorizations of large sparse matrices is impossible in general. However, there are a large number of pivoting strategies that — while not minimizing fill-in — efficiently limit the amount of fill-in for many important classes of large sparse matrices. (See, e.g., [DER89].)
4. A sparse triangular solve with the matrix T requires at most $2nnz(T)$ flops.

5. Not every large sparse matrix A has a sparse LU factorization with limited amounts of fill-in. For example, LU or Cholesky factorizations of sparse matrices A arising from discretization of partial differential equations for three-dimensional problems are often prohibitive due to the large amount of fill-in.

Examples:

1. Given a sparse LU factorization $A = PLUQ$ of a sparse nonsingular matrix $A \in \mathbb{C}^{n\times n}$, the solution $\mathbf{x}$ of the linear system $A\mathbf{x} = \mathbf{b}$ with any right-hand side $\mathbf{b} \in \mathbb{C}^n$ can be computed as follows:

$$\begin{aligned} \text{Set} \quad & \mathbf{c} = P^T\mathbf{b}, \\ \text{Solve} \quad & L\mathbf{z} = \mathbf{c} \quad \text{for} \quad \mathbf{z}, \\ \text{Solve} \quad & U\mathbf{y} = \mathbf{z} \quad \text{for} \quad \mathbf{y}, \\ \text{Set} \quad & \mathbf{x} = Q^T\mathbf{y}. \end{aligned}$$

   Since P and Q are permutation matrices, the first and the last steps are just reorderings of the entries of the vectors $\mathbf{b}$ and $\mathbf{y}$, respectively. Therefore, the main computational cost is the two triangular solves with L and U, which requires at most $2(nnz(L) + nnz(U))$ flops.
2. Given a sparse Cholesky factorization $A = PLL^*P^T$ of a sparse Hermitian positive definite matrix $A \in \mathbb{C}^{n\times n}$, the solution $\mathbf{x}$ of the linear system $A\mathbf{x} = \mathbf{b}$ with any right-hand side $\mathbf{b} \in \mathbb{C}^n$ can be computed as follows:

$$\begin{aligned} \text{Set} \quad & \mathbf{c} = P^T\mathbf{b}, \\ \text{Solve} \quad & L\mathbf{z} = \mathbf{c} \quad \text{for} \quad \mathbf{z}, \\ \text{Solve} \quad & L^*\mathbf{y} = \mathbf{z} \quad \text{for} \quad \mathbf{y}, \\ \text{Set} \quad & \mathbf{x} = P^T\mathbf{y}. \end{aligned}$$

   Since P is a permutation matrix, the first and the last steps are just reorderings of the entries of the vectors $\mathbf{b}$ and $\mathbf{y}$, respectively. Therefore, the main computational cost is the two triangular solves with L and L^*, which requires at most $4nnz(L)$ flops.
3. In large-scale matrix computations, sparse factorizations are often not applied to a given sparse matrix $A \in \mathbb{C}^{n\times n}$, but to a suitable "approximation" $A_0 \in \mathbb{C}^{n\times n}$ of A. For example, if sparse factorizations of A itself are prohibitive due to excessive fill-in, such approximations A_0 can often be obtained by computing an "incomplete" factorization of A that simply discards unwanted fill-in entries. Given a sparse LU factorization

$$A_0 = PLUQ$$

   of a sparse nonsingular matrix $A_0 \in \mathbb{C}^{n\times n}$, which in some sense approximates the original matrix $A \in \mathbb{C}^{n\times n}$, one then uses iterative procedures that only involve matrix-vector products with the matrix

$$C := A_0^{-1}A = Q^TU^{-1}L^{-1}P^TA,$$

   or possibly its transpose C^T. In the context of solving linear systems $A\mathbf{x} = \mathbf{b}$, the matrix A_0 is called a **preconditioner**, and the matrix C is called the **preconditioned** coefficient matrix.

   In general, the matrix $C = A_0^{-1}A$ is full. However, if C is only used in the form of matrix-vector products, then there is no need to explicitly form C. Instead, for any $\mathbf{v} \in \mathbb{C}^n$, the result of the matrix-vector product $\mathbf{y} = C\mathbf{v}$ can be computed as follows:

$$\begin{aligned} \text{Set} \quad & \mathbf{c} = A\mathbf{v}, \\ \text{Set} \quad & \mathbf{d} = P^T\mathbf{c}, \\ \text{Solve} \quad & L\mathbf{f} = \mathbf{d} \quad \text{for} \quad \mathbf{f}, \\ \text{Solve} \quad & U\mathbf{z} = \mathbf{f} \quad \text{for} \quad \mathbf{z}, \\ \text{Set} \quad & \mathbf{y} = Q^T\mathbf{z}. \end{aligned}$$

Since P and Q are permutation matrices, the second and the last steps are just reorderings of the entries of the vectors $\mathbf{c}$ and $\mathbf{z}$, respectively. Therefore, the main computational cost is the matrix-vector product with the sparse matrix A in the first step, the triangular solve with L in the third step, and the triangular solve with U in the fourth step, which requires a total of at most $2(nnz(A) + nnz(L) + nnz(U))$ flops. Similarly, each matrix product with C^T can be computed with at most $2(nnz(A) + nnz(L) + nnz(U))$ flops. In particular, matrix-vector products with both C and C^T are fast.

4. For sparse Hermitian matrices $A = A^* \in \mathbb{C}^{n\times n}$, preconditioning is often applied in a symmetric manner. Suppose

$$A_0 = PLL^*P^T$$

is a sparse Cholesky factorization of a sparse matrix $A_0 = A_0^* \in \mathbb{C}^{n\times n}$, $A_0 \succ 0$, which in some sense approximates the original matrix A. Then the symmetrically preconditioned matrix C is defined as

$$C := (PL)^{-1}A(L^*P^T)^{-1} = L^{-1}P^TAP(L^*)^{-1}.$$

Note that $C = C^*$ is a Hermitian matrix. For any $\mathbf{v} \in \mathbb{C}^n$, the result of the matrix-vector product $\mathbf{y} = C\mathbf{v}$ can be computed as follows:

$$\begin{aligned} \text{Solve} \quad & L^*\mathbf{c} = \mathbf{v} \quad \text{for} \quad \mathbf{c}, \\ \text{Set} \quad & \mathbf{d} = P\mathbf{c}, \\ \text{Set} \quad & \mathbf{f} = A\mathbf{d}, \\ \text{Set} \quad & \mathbf{z} = P^T\mathbf{f}, \\ \text{Solve} \quad & L\mathbf{y} = \mathbf{z} \quad \text{for} \quad \mathbf{y}. \end{aligned}$$

The main computational cost is the triangular solve with L^* in the first step, the matrix-vector product with the sparse matrix A in the third step, and the triangular solve with L in the last step, which requires a total of at most $2(nnz(A) + 2nnz(L))$ flops. In particular, matrix-vector products with C are fast.

64.3 Krylov Subspaces

Petrov–Galerkin projections are often used in conjunction with Krylov subspaces. In this section, we present the basic concepts of Krylov subspaces. In the following, it is assumed that $C \in \mathbb{C}^{n\times n}$ and $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$.

Definitions:

The sequence

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \ldots, C^{j-1}\mathbf{r}, \ldots$$

is called the **Krylov sequence** induced by C and $\mathbf{r}$.

Let $j \geq 1$. The subspace

$$K_j(C, \mathbf{r}) := \operatorname{span}\{\, \mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \ldots, C^{j-1}\mathbf{r} \,\}$$

of $\mathbb{C}^n$ spanned by the first j vectors of the Krylov sequence is called the **jth Krylov subspace** induced by C and $\mathbf{r}$.

A sequence of linearly independent vectors

$$\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \in \mathbb{C}^n$$

is said to be a **nested basis** for the jth Krylov subspace $K_j(C, \mathbf{r})$ if

$$\operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_i \,\} = K_i(C, \mathbf{r}) \quad \text{for all} \quad i = 1, 2, \ldots, j.$$

Let $p(\lambda) = c_0 + c_1\lambda + c_2\lambda^2 + \cdots + c_{d-1}\lambda^{d-1} + \lambda^d$ be a monic polynomial of degree d with coefficients in $\mathbb{C}$. The **minimal polynomial of C with respect to $\mathbf{r}$** is the unique monic polynomial of smallest possible degree for which $p(C)\mathbf{r} = \mathbf{0}$.

The **grade of C with respect to $\mathbf{r}$**, $d(C, \mathbf{r})$, is the degree of the minimal polynomial of C and $\mathbf{r}$.

Facts:

The following facts can be found in [Hou75, Sect. 1.5], [SB02, Sect. 6.3], or [Saa03, Sect. 6.2].

1. The vectors

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \ldots, C^{j-1}\mathbf{r}$$

   are linearly independent if and only if $j \leq d(C, \mathbf{r})$.
2. Let $d = d(C, \mathbf{r})$. The vectors

$$\mathbf{r}, C\mathbf{r}, C^2\mathbf{r}, \ldots, C^{d-2}\mathbf{r}, C^{d-1}\mathbf{r}, C^j\mathbf{r}$$

   are linearly dependent for all $j > d$.
3. The dimension of the jth Krylov subspace $K_j(C, \mathbf{r})$ is given by

$$\dim K_j(C, \mathbf{r}) = \begin{cases} j & \text{if } j \leq d(C, \mathbf{r}), \\ d(C, \mathbf{r}) & \text{if } j > d(C, \mathbf{r}). \end{cases}.$$

4. $d(C, \mathbf{r}) = \operatorname{rank} [\mathbf{r} \quad C\mathbf{r} \quad C^2\mathbf{r} \quad \cdots \quad C^{n-1}\mathbf{r}]$.

64.4 The Symmetric Lanczos Process

In this section, we assume that $C = C^* \in \mathbb{C}^{n \times n}$ is a Hermitian matrix and that $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$ is a nonzero starting vector. We discuss the **symmetric Lanczos process** [Lan50] for constructing a nested basis for the Krylov subspace $K_j(C, \mathbf{r})$ induced by C and $\mathbf{r}$.

```
Algorithm (Symmetric Lanczos process)
Compute $\beta_1 = \|\mathbf{r}\|_2$ and set $\mathbf{v}_1 = \mathbf{r}/\beta_1$, and $\mathbf{v}_0 = \mathbf{0}$.
For $j = 1, 2, \ldots,$ do:
    1) Compute $\mathbf{v} = C\mathbf{v}_j$ and set $\mathbf{v} = \mathbf{v} - \mathbf{v}_{j-1}\beta_j$.
    2) Compute $\alpha_j = \mathbf{v}_j^*\mathbf{v}$ and set $\mathbf{v} = \mathbf{v} - \mathbf{v}_j\alpha_j$.
    3) Compute $\beta_{j+1} = \|\mathbf{v}\|_2$.
       If $\beta_{j+1} = 0$, stop.
       Otherwise, set $\mathbf{v}_{j+1} = \mathbf{v}/\beta_{j+1}$.
end for
```

Facts:

The following facts can be found in [CW85], [SB02, Sect. 6.5.3], or [Saa03, Sect. 6.6].

1. In exact arithmetic, the algorithm stops after a finite number of iterations. More precisely, it stops when $j = d(C, \mathbf{r})$ is reached.
2. The *Lanczos vectors*
$$\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j$$
generated during the first j iterations of the algorithm form a nested basis for the jth Krylov subspace $K_j(C, \mathbf{r})$.
3. The Lanczos vectors satisfy the three-term recurrence relations
$$\mathbf{v}_{i+1}\beta_{i+1} = C\mathbf{v}_i - \mathbf{v}_i\alpha_i - \mathbf{v}_{i-1}\beta_i, \quad i = 1, 2, \ldots, j.$$
4. These three-term recurrence relations can be written in compact matrix form as follows:
$$CV_j = V_jT_j + \beta_{j+1}\mathbf{v}_{j+1}\mathbf{e}_j^T = V_{j+1}T_j^{(e)}.$$
Here, we set
$$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j], \quad \mathbf{e}_j^T = [0 \quad 0 \quad \cdots \quad 0 \quad 1] \in \mathbb{R}^{1\times j},$$
$$T_j = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \cdots & 0 \\ \beta_2 & \alpha_2 & \beta_3 & \ddots & \vdots \\ 0 & \beta_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_j \\ 0 & \cdots & 0 & \beta_j & \alpha_j \end{bmatrix}, \quad T_j^{(e)} = \begin{bmatrix} T_j \\ \beta_{j+1}\mathbf{e}_j^T \end{bmatrix}, \quad \text{and} \quad V_{j+1} = [V_j \quad \mathbf{v}_{j+1}].$$
Note that $T_j \in \mathbb{C}^{j\times j}$ and $T_j^{(e)} \in \mathbb{C}^{(j+1)\times j}$ are tridiagonal matrices.
5. In exact arithmetic, the Lanczos vectors are orthonormal. Since the Lanczos vectors are the columns of V_j, this orthonormality can be stated compactly as follows:
$$V_j^*V_j = I_j \quad \text{and} \quad V_j^*\mathbf{v}_{j+1} = \mathbf{0}.$$
6. These orthogonality relations, together with the above compact form of the three-term recurrence relations, imply that
$$T_j = V_j^*CV_j.$$
Thus, the jth *Lanczos matrix* T_j is the orthogonal Petrov–Galerkin projection of C onto the jth Krylov subspace $K_j(C, \mathbf{r})$.

7. The computational cost of each jth iteration of the symmetric Lanczos process is fixed, and it is dominated by the matrix-vector product $\mathbf{v} = C\mathbf{v}_j$. In particular, the computational cost for generating the orthogonal Petrov–Galerkin projection T_j of C is dominated by the j matrix-vector products with C.
8. If C is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix–vector products with C are fast. In this case, the symmetric Lanczos process is a very efficient procedure for computing orthogonal Petrov–Galerkin projections T_j of C onto Krylov subspaces $K_j(C, \mathbf{r})$.
9. The three-term recurrence relations used to generate the Lanczos vectors explicitly enforce orthogonality only among each set of three consecutive vectors, $\mathbf{v}_{j-1}$, $\mathbf{v}_j$, and $\mathbf{v}_{j+1}$. As a consequence, in finite-precision arithmetic, round-off error will usually cause loss of orthogonality among all Lanczos vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_{j+1}$.
10. For applications of the Lanczos process in large-scale matrix computations, this loss of orthogonality is often benign, and only delays convergence. More precisely, in such applications, the Lanczos matrix $T_j \in \mathbb{C}^{j\times j}$ for some $j \ll n$ is used to obtain an approximate solution of a matrix problem involving the large matrix $C \in \mathbb{C}^{n\times n}$. Due to round-off error and the resulting loss of orthogonality, the number j of iterations that is needed to obtain a satisfactory approximate solution is larger than the number of iterations that would be needed in exact arithmetic.

64.5 The Nonsymmetric Lanczos Process

In this section, we assume that $C \in \mathbb{C}^{n\times n}$ is a general square matrix, and that $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$, and $\mathbf{l} \in \mathbb{C}^n$, $\mathbf{l} \neq \mathbf{0}$, is a pair of right and left nonzero starting vectors. The **nonsymmetric Lanczos process** [Lan50] is an extension of the symmetric Lanczos process that simultaneously constructs a nested basis for the Krylov subspace $K_j(C, \mathbf{r})$ induced by C and $\mathbf{r}$, and a nested basis for the Krylov subspace $K_j(C^T, \mathbf{l})$ induced by C^T and $\mathbf{l}$. In the context of the nonsymmetric Lanczos process, $K_j(C, \mathbf{r})$ is called the jth **right** Krylov subspace, and $K_j(C^T, \mathbf{l})$ is called the jth **left** Krylov subspace.

Algorithm (Nonsymmetric Lanczos process)

```
Compute $\rho_1 = \|\mathbf{r}\|_2$ and $\eta_1 = \|\mathbf{l}\|_2$. Set $\mathbf{v}_1 = \mathbf{r}/\beta_1$, $\mathbf{w}_1 = \mathbf{l}/\eta_1$, $\mathbf{v}_0 = \mathbf{w}_0 = \mathbf{0}$, and
$\delta_0 = 1$.
For $j = 1, 2, \ldots,$ do:
    1) Compute $\delta_j = \mathbf{w}_j^T \mathbf{v}_j$.
       If $\delta_j = 0$, stop.
    2) Compute $\mathbf{v} = C\mathbf{v}_j$. Set $\beta_j = \eta_j \delta_j / \delta_{j-1}$ and $\mathbf{v} = \mathbf{v} - \mathbf{v}_{j-1}\beta_j$.
    3) Compute $\alpha_j = \mathbf{w}_j^T \mathbf{v}$, and set $\mathbf{v} = \mathbf{v} - \mathbf{v}_j \alpha_j$.
    4) Compute $\mathbf{w} = C^T \mathbf{w}_j$. Set $\gamma_j = \rho_j \delta_j / \delta_{j-1}$ and $\mathbf{w} = \mathbf{w} - \mathbf{w}_j \alpha_j - \mathbf{w}_{j-1}\gamma_j$.
    5) Compute $\rho_{j+1} = \|\mathbf{v}\|_2$ and $\eta_{j+1} = \|\mathbf{w}\|_2$.
       If $\rho_{j+1} = 0$ or $\eta_{j+1} = 0$, stop.
       Otherwise, set $\mathbf{v}_{j+1} = \mathbf{v}/\rho_{j+1}$ and $\mathbf{w}_{j+1} = \mathbf{w}/\eta_{j+1}$.
end for
```

Facts:

The following facts can be found in [SB02, Sect. 8.7.3] or [Saa03, Sect. 7.1].

1. The occurrence of $\delta_j = 0$ in Step 1 of the nonsymmetric Lanczos process is called an *exact breakdown.* In finite-precision arithmetic, one also needs to check for $\delta_j \approx 0$, which is called a *near-breakdown.* It is possible to continue the nonsymmetric Lanczos process even if an exact breakdown or a near-breakdown has occurred, by using so-called "look-ahead" techniques. (See, e.g., [FGN93] and the references given there.) However, in practice, exact breakdowns and even near-breakdowns are fairly rare and, therefore, here we consider only the basic form of the nonsymmetric Lanczos process without look-ahead.
2. In exact arithmetic and if no exact breakdowns occur, the algorithm stops after a finite number of iterations. More precisely, it stops when $j = \min\{\, d(C,\mathbf{r}), d(C^T,\mathbf{l})\,\}$ is reached.
3. The *right Lanczos vectors* and the *left Lanczos vectors*

   $$\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \quad \text{and} \quad \mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_j$$

   generated during the first j iterations of the algorithm form a nested basis for the jth right Krylov subspace $K_j(C,\mathbf{r})$ and the jth left Krylov subspace $K_j(C^T,\mathbf{l})$, respectively.
4. The right and left Lanczos vectors satisfy the three-term recurrence relations

   $$\mathbf{v}_{i+1}\rho_{i+1} = C\mathbf{v}_i - \mathbf{v}_i\alpha_i - \mathbf{v}_{i-1}\beta_i, \quad i = 1, 2, \ldots, j,$$

   and

   $$\mathbf{w}_{i+1}\eta_{i+1} = C^T\mathbf{w}_i - \mathbf{w}_i\alpha_i - \mathbf{w}_{i-1}\gamma_i, \quad i = 1, 2, \ldots, j,$$

   respectively.
5. These three-term recurrence relations can be written in compact matrix form as follows:

   $$\begin{aligned} CV_j &= V_jT_j + \rho_{j+1}\mathbf{v}_{j+1}\mathbf{e}_j^T = V_{j+1}T_j^{(e)}, \\ C^TW_j &= W_j\tilde{T}_j + \eta_{j+1}\mathbf{w}_{j+1}\mathbf{e}_j^T. \end{aligned}$$

   Here, we set

   $$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j], \quad W_j = [\mathbf{w}_1 \quad \mathbf{w}_2 \quad \cdots \quad \mathbf{w}_j],$$

   $$T_j = \begin{bmatrix} \alpha_1 & \beta_2 & 0 & \cdots & 0 \\ \rho_2 & \alpha_2 & \beta_3 & \ddots & \vdots \\ 0 & \rho_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \beta_j \\ 0 & \cdots & 0 & \rho_j & \alpha_j \end{bmatrix}, \quad \tilde{T}_j = \begin{bmatrix} \alpha_1 & \gamma_2 & 0 & \cdots & 0 \\ \eta_2 & \alpha_2 & \gamma_3 & \ddots & \vdots \\ 0 & \eta_3 & \ddots & \ddots & 0 \\ \vdots & \ddots & \ddots & \ddots & \gamma_j \\ 0 & \cdots & 0 & \eta_j & \alpha_j \end{bmatrix},$$

   $$\mathbf{e}_j^T = [0 \quad 0 \quad \cdots \quad 0 \quad 1] \in \mathbb{R}^{1\times j}, \quad \text{and} \quad T_j^{(e)} = \begin{bmatrix} T_j \\ \rho_{j+1}\mathbf{e}_j^T \end{bmatrix}.$$

   Note that T_j, $\tilde{T}_j \in \mathbb{C}^{j\times j}$, and $T_j^{(e)} \in \mathbb{C}^{(j+1)\times j}$ are tridiagonal matrices.
6. The matrix $T_j^{(e)}$ has full rank, i.e., $\operatorname{rank} T_j^{(e)} = j$.
7. In exact arithmetic, the right and left Lanczos vectors are **biorthogonal** to each other, i.e.,

   $$\mathbf{w}_i^T\mathbf{v}_k = \begin{cases} 0 & \text{if } i \neq k, \\ \delta_i & \text{if } i = k, \end{cases} \quad \text{for all} \quad i, k = 1, 2, \ldots, j.$$

Since the right and left Lanczos vectors are the columns of V_j and W_j, respectively, the biorthogonality can be stated compactly as follows:

$$W_j^T V_j = D_j, \quad W_j^T \mathbf{v}_{j+1} = \mathbf{0}, \quad \text{and} \quad V_j^T \mathbf{w}_{j+1} = \mathbf{0}.$$

Here, D_j is the diagonal matrix

$$D_j = \operatorname{diag}(\delta_1, \delta_2, \ldots, \delta_j).$$

Note that D_j is nonsingular, as long as no exact breakdowns occur.

8. These biorthogonality relations, together with the above compact form of the three-term recurrence relations, imply that

$$T_j = D_j^{-1} V_j^* C V_j = \left(W_j^T V_j\right)^{-1} W_j^T C V_j.$$

Thus, the jth **Lanczos matrix** T_j is the oblique Petrov–Galerkin projection of C onto the jth right Krylov subspace $K_j(C, \mathbf{r})$, and orthogonally to the jth left Krylov subspace $K_j(C^T, \mathbf{l})$.

9. The matrices T_j and $\tilde{T}_j^T$ are diagonally similar:

$$\tilde{T}_j^T = D_j T_j D_j^{-1}.$$

10. The computational cost of each jth iteration of the nonsymmetric Lanczos process is fixed, and it is dominated by the matrix-vector product $\mathbf{v} = C\mathbf{v}_j$ with C and by the matrix-vector product $\mathbf{w} = C^T \mathbf{w}_j$ with C^T. In particular, the computational cost for generating the oblique Petrov–Galerkin projection T_j of C is dominated by the j matrix-vector products with C and the j matrix-vector products with C^T.
11. If C is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix-vector products with C and C^T are fast. In this case, the nonsymmetric Lanczos process is a very efficient procedure for computing oblique Petrov–Galerkin projections T_j of C onto right Krylov subspaces $K_j(C, \mathbf{r})$, and orthogonally to left Krylov subspaces $K_j(C^T, \mathbf{l})$.
12. The three-term recurrence relations, which are used to generate the right and left Lanczos vectors, explicitly enforce biorthogonality only between three consecutive right vectors, $\mathbf{v}_{j-1}$, $\mathbf{v}_j$, $\mathbf{v}_{j+1}$, and three consecutive left vectors, $\mathbf{w}_{j-1}$, $\mathbf{w}_j$, $\mathbf{w}_{j+1}$. As a consequence, in finite-precision arithmetic, round-off error will usually cause loss of biorthogonality between all right vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_{j+1}$ and all left vectors $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_{j+1}$.
13. For applications of the Lanczos process in large-scale matrix computations, this loss of orthogonality is often benign, and only delays convergence. More precisely, in such applications, the Lanczos matrix $T_j \in \mathbb{C}^{j \times j}$ for some $j \ll n$ is used to obtain an approximate solution of a matrix problem involving the large matrix $C \in \mathbb{C}^{n \times n}$. Due to round-off error and the resulting loss of biorthogonality, the number j of iterations that is needed to obtain a satisfactory approximate solution is larger than the number of iterations that would be needed in exact arithmetic. (See, e.g., [CW86].)
14. If $C = C^*$ is a Hermitian matrix and $\mathbf{l} = \overline{\mathbf{r}}$, i.e., the left starting vector $\mathbf{l}$ is the complex conjugate of the right starting vector $\mathbf{r}$, then the right and left Lanczos vectors satisfy

$$\mathbf{w}_i = \overline{\mathbf{v}_i} \quad \text{for all} \quad i = 1, 2, \ldots, j+1,$$

and the nonsymmetric Lanczos process reduces to the symmetric Lanczos process.

64.6 The Arnoldi Process

The **Arnoldi process** [Arn51] is another extension of the symmetric Lanczos process for Hermitian matrices to general square matrices. Unlike the nonsymmetric Lanczos process, which produces bases for both right and left Krylov subspaces, the Arnoldi process generates basis vectors only for the right Krylov subspaces. However, these basis vectors are constructed to be orthonormal, resulting in a numerical procedure that is much more robust than the nonsymmetric Lanczos process.

In this section, we assume that $C \in \mathbb{C}^{n\times n}$ is a general square matrix, and that $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$, is a nonzero starting vector.

```
Algorithm (Arnoldi process)
Compute $\rho_1 = \|\mathbf{r}\|_2$ and set $\mathbf{v}_1 = \mathbf{r}/\rho_1$.
For $j = 1, 2, \ldots,$ do:
    1) Compute $\mathbf{v} = C\mathbf{v}_j$.
    2) For $i = 1, 2, \ldots, j$, do:
           Compute $h_{ij} = \mathbf{v}^*\mathbf{v}_i$ and set $\mathbf{v} = \mathbf{v} - \mathbf{v}_j h_{ij}$.
       end for
    3) Compute $h_{j+1,j} = \|\mathbf{v}\|_2$.
       If $h_{j+1,j} = 0$, stop.
       Otherwise, set $\mathbf{v}_{j+1} = \mathbf{v}/h_{j+1,j}$.
end for
```

Facts:

The following facts can be found in [Saa03, Sect. 6.3].

1. In exact arithmetic, the algorithm stops after a finite number of iterations. More precisely, it stops when $j = d(C, \mathbf{r})$ is reached.
2. The *Arnoldi vectors*

$$\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j$$

   generated during the first j iterations of the algorithm form a nested basis for the jth Krylov subspace $K_j(C, \mathbf{r})$.
3. The Arnoldi vectors satisfy the $(i+1)$-term recurrence relations

$$\mathbf{v}_{i+1}h_{i+1,i} = C\mathbf{v}_i - \mathbf{v}_i h_{ii} - \mathbf{v}_{i-1}h_{i-1,i} - \cdots - \mathbf{v}_2 h_{2i} - \mathbf{v}_1 h_{1i}, \quad i = 1, 2, \ldots, j.$$

   These $(i+1)$-term recurrence relations can be written in compact matrix form as follows:

$$CV_j = V_j H_j + h_{j+1,j}\mathbf{v}_{j+1}\mathbf{e}_j^T = V_{j+1}H_j^{(e)}.$$

   Here, we set

$$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j], \quad \mathbf{e}_j^T = [0 \quad 0 \quad \cdots \quad 0 \quad 1] \in \mathbb{R}^{1\times j},$$

$$H_j = \begin{bmatrix} h_{11} & h_{12} & h_{13} & \cdots & h_{1j} \\ h_{21} & h_{22} & h_{23} & \ddots & \vdots \\ 0 & h_{32} & \ddots & \ddots & h_{j-2,j} \\ \vdots & \ddots & \ddots & \ddots & h_{j-1,j} \\ 0 & \cdots & 0 & h_{j,j-1} & h_{jj} \end{bmatrix},$$

$$H_j^{(e)} = \begin{bmatrix} H_j \\ h_{j+1,j}\mathbf{e}_j^T \end{bmatrix}, \quad \text{and} \quad V_{j+1} = [V_j \quad \mathbf{v}_{j+1}].$$

Note that $H_j \in \mathbb{C}^{j\times j}$ and $H_j^{(e)} \in \mathbb{C}^{(j+1)\times j}$ are upper Hessenberg matrices.

4. The matrix $H_j^{(e)}$ has full rank, i.e., $\operatorname{rank} H_j^{(e)} = j$.
5. Since the Arnoldi vectors are the columns of V_j, this orthonormality can be stated compactly as follows:

$$V_j^* V_j = I_j \quad \text{and} \quad V_j^* \mathbf{v}_{j+1} = \mathbf{0}.$$

6. These orthogonality relations, together with the above compact form of the recurrence relations, imply that

$$H_j = V_j^* C V_j.$$

Thus, the jth *Arnoldi matrix* H_j is the orthogonal Petrov–Galerkin projection of C onto the jth Krylov subspace $K_j(C, \mathbf{r})$.
7. As in the case of the symmetric Lanczos process, each jth iteration of the Arnoldi process requires only a single matrix-vector product $\mathbf{v} = C\mathbf{v}_j$. If C is a sparse matrix or a preconditioned matrix with a sparse preconditioner, then the matrix-vector products with C are fast.
8. However, unlike the Lanczos process, the additional computations in each jth iteration do increase with j. In particular, each jth iteration requires the computation of j inner products of vectors of length n, and the computation of j SAXPY-type updates of the form $\mathbf{v} = \mathbf{v} - \mathbf{v}_j h_{ij}$ with vectors of length n.
9. For most large-scale matrix computations, the increasing work per iteration limits the number of iterations that the Arnoldi process can be run. Therefore, in practice, the Arnoldi process is usually combined with restarting; i.e., after a number of iterations (with the matrix C and starting vector $\mathbf{r}$), the algorithm is started again with the same matrix C, but a different starting vector, say $\mathbf{r}_1$.
10. On the other hand, the $(i+1)$-term recurrence relations used to generate the Arnoldi vectors explicitly enforce orthogonality among the first $i+1$ vectors, $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_{i+1}$. As a result, the Arnoldi process is much less susceptible to round-off error in finite-precision arithmetic than the Lanczos process.

64.7 Eigenvalue Computations

In this section, we consider the problem of computing a few eigenvalues, and possibly eigenvectors, of a large matrix $C \in \mathbb{C}^{n\times n}$. We assume that matrix-vector products with C are fast. In this case, orthogonal and, in the non-Hermitian case, oblique Petrov–Galerkin projections of C onto Krylov subspaces $K_j(C, \mathbf{r})$ can be computed efficiently, as long as $j \ll n$.

Facts:

The following facts can be found in [CW85], [CW86], and [BDD00].

1. Assume that $C = C^* \in \mathbb{C}^{n\times n}$ is a Hermitian matrix. We choose any nonzero starting vector $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$, e.g., a vector with random entries, and run the symmetric Lanczos process. After j iterations of the algorithm, we have computed the jth Lanczos matrix T_j, which — in exact arithmetic — is the orthogonal Petrov–Galerkin projection of C onto the jth Krylov subspace $K_j(C, \mathbf{r})$. Neglecting the last term in the compact form of the three-term recurrence relations used in the first j iterations of the symmetric Lanczos process, we obtain the approximation

   $$CV_j \approx V_j T_j.$$

   This approximation suggests to use the j eigenvalues $\lambda_i^{(j)}$, $i = 1, 2, \ldots, j$, of the jth Lanczos matrix $T_j \in \mathbb{C}^{j\times j}$ as approximate eigenvalues of the original matrix C. Furthermore, if one is also interested in approximate eigenvectors, then the above approximation suggests to use

   $$\mathbf{x}_i^{(j)} = V_j \mathbf{z}_i^{(j)} \in \mathbb{C}^n, \quad \text{where} \quad T_j \mathbf{z}_i^{(j)} = \mathbf{z}_i^{(j)} \lambda_i^{(j)}, \quad \mathbf{z}_i^{(j)} \neq \mathbf{0},$$

   as an approximate eigenvector of C corresponding to the approximate eigenvalue $\lambda_i^{(j)}$ of C.
2. Assume that $C \in \mathbb{C}^{n\times n}$ is a general square matrix. Here one can use either the nonsymmetric Lanczos process or the Arnoldi process to obtain approximate eigenvalues.
3. In the case of the nonsymmetric Lanczos process, one chooses any nonzero starting vectors $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$, and $\mathbf{l} \in \mathbb{C}^n$, $\mathbf{l} \neq \mathbf{0}$, $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$. In analogy to the symmetric case, the eigenvalues of Lanczos matrix $T_j \in \mathbb{C}^{j\times j}$ computed by j iterations of the nonsymmetric Lanczos process are used as approximate eigenvalues of the original matrix C. Corresponding approximate right eigenvectors are given by the same formula as above. Furthermore, one can also obtain approximate left eigenvectors from the left eigenvectors of T_j and the first j left Lanczos vectors. A discussion of many practical aspects of using the nonsymmetric Lanczos process for eigenvalue computations can be found in [CW86].
4. In the case of the Arnoldi process, one only needs to choose a single nonzero starting vector $\mathbf{r} \in \mathbb{C}^n$, $\mathbf{r} \neq \mathbf{0}$. Here, one has the approximation

   $$CV_j \approx V_j H_j,$$

   where V_j is the matrix containing the first j Arnoldi vectors as columns and H_j is the jth Arnoldi matrix. The eigenvalues $\lambda_i^{(j)}$, $i = 1, 2, \ldots, j$, of $H_j \in \mathbb{C}^{j\times j}$ are used as approximate eigenvalues of C. Furthermore, for each i,

   $$\mathbf{x}_i^{(j)} = V_j \mathbf{z}_i^{(j)} \in \mathbb{C}^n, \quad \text{where} \quad H_j \mathbf{z}_i^{(j)} = \mathbf{z}_i^{(j)} \lambda_i^{(j)}, \quad \mathbf{z}_i^{(j)} \neq \mathbf{0},$$

   is an approximate eigenvector of C corresponding to the approximate eigenvalue $\lambda_i^{(j)}$ of C.

64.8 Linear Systems of Equations

In this section, we consider the problem of solving large systems of linear equations,

$$C\mathbf{x} = \mathbf{b},$$

where $C \in \mathbb{C}^{n\times n}$ is a nonsingular matrix and $\mathbf{b} \in \mathbb{C}^n$. We assume that any possible preconditioning was already applied and so, in general, C is a preconditioned version of the original coefficient matrix. In particular, the matrix C may actually be dense. However, we assume that matrix-vector products with C and possibly C^T are fast. This is the case when C is a preconditioned version of a sparse matrix A and a preconditioner A_0 that allows a sparse LU or Cholesky factorization.

Facts:

The following facts can be found in [FGN92] or [Saa03].

1. Let $\mathbf{x}_0 \in \mathbb{C}^n$ be an arbitrary initial guess for the solution of the linear system, and denote by
$$\mathbf{r}_0 = \mathbf{b} - C\mathbf{x}_0$$
the corresponding residual vector. A Krylov subspace-based iterative method for the solution of the above linear system constructs a sequence of approximate solutions of the form
$$\mathbf{x}_j \in \mathbf{x}_0 + K_j(C, \mathbf{r}_0), \quad j = 1, 2, \ldots,$$
i.e., the jth iterate is an additive correction of the initial guess, where the correction is chosen from the jth Krylov subspace $K_j(C, \mathbf{r}_0)$ induced by the coefficient matrix C and the initial residual $\mathbf{r}_0$. Now let $V_j \in \mathbb{C}^{n\times j}$ be a matrix the columns of which form a nested basis for $K_j(C, \mathbf{r}_0)$. Then, any possible jth iterate can be parametrized in the form
$$\mathbf{x}_j = \mathbf{x}_0 + V_j\mathbf{z}_j, \quad \text{where} \quad \mathbf{z}_j \in \mathbb{C}^j.$$
Moreover, the corresponding residual vector is given by
$$\mathbf{r}_j = \mathbf{b} - C\mathbf{x}_j = \mathbf{r}_0 - CV_j\mathbf{z}_j.$$
Different Krylov subspace-based iterative methods are then obtained by specifying the choice of the basis matrix V_j and the choice of the parameter vector $\mathbf{z}_j$.
2. The *biconjugate gradient algorithm* (BCG) [Lan52] employs the nonsymmetric Lanczos process to generate nested bases for the right Krylov subspaces $K_j(C, \mathbf{r}_0)$ and the left Krylov subspaces $K_j(C^T, \mathbf{l})$. Here, $\mathbf{l} \in \mathbb{C}^n$, $\mathbf{l} \neq \mathbf{0}$, is an arbitrary nonzero starting vector. The biorthogonality of the right and left Lanczos vectors is exploited to construct the jth iterate $\mathbf{x}_j$ such that the corresponding residual vector $\mathbf{r}_j$ is orthogonal to the left Lanczos vectors, i.e., $W_j^T\mathbf{r}_j = \mathbf{0}$. Using the recurrence relations of the Lanczos process and the above relation for $\mathbf{r}_j$, one can show that the defining condition $W_j^T\mathbf{r}_j = \mathbf{0}$ is equivalent to $\mathbf{z}_j$ being the solution of the linear system
$$T_j\mathbf{z}_j = \mathbf{e}_1^{(j)}\rho_1,$$
where $\mathbf{e}_1^{(j)}$ denotes the first unit vector of length j. Moreover, the corresponding iterates $\mathbf{x}_j$ can be obtained via a simple update from the previous iterate $\mathbf{x}_{j-1}$, resulting in an elegant overall computational procedure. Unfortunately, in general, it cannot be guaranteed that all Lanczos matrices T_j are nonsingular. As a result, BCG iterates $\mathbf{x}_j$ may not exist for every j. More precisely, BCG breaks down if T_j is singular, and it exhibits erratic convergence behavior when T_j is nearly singular.
3. The possible breakdowns and the erratic convergence behavior can be avoided by replacing the $j \times j$ linear system $T_j\mathbf{z}_j = \mathbf{e}_1^{(j)}\rho_1$ by the $(j+1) \times j$ least-squares problem
$$\min_{\mathbf{z}\in\mathbb{C}^j} \left\| \mathbf{e}_1^{(j+1)}\rho_1 - T_j^{(e)}\mathbf{z} \right\|_2.$$

Since $T_j^{(e)} \in \mathbb{C}^{(j+1)\times j}$ always has full rank j, the above least-squares problem has a unique solution $\mathbf{z}_j$. The resulting iterative procedure is the *quasi-minimal residual method* (QMR) [FN91].

4. The *generalized minimal residual algorithm* (GMRES) [SS86] uses the Arnoldi process to generate orthonormal basis vectors for the Krylov subspaces $K_j(C, \mathbf{r}_0)$. The orthonormality of the columns of the Arnoldi basis matrix V_j allows one to choose $\mathbf{z}_j$ such that the residual vector $\mathbf{r}_j$ has the smallest possible norm, i.e.,

$$\|\mathbf{r}_j\|_2 = \|\mathbf{r}_0 - CV_j\mathbf{z}_j\|_2 = \min_{\mathbf{z}\in\mathbb{C}^j} \|\mathbf{r}_0 - CV_j\mathbf{z}\|_2.$$

Using the compact form of the recurrence relations used to generate the Arnoldi vectors, one readily verifies that the above minimal residual property is equivalent to $\mathbf{z}_j$ being the solution of the least-squares problem

$$\min_{\mathbf{z}\in\mathbb{C}^j} \left\| \mathbf{e}_1^{(j+1)}\rho_1 - H_j^{(e)}\mathbf{z} \right\|_2,$$

where $H_j^{(e)} \in \mathbb{C}^{(j+1)\times j}$ is an upper Hessenberg matrix.

5. The idea of quasi-minimization of the residual vector can also be applied to Lanczos-type iterations that, in each jth step, perform two matrix–vector products with C, instead of one product with C and one product with C^T. The resulting algorithm is called the *transpose-free quasi-minimal residual method* (TFQMR) [Fre93]. We stress that QMR and TFQMR produce different sequences of iterates and, thus, QMR and TFQMR are not mathematically equivalent algorithms.

64.9 Dimension Reduction of Linear Dynamical Systems

In this section, we discuss the application of the nonsymmetric Lanczos process to a large-scale matrix problem that arises in dimension reduction of time-invariant linear dynamical systems. A more detailed description can be found in [Fre03].

Definitions:

Let A, $E \in \mathbb{C}^{n\times n}$. The matrix pencil $A - sE$, $s \in \mathbb{C}$, is said to be **regular** if the matrix $A - sE$ is singular only for finitely many values $s \in \mathbb{C}$.

A **single-input, single-output, time-invariant linear dynamical system** is a system of differential-algebraic equations (DAEs) of the form

$$E\frac{d}{dt}\mathbf{x} = A\mathbf{x} + \mathbf{b}u(t),$$
$$y(t) = \mathbf{l}^T\mathbf{x}(t),$$

together with suitable initial conditions. Here, A, $E \in \mathbb{C}^{n\times n}$ are given matrices such that $A - sE$ is a regular matrix pencil, $\mathbf{b} \in \mathbb{C}^n$, $\mathbf{b} \neq \mathbf{0}$, and $\mathbf{l} \in \mathbb{C}^n$, $\mathbf{l} \neq \mathbf{0}$, are given nonzero vectors, $\mathbf{x}(t) \in \mathbb{C}^n$ is the vector of **state variables**, $u(t) \in \mathbb{C}$ is the given input function, $y(t) \in \mathbb{C}$ is the output function, and n is the **state-space dimension**.

The rational function

$$H : \mathbb{C} \mapsto \mathbb{C} \cup \infty, \quad H(s) := \mathbf{l}^T\,(sE - A)^{-1}\,\mathbf{b},$$

is called the **transfer function** of the above time-invariant linear dynamical system.

A **reduced-order model** of state-space dimension j ($< n$) of the above system is a single-input, single-output, time-invariant linear dynamical system of the form

$$E_j \frac{d}{dt}\mathbf{z} = A_j \mathbf{z} + \mathbf{b}_j u(t),$$
$$y(t) = \mathbf{l}_j^T \mathbf{z}(t),$$

where A_j, $E_j \in \mathbb{C}^{j\times j}$ and $\mathbf{b}_j$, $\mathbf{l}_j \in \mathbb{C}^j$, together with suitable initial conditions.

Let $s_0 \in \mathbb{C}$ be such that the matrix $A - s_0E$ is nonsingular. A reduced-order model of state-space dimension j of the above system is said to be a **Padé model** about the expansion point s_0 if the matrices A_j, E_j and the vectors $\mathbf{b}_j$, $\mathbf{l}_j$ are chosen such that the Taylor expansions about s_0 of the transfer function H of the original system and of the reduced-order transfer function

$$H_j : \mathbb{C} \mapsto \mathbb{C} \cup \infty, \quad H_j(s) := \mathbf{l}_j^T (sE_j - A_j)^{-1}\mathbf{b}_j,$$

agree in as many leading Taylor coefficients as possible, i.e.,

$$H_j(s) = H(s) + \mathcal{O}\big((s - s_0)^{q(j)}\big),$$

where $q(j)$ is as large as possible.

Facts:

The following facts can be found in [FF94], [FF95], or [Fre03].

1. In the "generic" case, $q(j) = 2j$.
2. In the general case, $q(j) \geq 2j$; the case $q(j) > 2j$ occurs only in certain degenerate situations.
3. The transfer function H can be rewritten in terms of a single square matrix $C \in \mathbb{C}^{n\times n}$ as follows:

   $$H(s) = \mathbf{l}^T\big(I_n + (s - s_0)C\big)^{-1}\mathbf{r}, \quad \text{where} \quad C := \big(s_0E - A\big)^{-1}E, \quad \mathbf{r} := \big(s_0E - A\big)^{-1}\mathbf{b}.$$

   Note that the matrix C can be viewed as a preconditioned version of the matrix E using the "shift-and-invert" preconditioner $s_0E - A$.
4. In many cases, the state-space dimension n of the original time-invariant linear dynamical system is very large, but the large square matrices A, $E \in \mathbb{C}^{n\times n}$ are sparse. Furthermore, these matrices are usually such that sparse LU factorizations of the shift-and-invert preconditioner $s_0E - A$ can be computed with limited amounts of fill-in. In this case, matrix-vector products with the preconditioned matrix C and its transpose C^T are fast.
5. The above definition of Padé models suggests the computation of these reduced-order models by first explicitly generating the leading $q(j)$ Taylor coefficients of H about the expansion point s_0, and then constructing the Padé model from these. However, this process is extremely ill-conditioned and numerically unstable. (See the discussion in [FF94] or [FF95].)
6. A much more stable way to compute Padé models without explicitly generating the Taylor coefficients is based on the nonsymmetric Lanczos process. The procedure is simply as follows: One uses the vectors $\mathbf{r}$ and $\mathbf{l}$ from the above representation of the transfer function H as right and left starting vectors, and applies the nonsymmetric Lanczos process to the preconditioned matrix C. After j iterations, the algorithm has produced the $j \times j$ tridiagonal Lanczos matrix T_j. The reduced-order model defined by

   $$A_j := s_0T_j - I_j, \quad E_j := T_j, \quad \mathbf{b}_j := (\mathbf{l}^T\mathbf{r})\,\mathbf{e}_1^{(j)}, \quad \mathbf{l}_j := \mathbf{e}_1^{(j)}$$

is a Padé model of state-space dimension j about the expansion point s_0. Here, $\mathbf{e}_1^{(j)}$ denotes the first unit vector of length j.

7. In the large-scale case, Padé models of state-space dimension $j \ll n$ often provide very accurate approximations of the original system of state-space dimension n. In particular, this is the case for applications in VLSI circuit simulation, as discussed in [FF95], [Fre03], [Fre11], and the references given there.
8. Multiple-input multiple-output time-invariant linear dynamical systems are extensions of the above single-input single-output case with the vectors $\mathbf{b}$ and $\mathbf{l}$ replaced by matrices $B \in \mathbb{C}^{n\times m}$ and $L \in \mathbb{C}^{n\times p}$, respectively, where m is the number of inputs and p is the number of outputs. The approach outlined in this section can be extended to the general multiple-input multiple-output case. A suitable extension of the nonsymmetric Lanczos process that can handle multiple right and left starting vectors is needed in this case. For a discussion of such a Lanczos-type algorithm and its application in dimension reduction of general multiple-input multiple-output time-invariant linear dynamical systems, we refer the reader to [ABF00], [Fre03] and the references given there.
9. Large-scale linear dynamical systems arising in VLSI circuit simulation often exhibit special structures that should be preserved by the reduced-order model. Krylov subspace methods can also be employed to generate such **structure-preserving** reduced-order models. One such technique is the SPRIM algorithm [Fre11]. It involves the generation of basis vectors for so-called block Krylov subspaces. The band Arnoldi process, which is described in Section 64.10, is one possible algorithm for this task.

64.10 A Band Arnoldi Process for Multiple Starting Vectors

Large-scale matrix computations often involve multiple input vectors, instead of just one single vector. Examples include linear systems of equations with the same coefficient matrix, but several right-hand side vectors, and linear dynamical systems with multiple input vectors and multiple output vectors. Block Krylov subspaces are an extension of the concept of Krylov subspaces described in Section 64.3 to the case of multiple starting vectors. In this section, we briefly introduce the concept of block Krylov subspaces and present a variant of the Arnoldi process for computing orthonormal basis vectors for block Krylov subspaces.

In the following, the integer $m \geq 1$ denotes the number of multiple starting vectors. We assume that $C \in \mathbb{C}^{n\times n}$ is a general square matrix and that

$$R = [\mathbf{r}_1 \quad \mathbf{r}_2 \quad \cdots \quad \mathbf{r}_m] \in \mathbb{C}^{n\times m}, \quad R \neq 0,$$

is a matrix the columns $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_m$ of which are the m multiple starting vectors. Note that at least one $\mathbf{r}_i \neq \mathbf{0}$, since $R \neq 0$.

Definitions:

Let $\ell \geq 1$. The matrix

$$B_\ell(C,R) := [R \quad CR \quad C^2R\cdots \quad C^{\ell-1}R] \in \mathbb{C}^{n\times \ell m}$$

is called the **ℓth block Krylov matrix**.

The smallest integer ℓ_0 such that

$$n_0 := \operatorname{rank} B_{\ell_0}(C,R) = \operatorname{rank} B_{\ell_0+1}(C,R)$$

is called the **block grade of C with respect to R** [GS09]. The assumption $R \neq 0$ guarantees that $\ell_0 \geq 1$ and $n_0 \geq 1$. Note that the integer n_0 is the largest possible dimension of all the subspaces of $\mathbb{C}^n$ spanned by the subsets of the column vectors of the ℓ_0th block Krylov matrix $B_{\ell_0}(C,R)$.

By scanning the column vectors of the matrix $B_{\ell_0}(C,R)$ from left to right and by deleting any column that is linearly dependent on columns to its left, we obtain the **deflated** block Krylov matrix

$$B^{\text{defl}}(C,R) := [R_1 \quad CR_2 \quad C^2R_3 \cdots \quad C^{\ell-1}R_{\ell_0}] \in \mathbb{C}^{n\times n_0}.$$

This process of detecting and deleting the linearly dependent columns is called **exact deflation**. Note that by construction, the matrix R_l is a submatrix of R_{l-1} for each $l = 1,2,\ldots,\ell_0$, where, for $l = 1$, we set $R_0 = R$. Denoting by m_l the number of columns of R_l, we have

$$m \ge m_1 \ge m_2 \ge \cdots \ge m_{\ell_0} \ge 1 \quad \text{and} \quad m_1 + m_2 + \cdots + m_{\ell_0} = n_0.$$

Let $1 \le j \le n_0$. The subspace of $\mathbb{C}^n$ spanned by the leading j column vectors of the $B^{\text{defl}}(C,R)$ is called the **jth block Krylov subspace** induced by C and R. We use $K_j(C,R)$ to denote the jth block Krylov subspace. Note that by construction, $\dim K_j(C,R) = j$. Note that for the case $m = 1$ of a single starting vector $\mathbf{r} = R$, the jth "block" Krylov subspace $K_j(C,R)$ is identical to the jth Krylov subspace $K_j(C,\mathbf{r})$ introduced in Section 64.3.

Algorithm (Band Arnoldi process)

```
For $i = 1,2,\ldots,m$, set $\hat{\mathbf{v}}_i = \mathbf{r}_i$.
Set $m_c = m$ and $\mathcal{I} = \emptyset$.
For $j = 1,2,\ldots,$ until convergence or $m_c = 0$ do:
  1) Compute $\|\hat{\mathbf{v}}_j\|_2$.
     Decide if $\hat{\mathbf{v}}_j$ should be deflated. If yes, do the following:
       a) Set $\hat{\mathbf{v}}^{\text{defl}}_{j-m_c} = \hat{\mathbf{v}}_j$ and store this vector. Set $\mathcal{I} = \mathcal{I} \cup \{\, j - m_c \,\}$.
       b) Set $m_c = m_c - 1$. If $m_c = 0$, set $j = j - 1$ and stop.
       c) For $i = j, j+1, \ldots, j+m_c-1$, set $\hat{\mathbf{v}}_i = \hat{\mathbf{v}}_{i+1}$.
       d) Repeat all of Step 1.
  2) Set $h_{j,j-m_c} = \|\hat{\mathbf{v}}_j\|_2$ and $\mathbf{v}_j = \hat{\mathbf{v}}_j / h_{j,j-m_c}$.
  3) For $i = j+1, j+2, \ldots, j+m_c-1$, do:
         Compute $h_{j,i-m_c} = \mathbf{v}_j^*\hat{\mathbf{v}}_i$ and set $\hat{\mathbf{v}}_i = \hat{\mathbf{v}}_i - \mathbf{v}_j h_{j,i-m_c}$.
     end for
  4) Compute $\hat{\mathbf{v}}_{j+m_c} = C\,\mathbf{v}_j$.
  5) For $i = 1,2,\ldots,j$, do:
         Compute $h_{ij} = \mathbf{v}_i^*\hat{\mathbf{v}}_{j+m_c}$ and set $\hat{\mathbf{v}}_{j+m_c} = \hat{\mathbf{v}}_{j+m_c} - \mathbf{v}_i h_{ij}$.
     end for
  6)   a) For all $i \in \mathcal{I}$, set $h_{ji} = v_j^*\hat{\mathbf{v}}^{\text{defl}}_i$.
       b) Set $H_j = \left[h_{ik}\right]_{i,k=1,2,\ldots,j}$.
       c) Set $k_\rho = m + \min\{\, 0,\ j - m_c \,\}$ and $\rho_j = \left[h_{i,k-m}\right]_{i=1,2,\ldots,j;\,k=1,2,\ldots,k_\rho}$.
  7) Check if $j$ is large enough. If yes, stop.
end for
```

Facts:

The following facts can be found in [ABF00, Sect. 2] or [Fre03, Sect. 5.1].

1. The *band Arnoldi process* is an extension of the Arnoldi process [Arn51] for a single starting vector $\mathbf{r}$ to multiple starting vectors $\mathbf{r}_1, \mathbf{r}_2, \ldots, \mathbf{r}_m$.

2. The above algorithm for the band Arnoldi process first appeared in this particular form in [Fre03, Sect. 6]. It uses j as the iteration counter. After the first j iterations, the algorithm has generated orthonormal vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \in \mathbb{C}^n$, together with m_{c} so-called *candidate vectors* $\hat{\mathbf{v}}_{j+1}, \hat{\mathbf{v}}_{j+2}, \ldots, \hat{\mathbf{v}}_{j+m_{\mathrm{c}}} \in \mathbb{C}^n$. Here, m_{c} is an integer that is initialized to $m_c = m$ and then reduced by one every time a deflation is peformed. The vectors $\hat{\mathbf{v}}_{j+1}, \hat{\mathbf{v}}_{j+2}, \ldots, \hat{\mathbf{v}}_{j+m_{\mathrm{c}}}$ are constructed to satisfy the orthonality relations

   $$\mathbf{v}_i^* \hat{\mathbf{v}}_{j+k} = 0 \quad \text{for all} \quad i = 1, 2, \ldots, j, \quad k = 1, 2, \ldots, m_{\mathrm{c}},$$

   but, in general, they are not orthogonal to each other. At the next, $(j+1)$st, iteration of the band Arnoldi process, the candidate vector $\hat{\mathbf{v}}_{j+1}$ is first checked for necessary deflation. *Exact deflation* at this iteration occurs if, and only if, $\hat{\mathbf{v}}_{j+1} = \mathbf{0}$ is the zero vector. If $\hat{\mathbf{v}}_{j+1} \neq \mathbf{0}$, the vector is normalized to become the next orthonormal vector $\mathbf{v}_{j+1} = \hat{\mathbf{v}}_{j+1} / \|\hat{\mathbf{v}}_{j+1}\|_2$. Otherwise, $\hat{\mathbf{v}}_{j+1}$ is deleted from the candidate vectors and m_{c} is reduced by one. In finite-precision arithmetic, one actually peforms *inexact deflation.* This means that one checks if $\|\hat{\mathbf{v}}_{j+1}\|_2 \geq \mathtt{tol}$, where $\mathtt{tol} > 0$ is a suitably chosen small *deflation tolerance*, and sets $\mathbf{v}_{j+1} = \hat{\mathbf{v}}_{j+1} / \|\hat{\mathbf{v}}_{j+1}\|_2$ only if this check is passed. Otherwise, $\hat{\mathbf{v}}_{j+1}$ is deleted from the candidate vectors and m_{c} is reduced by one.
3. If the band Arnoldi process is run in exact arithmetic and only exact deflation is performed, the algorithm stops after $j = n_0$ iterations with $m_{\mathrm{c}} = 0$.

   Notation for Facts 4–9 *below*:
   Let $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j \in \mathbb{C}^n$ and $\hat{\mathbf{v}}_{j+1}, \hat{\mathbf{v}}_{j+2}, \ldots, \hat{\mathbf{v}}_{j+m_{\mathrm{c}}} \in \mathbb{C}^n$ be the vectors and ρ_j and H_j be the matrices that were generated during the first j iterations of the band Arnoldi process, either with inexact deflation or only exact deflation. We set

   $$V_j = [\mathbf{v}_1 \quad \mathbf{v}_2 \quad \cdots \quad \mathbf{v}_j] \in \mathbb{C}^{n \times j}.$$

   Note that the actual value of $m_{\mathrm{c}} = m_{\mathrm{c}}(j)$ changes in the course of the algorithm. In fact, it decreases by one every time an exact or inexact deflation occurs.

4. We have the orthogonality relations

   $$V_j^* V_j = I_j \quad \text{and} \quad V_j^* \hat{\mathbf{v}}_{j+k} = 0, \quad k = 1, 2, \ldots, m_c.$$

   In particular, the vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j$ are orthonormal.
5. If the algorithm is run in exact arithmetic and only exact deflation is performed, the vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_j$ are an orthonormal nested basis for the jth block Krylov subspace $K_j(C, R)$:

   $$\operatorname{span}\{\, \mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_i \,\} = K_i(C, R) \quad \text{for all} \quad i = 1, 2, \ldots, j.$$

6. The matrices ρ_j and H_j satisfy the relations

   $$\rho_j = V_j^* R \quad \text{and} \quad H_j = V_j^* C V_j.$$

   In particular, the matrix H_j is the orthogonal Petrov-Galerkin projection of C onto the subspace spanned by the columns of V_j.
7. If the algorithm is run in exact arithmetic and only exact deflation is performed, the matrix H_j is the orthogonal Petrov-Galerkin projection of C onto the jth block Krylov subspace $K_j(C, R)$.
8. The matrix H_j is a banded upper-Hessenberg matrix with m_{c} subdiagonals below the main diagonal; this structure motivated the name “band” Arnolid process. Moreover, every time a deflation occurs, the most outer subdiagonal ends and from that point

on the bandwidth is reduced by one. If inexact deflation is allowed, then every time an inexact deflation occurs, potentially nonzero entries appear in the column of H_j where the most outer subdiagonal ends. Similarly, the matrix ρ_j is upper-triangular with the most outer diagonal ending when deflation occurs for a candidate vector originating from the m starting vectors. In the case of inexact deflation, potentially nonzero entries appear in the corresponding column of ρ_j.

9. The following example illustrates the structure of H_j and ρ_j. We assume that $m = 4$ and that two deflations occur during the first $j = 8$ iterations of the band Arnoldi process. The first deflation is due to $\hat{\mathbf{v}}_3$ being deflated during iteration $j = 3$ and the second deflation is due to $\hat{\mathbf{v}}_6$ being deflated during iteration $j = 6$. After the completion of the iteration $j = 8$, the matrices H_8 and ρ_8 have the following sparsity structure:

$$H_8 = \begin{bmatrix} * & * & * & * & * & * & * & * \\ * & * & * & * & * & * & * & * \\ * & * & * & * & * & * & * & * \\ + & * & * & * & * & * & * & * \\ 0 & + & * & * & * & * & * & * \\ 0 & 0 & \times & + & * & * & * & * \\ 0 & 0 & \times & 0 & + & * & * & * \\ 0 & 0 & \times & 0 & 0 & + & * & * \end{bmatrix} \quad \text{and} \quad \rho_8 = \begin{bmatrix} + & * & * & * \\ 0 & + & * & * \\ 0 & 0 & \times & + \\ 0 & 0 & \times & 0 \\ 0 & 0 & \times & 0 \\ 0 & 0 & \times & 0 \\ 0 & 0 & \times & 0 \\ 0 & 0 & \times & 0 \end{bmatrix}.$$

Here, "$*$" indicates a potentially nonzero matrix entry, "+" indicates a guaranteed positive entry, and "×" indicates an entry that is exactly zero for exact deflation and potentially nonzero for inexact deflation. Note that $m_c = m_c(8) = m - 2 = 2$ since two deflations have occurred.

65.1 Introduction

Linear algebra appears throughout physics. Linear differential equations, both ordinary and partial, appear through classical and quantum physics. Even where the equations are nonlinear, linear approximations are extremely powerful.

Two big ideas underpin linear analysis in physics. The first is the *Superposition Principle.* Suppose we have a linear problem where we need to compute the output for an arbitrary input. If there is a solution to the problem with input I_1 and output O_1, a solution with input I_2 and output O_2, etc., then the response to the input $c_1 I_1 + \cdots + c_k I_k$ is $c_1 O_1 + \cdots c_k O_k$. It is, therefore, enough to solve our problem for a limited set of inputs I_k, as long as an arbitrary input can be written as a linear combination of these special cases.

The second big idea is the *Decoupling Principle.* If a system of coupled differential equations (or difference equations) involves a diagonalizable square matrix A, then it is helpful to pick new coordinates $\mathbf{y} = [\mathbf{x}]_{\mathcal{B}}$, where $\mathcal{B}$ is a basis of eigenvectors of A. Rewriting our equations in terms of the y variables, we discover that the evolution of each variable y_k depends only on y_k, and not on the other variables, and that the form of the equation depends only on the kth eigenvalue of A. We can then solve our equations, one variable at a time, to get $\mathbf{y}$ as a function of time and, hence, get $\mathbf{x}$ as a function of time. (When A is not diagonalizable, one uses a basis for which $[A]_{\mathcal{B}}$ is in Jordan canonical form. The resulting equations for $\mathbf{y}$ are not completely decoupled, but are still relatively easy.)

Thanks to Newton's Law, $F = ma$, much of classical physics is expressed in terms of systems of second order ordinary differential equations. If the force is a linear function of position, the resulting equations are linear, and the special solutions that come from eigenvectors of the force matrix are called *normal modes of oscillation.* For nonlinear problems near equilibrium, the force can always be expanded in a Taylor series, and for small oscillations the leading (linear) term is dominant. Solutions to realistic nonlinear problems, such as small oscillations of a pendulum, are then closely approximated by solutions to linear problems.

Linear field equations also permeate classical physics. Maxwell's equations, which govern electromagnetism, are linear. There are an infinite number of degrees of freedom, namely the value of the field at each point, but the Superposition Principle and the Decoupling Principle still apply. We use a continuous basis of possible inputs, namely Dirac δ functions, and the resulting outputs are called Green's functions. The response to an arbitrary input is then the convolution of the input and the relevant Green's function.

Nonrelativistic quantum mechanics is governed by Schrödinger's equation, which is also linear. Much of quantum mechanics reduces to diagonalizing the Hamiltonian operator and applying the Decoupling Principle.

Symmetry plays a big role in quantum mechanics. Both vectors and operators decompose into representations of the rotation groups $SO(3)$ and $SU(2)$. The irreducible representations are finite-dimensional, so the study of rotations (and angular momentum) often reduces to a study of finite matrices.

65.2 Normal Modes of Oscillation

Suppose we have two blocks, each with mass m, attached to three springs, as in Figure 65.1, with the spring constants as shown, and let $x_i(t)$ be the displacement of the ith block from equilibrium at time t. It is easy to see that if $x_1(0) = x_2(0)$, and if $\dot{x}_1(0) = \dot{x}_2(0)$, then $x_1(t) = x_2(t)$ for all time. The middle spring never gets stretched, and the two blocks oscillate, in phase, with angular frequency $\omega_1 = \sqrt{k_1/m}$. If $x_2(0) = -x_1(0)$ and $\dot{x}_2(0) = -\dot{x}_1(0)$, then by symmetry $x_2(t) = -x_1(t)$ for all time, and each block oscillates with angular frequency $\omega_2 = \sqrt{(k_1 + 2k_2)/m}$. (This t t is worked out in detail below.) These two solutions, with $x_1(t) = \pm x_2(t)$, are called *normal modes of oscillation*. Remarkably, every solution to the equations of motion is a linear combination of these two normal modes.

Definitions:

Suppose we have an arrangement of blocks, all of the same mass m, and springs with varying spring constants. Let $x_1(t), \ldots, x_n(t)$ denote the locations of the blocks, relative to equilibrium, and $\mathbf{x} = [x_1, \ldots, x_n]^T$. For any function $f(t)$, let $\dot{f}(t) = df/dt$.

The **kinetic energy** is $T = m \sum_k \dot{x}_k^2/2$.

The **potential energy** is $V(\mathbf{x}) = \sum_{ij} a_{ij} x_i x_j/2$, where $A = (a_{ij})$ is a symmetric matrix.

The **equations of motion** are

$$m \frac{d^2\mathbf{x}}{dt^2} = -A\mathbf{x}.$$

Let $\mathcal{B} = \{\mathbf{z}_1, \ldots, \mathbf{z}_n\}$ be a basis of eigenvectors of A, and let $\mathbf{y}(t) = [\mathbf{x}(t)]_{\mathcal{B}}$ be the coordinates of $\mathbf{x}(t)$ in this basis.

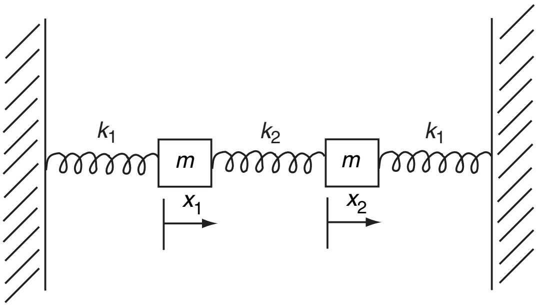

FIGURE 65.1 Coupled oscillators.

Facts:

(See Chapter 13 of [Mar70], Chapter 6 of [Gol80], and Chapter 5 of [Sad08].)

1. A is diagonalizable, and the eigenvalues of A are all real.
2. The eigenvectors can be chosen orthonormal with respect to the standard inner product: $\langle \mathbf{z}_i, \mathbf{z}_j \rangle = \delta_{ij}$.
3. The initial conditions for $\mathbf{y}(t)$ can be computed using the inner product: $y_k(0) = \langle \mathbf{z}_k, \mathbf{x}(0) \rangle, \dot{y}_k(0) = \langle \mathbf{z}_k, \dot{\mathbf{x}}(0) \rangle$.
4. In terms of the $\mathbf{y}$ variables, the equations of motion reduce to $md^2y_k/dt^2 = -\lambda_k y_k$, where λ_k is the eigenvalue corresponding to the eigenvector $\mathbf{z}_k$.
5. The solution to this equation depends on the sign of λ_k. If $\lambda_k > 0$, set $\omega_k = \sqrt{\lambda_k/m}$. We then have
$$y_k(t) = y_k(0)\cos(\omega_k t) + \frac{\dot{y}_k(0)}{\omega_k}\sin(\omega_k t).$$
If $\lambda_k < 0$, set $\kappa_k = \sqrt{-\lambda_k/m}$ and we have
$$y_k(t) = y_k(0)\cosh(\kappa_k t) + \frac{\dot{y}_k(0)}{\kappa_k}\sinh(\kappa_k t).$$
Finally, if $\lambda_k = 0$, then
$$y_k(t) = y_k(0) + \dot{y}_k(0)t.$$
6. If the system has translational symmetry, then there is a $\lambda = 0$ mode describing uniform motion of the system.
7. If the system has rotational symmetry, then there is a $\lambda = 0$ mode describing uniform rotation.
8. All solutions of the equations of motion are of the form $\mathbf{x}(t) = \sum y_k(t)\mathbf{z}_k$, where for each nonzero λ_k, $y_k(t)$ is of the form given in Fact 5.

Examples:

1. In the block-and-spring example above, the kinetic energy is $m(\dot{x}_1^2+\dot{x}_2^2)/2$, while the potential energy is $(k_1x_1^2 + k_2(x_1 - x_2)^2 + k_1x_2^2)/2 = \langle \mathbf{x}, A\mathbf{x} \rangle/2$, where $A = \begin{pmatrix} k_1 + k_2 & -k_2 \\ -k_2 & k_1 + k_2 \end{pmatrix}$. The eigenvalues of A are k_1 and $k_1 + 2k_2$, with normalized eigenvectors $(\sqrt{2}/2, \sqrt{2}/2)^T$ and $(\sqrt{2}/2, -\sqrt{2}/2)^T$. Both eigenvalues are positive, so we have oscillations with angular frequencies $\omega_1 = \sqrt{k_1/m}$ and $\omega_2 = \sqrt{(k_1 + 2k_2)/m}$. Suppose we start by pushing the first block to the right and letting go. That is, suppose $\mathbf{x}(0) = (1, 0)^T$ and $\dot{\mathbf{x}}(0) = (0, 0)^T$. From the initial data we compute
$$\begin{aligned} y_1(0) &= \frac{\sqrt{2}}{2}(x_1(0) + x_2(0)) = \sqrt{2}/2 \\ y_2(0) &= \frac{\sqrt{2}}{2}(x_1(0) - x_2(0)) = \sqrt{2}/2 \\ \dot{y}_1(0) &= \frac{\sqrt{2}}{2}(\dot{x}_1(0) + \dot{x}_2(0)) = 0 \\ \dot{y}_1(0) &= \frac{\sqrt{2}}{2}(\dot{x}_1(0) - \dot{x}_2(0)) = 0 \\ y_1(t) &= y_1(0)\cos(\omega_1 t) + \frac{\dot{y}_1(0)}{\omega_1}\sin(\omega_1 t) = \sqrt{2}\cos(\omega_1 t)/2 \end{aligned}$$

$$y_2(t) = y_2(0)\cos(\omega_2 t) + \frac{\dot{y}_2(0)}{\omega_2}\sin(\omega_2 t) = \sqrt{2}\cos(\omega_2 t)/2$$

$$\mathbf{x}(t) = y_1(t)\mathbf{z}_1 + y_2(t)\mathbf{z}_2 = \frac{1}{2}\begin{pmatrix}\cos(\omega_1 t) + \cos(\omega_2 t)\\ \cos(\omega_1 t) - \cos(\omega_2 t)\end{pmatrix}.$$

2. LC circuits obey the same equations as blocks and springs, with the capacitances playing the role of spring constants and the inductances playing the role of mass, and with the current around each loop playing the role of x_i.
3. Small oscillations: A particle in an arbitrary potential $V(\mathbf{x})$, or a system of identical-mass particles in an arbitrary n-body potential, follows the equation $md^2\mathbf{x}/dt^2 = -\nabla V(\mathbf{x})$. If $\mathbf{x} = \mathbf{x}_0$ is a critical point of the potential, so $\nabla V(\mathbf{x}_0) = 0$, then we expand $V(\mathbf{x})$ around $\mathbf{x} = \mathbf{x}_0$ in a Taylor series:

$$V(\mathbf{x}) = V(\mathbf{x}_0) + \frac{1}{2}\sum_{ij} a_{ij}(\mathbf{x}-\mathbf{x}_0)_i(\mathbf{x}-\mathbf{x}_0)_j + O(|\mathbf{x}-\mathbf{x}_0|^3),$$

where $a_{ij} = \left.\frac{\partial^2 V}{\partial x_i \partial x_j}\right|_{\mathbf{x}=\mathbf{x}_0}$, so $\nabla V(\mathbf{x}) = A(\mathbf{x}-\mathbf{x}_0) + O(|\mathbf{x}-\mathbf{x}_0|^2)$, and our displacement $\mathbf{x}-\mathbf{x}_0$ from equilibrium is governed by the approximate equation $md^2(\mathbf{x}-\mathbf{x}_0)/dt^2 = -A(\mathbf{x}-\mathbf{x}_0)$.

For example, a pendulum of mass m and length ℓ has quadratic kinetic energy $m\ell^2\dot{\theta}^2/2$ and nonlinear potential energy $mg\ell(1-\cos(\theta))$. For θ small, this potential energy is approximated by $mg\ell\theta^2/2$, and the equations of motion are approximated by $\ell d^2\theta/dt^2 = -g\theta$, and yields oscillations of angular frequency $\sqrt{g/\ell}$. The same ideas apply to motion of a pendulum near the top of the circle: $\theta = \pi$. Then $V(\theta) \approx mg\ell(2 - (\theta-\pi)^2/2)$, and our equations of motion are approximately $\ell d^2(\theta-\pi)/dt^2 = +g(\theta-\pi)$. The deviation of θ from the unstable equilibrium grows as $e^{\kappa t}$, with $\kappa = \sqrt{g/\ell}$, until $\theta - \pi$ is large enough that our quadratic approximation for $V(\theta)$ is no longer valid.

Finally, one can consider two pendula, near their stable equilibria, attached by a weak spring. The resulting equations are almost identical to those of the coupled springs of Figure 65.1.
4. Central force motion (see Chapter 3 of [Gol80] or Chapter 8 of [Mar70]): In systems with symmetry, it is often possible to use conserved quantities to integrate out some of the variables, obtaining reduced equations for the remaining variables. For instance, if an object is moving in a central force (e.g., a planet around a star or a classical electron around the nucleus), conservation of angular momentum allows us to integrate out the angular variables and get an equation for the distance r. The radius then oscillates in a pseudopotential $V(r)$, obtained by adding a $1/r^2$ centrifugal term to the true potential $V_0(r)$. Orbits that are almost circular are described by small oscillations of the variable r around the minimum of the pseudopotential $V(r)$, and the frequency of oscillation is $\sqrt{V''(r_0)/m}$, where the pseudopotential has a minimum at $r = r_0$. When the true potential is a $1/r$ attraction (as with gravitation and electromagnetism), these oscillations have the same period as the orbital motion itself. Planets traverse elliptical orbits, with the sun at a focus, and the nearest approach to the sun (the perihelion) occurs at the same point each year. When the true potential is an r^2 attraction (simple harmonic motion), the radial oscillations occur with frequency twice that of the orbit. The motion is elliptical with the center of force at the center of the orbit, and there are two perihelia per cycle. For almost any other kind of force, the radial oscillations and the rotation are incommensurate, the orbit is not a closed curve, and the perihelion precesses.

65.3 Lagrangian Mechanics

In the previous section, we assumed that all the particles had the same mass or, equivalently, that the kinetic energy was proportional to the squared norm of the velocity. Here we relax this assumption and we also allow generalized coordinates.

Definitions:

The **Lagrangian function** is $L(\mathbf{q}, \dot{\mathbf{q}}) = T - V$, where T is the kinetic energy and V is the potential energy. One can express the Lagrangian in terms of arbitrary generalized coordinates $\mathbf{q}$ and their derivatives $\dot{\mathbf{q}}$.

The **kinetic energy** is typically quadratic in the velocity: $T = \langle \dot{\mathbf{q}}, B(\mathbf{q})\dot{\mathbf{q}} \rangle/2$, where the symmetric "mass matrix" B may depend on the coordinates $\mathbf{q}$, but not on the velocities $\dot{\mathbf{q}}$.

The **potential energy** V depends only on the coordinates $\mathbf{q}$ (and not on $\dot{\mathbf{q}}$), but may be nonlinear.

If $\mathbf{q}_0$ is a critical point of V, we consider motion with $\mathbf{q}$ close to $\mathbf{q}_0$ and $\dot{\mathbf{q}}$ small.

Facts:

(See Chapter 7 of [Mar70] or Chapters 2 and 6 of [Gol80].)

1. The Euler–Lagrange equations
$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{q}_k}\right) = \frac{\partial L}{\partial q_k}$$
reduce to the approximate equations of motion
$$B\frac{d^2(\mathbf{q} - \mathbf{q}_0)}{dt^2} = -A(\mathbf{q} - \mathbf{q}_0),$$
where $a_{ij} = \left.\frac{\partial^2 V}{\partial q_i \partial q_j}\right|_{\mathbf{q}=\mathbf{q}_0}$, essentially as before, and the mass matrix B is evaluated at $\mathbf{q} = \mathbf{q}_0$. Instead of looking for eigenvalues and eigenvectors of A, we look for numbers λ_k and vectors $\mathbf{z}_k$ such that $A\mathbf{z}_k = \lambda_k B\mathbf{z}_k$. (See Chapter 56.) We then let $\mathbf{y} = [\mathbf{q} - \mathbf{q}_0]_{\mathcal{B}}$.
2. The matrices A and B are symmetric, and the eigenvalues of B are all positive.
3. The numbers λ_k are the roots of the polynomial $\det(xB - A)$. When B is the identity matrix, these reduce to the eigenvalues of A.
4. One can find a basis of solutions $\mathbf{z}_k$ to $A\mathbf{z}_k = \lambda_k B\mathbf{z}_k$, with λ_k real. The numbers λ_k are the eigenvalues of $B^{-1}A$, or equivalently of the symmetric matrix $B^{-1/2}AB^{-1/2}$, which explains why the λ_k's are real.
5. The eigenvectors can be chosen orthonormal with respect to an inner product involving B. (See Chapter 5.) That is, if $\langle \mathbf{u}, \mathbf{v} \rangle_B = \mathbf{u}^T B\mathbf{v}$, then $\langle \mathbf{z}_i, \mathbf{z}_j \rangle_B = \delta_{ij}$.
6. The initial conditions for $\mathbf{y}(t)$ can be computed using the modified inner product of the previous fact: $y_k(0) = \langle \mathbf{z}_k, \mathbf{q}(0) - \mathbf{q}_0(0) \rangle_B$, $\dot{y}_k(0) = \langle \mathbf{z}_k, \dot{\mathbf{q}}(0) \rangle_B$.
7. In terms of the $\mathbf{y}$ variables, the approximate equations of motion reduce to the decoupled equations $d^2 y_k/dt^2 = -\lambda_k y_k$.
8. The solution to these equations depends on the sign of λ_k. If $\lambda_k > 0$, set $\omega_k = \sqrt{\lambda_k}$; if $\lambda_k < 0$, set $\kappa_k = \sqrt{-\lambda_k}$. With values of ω_k or κ_k, the solutions take the same form as in Fact 65.2.5.
9. If the system is symmetric under the action of a continuous group, then there is a $\lambda = 0$ mode for each generator of this group.
10. All solutions of the approximate equations of motion are of the form $\mathbf{q}(t) = \mathbf{q}_0 + \sum y_k(t)\mathbf{z}_k$, where for each nonzero λ_k, $y_k(t)$ is of the form given by Fact 8 above (and Fact 65.2.5).

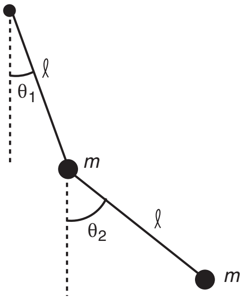

FIGURE 65.2 A double pendulum.

Examples:

1. Consider the double pendulum of Figure 65.2, where each ball has mass m and each rod has length ℓ. For large motions, this system is famously chaotic, but for small oscillations it is simple. The two coordinates are the angles θ_1 and θ_2, and the potential energy of the system is $mg\ell(3 - 2\cos(\theta_1) - \cos(\theta_2)) \approx mg\ell(\theta_1^2 + \theta_2^2/2)$, so $A = mg\ell \begin{pmatrix} 2 & 0 \\ 0 & 1 \end{pmatrix}$. The kinetic energy is $\frac{m\ell^2}{2}\left(\dot\theta_1^2 + (\sin(\theta_1)\dot\theta_1 + \sin(\theta_2)\dot\theta_2)^2 + (\cos(\theta_1)\dot\theta_1 + \cos(\theta_2)\dot\theta_2)^2\right)$. For small values of θ_1 and θ_2, this is approximately $\frac{m\ell^2}{2}(2\dot\theta_1^2 + \dot\theta_2^2 + 2\dot\theta_1\dot\theta_2)$, so $B = m\ell^2 \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}$. $\det(xB - A) = m^2\ell^4(x^2 - 4(g/\ell)x + 2g^2/\ell^2)$, with roots $\lambda_1 = (g/\ell)(2+\sqrt{2})$ and $\lambda_2 = (g/\ell)(2-\sqrt{2})$, and with $\mathbf{z}_i = c_i(1, \mp\sqrt{2})^T$, $i = 1, 2$, where c_i are normalization constants. The two normal modes are as follows: There is a fast mode, with $\omega_1 = \sqrt{(g/\ell)(2+\sqrt{2})} \approx 1.8478\sqrt{g/\ell}$, with the two pendula swinging in opposite directions, and with the bottom pendulum swinging $\sqrt{2}$ more than the top; there is a slow mode, with $\omega_2\sqrt{(g/\ell)(2-\sqrt{2})} \approx 0.7654\sqrt{g/\ell}$, with the two pendula swinging in the same direction, and with the bottom pendulum swinging $\sqrt{2}$ more than the top.

65.4 Schödinger's Equation

In quantum mechanics, the evolution of a particle of mass m, moving in a time-dependent potential $V(x,t)$, is described by Schrödinger's equation,

$$i\hbar\frac{\partial\psi(x,t)}{\partial t} = -\frac{\hbar^2}{2m}\nabla^2\psi(x,t) + V(x,t)\psi(x,t),$$

where $\hbar$ is Planck's constant divided by 2π, and the square of the complex wavefunction $\psi(x,t)$ describes the probability of finding a particle at position x at time t. Space and time are not treated on equal footing. We consider the wavefunction ψ to be a square-integrable function of x that evolves in time.

Definitions:

Let $\mathcal{H} = L^2(\mathbb{R}^n)$ be the Hilbert space of square-integrable functions on $\mathbb{R}^n$ with "inner product"

$$\langle\phi|\psi\rangle = \int_{\mathbb{R}^n} \overline{\phi(x)}\psi(x)d^nx.$$

Note that this inner product is linear in the *second* factor and conjugate-linear in the first factor. Although mathematicians usually choose their complex inner products $\langle u, v\rangle$ to be linear in u and conjugate-linear in v, among physicists the convention, and notation, is invariably that of the above equation. The bracket of ϕ and ψ can be viewed as a pairing of two pieces, the "bra" $\langle\phi|$ and the "ket" $|\psi\rangle$. The ket $|\psi\rangle$ is a vector in $\mathcal{H}$, while $\langle\phi|$ is a map from $\mathcal{H}$ to the complex numbers, namely, "take the inner product of ϕ with an input vector."

The Hermitian adjoint of an operator A, denoted A^*, is the unique operator such that $\langle A^*\phi|\psi\rangle = \langle\phi|A\psi\rangle$, for all vectors ϕ, ψ. An operator A is called **Hermitian**, or **self-adjoint**, if $A^* = A$, and **unitary** if $A^* = A^{-1}$.

The **commutator** of two operators A and B, denoted $[A, B]$, is the difference $AB - BA$. A and B are said to **commute** if $AB = BA$.

The **expectation value** of an operator A in the state $|\psi\rangle$ is the statistical average of repeated measurements of A in the state $|\psi\rangle$, and is denoted $\langle A\rangle$, with the dependence on $|\psi\rangle$ implicit. The **uncertainty in** A, denoted ΔA, is the root mean squared variation in measurements of A.

The **generalized eigenvalues** of an operator A are points in the spectrum of A, and the **generalized eigenvectors** are formal solutions to $A|\psi\rangle = \lambda|\psi\rangle$. These may not be true eigenvalues and eigenvectors if ψ is not square integrable. (See Facts 11 to 15 below.) This use of the term "generalized eigenvector," which is standard in physics, has *nothing* to do with the same term in matrix theory (where it signifies vectors $\mathbf{v}$ for which $(A - \lambda I)^k\mathbf{v} = 0$ for some positive integer k).

Facts:

(See Chapter 6 of [Sch68] or Chapters 5 and 7 of [Mes00].)

1. The Schrödinger equation can be recast as an ordinary differential equation with values in $\mathcal{H}$:
$$i\hbar\frac{d|\psi\rangle}{dt} = H(t)|\psi\rangle,$$
where $H = -\frac{\hbar^2}{2m}\nabla^2 + V$ is the Hamiltonian operator.
2. Physically measurable quantities, also called *observables*, are represented by Hermitian operators. It is easy to see that the position operator $(X\psi)(x) = x\psi(x)$, the momentum operator $(P\psi)(x) = -i\hbar\nabla\psi(x)$, and the Hamiltonian $H = P^2/2m + V$ are all self-adjoint.
3. If an observable a is represented by the operator A, then the possible values of a measurement of a are the (generalized) eigenvalues of A.
4. Two Hermitian operators A, B can be simultaneously diagonalized if and only if they commute.
5. Suppose the state of the system is described by the vector $|\psi\rangle = \sum_n c_n|\phi_n\rangle$, where $\sum |c_n|^2 = 1$ and each $|\phi_n\rangle$ is a normalized eigenvector of A with eigenvalue λ_n. Then the probability of a measurement of a yielding the value λ_n is $|c_n|^2$.
6. If $|\psi\rangle$ is as in the previous fact, then the expectation value of A is $\langle A\rangle = \sum_n \lambda_n|c_n|^2$.
7. The uncertainty of A satisfies $(\Delta A)^2 = \langle A^2\rangle - \langle A\rangle^2$.
8. If A, B, and C are Hermitian operators with $[A, B] = iC$, then $\Delta A\Delta B \geq |\langle C\rangle|/2$.
9. In particular, $XP - PX = i\hbar$, so $\Delta X\Delta P \geq \hbar/2$. This is *Heisenberg's uncertainty principle.*
10. If the Hamiltonian operator does not depend on time, then energy is conserved. In fact, if $|\psi(0)\rangle = \sum c_n|\phi_n\rangle$, where $H|\phi_n\rangle = E_n|\phi_n\rangle$, then $|\psi(t)\rangle = \sum c_n e^{-iE_nt/\hbar}|\phi_n\rangle$. (Eigenvalues of the Hamiltonian are usually denoted E_n, for energy.) Solving the Schrödinger equation is tantamount to diagonalizing the Hamiltonian and using a basis of eigenvectors.
11. Operators may have continuous spectrum, in which case the generalized eigenvectors are not square-integrable. In particular, e^{ikx} is a generalized eigenvector for $P = -i\hbar d/dx$ with generalized eigenvalue $\hbar k$, and the Dirac delta function $\delta(x - a)$ is a generalized eigenvector for X with eigenvalue a.

12. Let $|A, \alpha\rangle$ be a generalized eigenvector of the operator A with generalized eigenvalue α. If A has continuous spectrum, then the decomposition of a state $|\psi\rangle$ involves integrating over eigenvalues instead of summing: $|\psi\rangle = \int f(\alpha)|A, \alpha\rangle d\alpha$. The generalized eigenstates are usually normalized so that $\langle\psi|\psi\rangle = \int |f(\alpha)|^2 d\alpha$. Equivalently, $\langle A, \alpha|A, \beta\rangle = \delta(\alpha - \beta)$.
13. For continuous spectra, $|f(\alpha)|^2$ is not the probability of a measurement of A yielding the value α. Rather, $|f(\alpha)|^2$ is a probability *density*, and the probability of a measurement yielding a value between a and b is $\int_a^b |f(\alpha)|^2 d\alpha$.
14. The two most common expansions in terms of generalized eigenvalues are for the position operator and the momentum operator: $|\psi\rangle = \int \psi(x)|X, x\rangle dx = \int \hat{\psi}(k)|P, \hbar k\rangle dk$. The coefficients $\hat{\psi}(k)$ of $|\psi\rangle$ in the momentum basis are the Fourier transform of the coefficients $\psi(x)$ in the position basis. From this perspective, the Fourier transform is just a change-of-basis.
15. An operator may have both discrete and continuous spectrum, in which case eigenfunction expansions involve summing over discrete eigenvalues and integrating over continuous eigenvalues. For example, for the Hamiltonian of a hydrogen atom, there are discrete negative eigenvalues that describe bound states, and a continuum of positive eigenvalues that describe ionized hydrogen, with the electron having broken free of the nucleus.

Examples:

1. *The one-dimensional harmonic oscillator.* We have seen that a classical harmonic oscillator with potential energy $kx^2/2$ has frequency $\omega = \sqrt{k/m}$, so we write the Hamiltonian of a quantum mechanical harmonic oscillator as

$$H = \frac{P^2}{2m} + \frac{kX^2}{2} = \frac{P^2 + m^2\omega^2 X^2}{2m}.$$

We will compute the eigenvalues and eigenvectors of this Hamiltonian.

We define a *lowering operator*

$$a = \frac{P - im\omega X}{\sqrt{2m\hbar\omega}}.$$

The Hermitian conjugate of a is the *raising operator*

$$a^* = \frac{P + im\omega X}{\sqrt{2m\hbar\omega}}.$$

Note that a and a^* do not commute. Rather, $[a, a^*] = 1$. In terms of a and a^*, the Hamiltonian takes the form

$$H = \hbar\omega(a^*a + aa^*)/2 = \frac{\hbar\omega}{2}(2a^*a + 1) = \frac{\hbar\omega}{2}(2aa^* - 1).$$

Note that a^*a is positive-definite, since $\langle\psi|a^*a\psi\rangle = \langle a\psi|a\psi\rangle \geq 0$, so the eigenvalues of energy must all be at least $\hbar\omega/2$.

Since $Ha = a(H - \hbar\omega)$, the operator a serves to lower the energy of a state by $\hbar\omega$. If $|\phi\rangle$ is an eigenvector of H with eigenvalue E, then $Ha|\phi\rangle = a(H - \hbar\omega)|\phi\rangle = a(E - \hbar\omega)|\phi\rangle = (E - \hbar\omega)a|\phi\rangle$, so $a|\phi\rangle$ is either the zero vector or a state with energy $E - \hbar\omega$. Since we cannot reduce the energy below $\hbar\omega/2$, by applying a repeatedly (say, $n \geq 0$ times), we must eventually get a vector $|\phi_0\rangle$ for which $a|\phi_0\rangle = 0$. But then $H|\phi_0\rangle = \frac{\hbar\omega}{2}(2a^*a + 1)|\phi_0\rangle = \frac{\hbar\omega}{2}|\phi_0\rangle$. Since it took n lowerings to get the energy to $\hbar\omega/2$, our original state $|\phi\rangle$ must have had energy $(n + \frac{1}{2})\hbar\omega$.

The notation $|n\rangle$ is often used for this nth excited state, so $a|n\rangle$ is a constant times $|n - 1\rangle$. It remains to compute that constant. Normalizing $\langle n|n\rangle = 1$ and picking the phases such that $\langle n-1|an\rangle > 0$, we compute $\langle an|an\rangle = \langle n|a^*an\rangle = \frac{\langle n|Hn\rangle}{\hbar\omega} - \frac{1}{2} = n\langle n|n\rangle = n$, so $a|n\rangle = \sqrt{n}|n-1\rangle$. A similar calculation yields $a^*|n\rangle = \sqrt{n+1}|n+1\rangle$ and, hence, $|n\rangle = (a^*)^n|0\rangle/\sqrt{n!}$.

The state $|0\rangle$ is in the kernel of a. In a coordinate basis, where X is multiplication by x and $P = -i\hbar d/dx$, the equation $a|0\rangle = 0$ becomes a first-order differential equation

$$\frac{d\psi(x)}{dx} + \frac{m\omega x}{\hbar}\psi(x) = 0,$$

whose solution is the Gaussian $\psi(x) = \exp(-m\omega x^2/2\hbar)$ times a normalization constant. The nth state is obtained by applying the differential operater $\frac{d}{dx} - \frac{m\omega x}{\hbar}$ to the Gaussian n times. The result is an nth order (Hermite) polynomial in x times the Gaussian.

65.5 Angular Momentum and Representations of the Rotation Group

The same techniques that solved the harmonic oscillator also work to diagonalize the angular momentum operator.

Definitions:

Angular momentum is a vector: $\vec{L} = \vec{X} \times \vec{P}$, or in coordinates, $L_1 = X_2P_3 - X_3P_2$, $L_2 = X_3P_1 - X_1P_3$, $L_3 = X_1P_2 - X_2P_1$. Each L_i is a self-adjoint observable. We define $L^2 = L_1^2 + L_2^2 + L_3^2$, and define a **raising operator** $L_+ = L_1 + iL_2$ and a **lowering operator** $L_- = L_1 - iL_2$.

Facts:

(See Chapter 7 of [Sch68] or Chapter 13 of [Mes00].)

1. The three components of angular momentum do not commute. Rather,

$$[L_1, L_2] = i\hbar L_3, \qquad [L_2, L_3] = i\hbar L_1, \qquad [L_3, L_1] = i\hbar L_2.$$

   By the uncertainty principle, this means that only one component of the angular momentum can be known at a time.
2. L^2 is Hermitian, and each $[L_i, L^2] = 0$. It is possible to know both L^2 and L_3, and we consider simultaneous eigenstates $|\ell, m\rangle$ of L^2 and L_3, where ℓ labels the eigenvalue of L^2 and $\hbar m$ is the eigenvalue of L_3.
3. $[L^2, L_\pm] = 0$ and $[L_3, L_\pm] = \pm\hbar L_\pm$. This means that L_+ does not change the eigenvalue of L^2, but increases the eigenvalue of L_3 by $\hbar$. Likewise, L_- decreases the eigenvalue of L_3 by $\hbar$.
4. Since $L^2 - L_3^2 = L_1^2 + L_2^2 \geq 0$, there is a limit to how big m (or $-m$) can get. For each ℓ, there is a state $|\ell, m_{max}\rangle$ for which $L_+|\ell, m_{max}\rangle = 0$, and a state $|\ell, m_{min}\rangle$ for which $L_-|\ell, m_{min}\rangle = 0$. We set the label ℓ to be equal to m_{max}.
5. $L_-L_+ = L_1^2 + L_2^2 - \hbar L_3$ and $L_+L_- = L_1^2 + L_2^2 + \hbar L_3$, so we can write L^2 in terms of $L_\pm$ and L_3: $L^2 = L_-L_+ + L_3^2 + \hbar L_3 = L_+L_- + L_3^2 - \hbar L_3$.
6. The minimum value of m is $-\ell$. Since $2\ell = m_{max} - m_{min}$ is an integer, ℓ must be half of a nonnegative integer.
7. The states $|\ell, m\rangle$, with m ranging from $-\ell$ to ℓ, form a $(2\ell+1)$ dimensional irreducible representation of the Lie algebra of $SO(3)$. We denote this representation V_ℓ, and call it the "spin-ℓ" representation.
8. In V_ℓ, we have $L^2|\ell, m\rangle = \hbar^2\ell(\ell+1)|\ell, m\rangle$, $L_3|\ell, m\rangle = m\hbar|\ell, m\rangle$, and $L_\pm|\ell, m\rangle = \hbar\sqrt{\ell(\ell+1) - m(m\pm 1)}|\ell, m\pm 1\rangle$.

9. If u is a unit vector, then a rotation by the angle θ about the u axis is implemented by the unitary operator $\exp(-i\theta L \cdot u/\hbar)$.
10. Since rotation by 2π equals the identity, representations of the Lie group $SO(3)$ satisfy the additional condition $\exp(2\pi i L_3) = 1$, which forces m (and therefore ℓ) to be an integer.
11. If one particle has angular momentum ℓ_1 and another has angular momentum ℓ_2, then the combined angular momentum can be any integer between $|\ell_1 - \ell_2|$ and $\ell_1 + \ell_2$. In terms of representations, $V_{\ell_1} \otimes V_{\ell_2} = \oplus_{\ell=|\ell_1-\ell_2|}^{\ell_1+\ell_2} V_\ell$.
12. The Lie group $SU(2)$ is the double cover of $SO(3)$, and has the same Lie algebra. The generators are usually denoted J rather than L, and the maximum value of m is denoted j rather than ℓ, but otherwise the computations are the same. J describes the total angular momentum of a particle, including spin, and j can be either an integer or a half-integer.
13. Particles with j integral are called bosons, while particles with j half-integral are called fermions.
14. If the Hamiltonian is rotationally symmetric, then angular momentum is conserved, and our energy eigenstates can be chosen to be eigenstates of J^2 and J_3.

65.6 Green's Functions

Expansions in a continuous basis of eigenfunctions are not limited to quantum mechanics. The Dirac δ is an eigenfunction of position, and any function can be written trivially as an integral over δ functions:

$$f(x) = \int f(y)\delta(x-y)dy = \int f(y)|X, y\rangle dy.$$

It therefore suffices to solve linear input–output problems in the case where the input is a δ-function located at an arbitrary point y. The resulting solution $G(y,x)$ is called a **Green's function** (or in some texts, **Green function**) for the problem, and the solution for an arbitrary input $f(x)$ is the convolution $\int f(y)G(y,x)dy$.

Facts:

(See [Jac75], especially Chapters 1 to 3, for many applications to electrostatics, and see Chapter 11 of [Sad08] for a general introduction to Green's functions.)

1. Green's functions are sometimes called *integral kernels*, especially in the mathematics literature, or *propagators* in quantum field theory. The term *propagator* is also sometimes used for the Fourier transform of a Green's function.
2. Linear partial differential equations appear throughout physics. Examples include Maxwell's equations, Laplace's equation, Schrödinger's equation, the heat equation, the wave equation, and the Dirac equation. Each equation generates its own Green's function.
3. Some boundary value problems involve Neumann boundary conditions, in which the normal derivative of a function (as opposed to the value of a function) is specified on S, and some problems involve mixed Neumann and Dirichlet conditions. The formalism for these cases is a simple modification of the Dirichlet formalism.
4. Two common techniques for computing Green's functions are Fourier transforms and the method of images.
5. Fourier transforms apply when the problem has translational symmetry, as in the heat equation example, above. We decompose a δ function as a linear combination of

exponentials e^{ikx}, compute the response for each exponential, and re-sum.

6. The method of images is illustrated in Example 2, where the actual response $G(y,x)$ is a sum of two terms. The first is the response $G_0(y,x)$ to the actual charge at y, computed without boundary, and the second is the response to a mirror charge, located at a point outside D, and chosen so that the sum of the two terms is zero on S.

Examples:

1. *Electrostatics without boundaries.* The electrostatic potential $\phi(x)$ is governed by Poisson's equation:
$$\nabla^2\phi = -4\pi\rho(x),$$
where $\rho(x)$ is the charge density. Here, ρ is the input and ϕ is the output. Since the solution to $\nabla^2 G(y,x) = -4\pi\delta^3(x-y)$ is $G(y,x) = |x-y|^{-1}$, the potential due to a charge distribution $\rho(x)$ is $\phi(x) = \int d^3y\rho(y)/|x-y|$. (Note that when we write $\nabla^2 G(y,x)$, we are taking the second derivative of $G(y,x)$ with respect to x. The variable y is just a parameter.)
2. *Electrostatics with boundary conditions.* Poisson's equation on a domain D with boundary S is more subtle, as we need to apply boundary conditions on S. Suppose that D is the exterior of a ball of radius R, and that we apply the homogeneous Dirichlet boundary condition $\phi = 0$ on S. (This corresponds to S being a grounded conducting sphere.) The function $G_0(y,x) = 1/|x-y|$ satisfies $\nabla^2 G_0(y,x) = -4\pi\delta^3(x-y)$, but does not satisfy the boundary condition. The function $G(y,x) = G_0(y,x) - \frac{R}{|y|}G_0(R^2y/|y|^2, x)$ satisfies $\nabla^2 G(y,x) = -4\pi\delta^3(x-y)$ and $G(y,x) = 0$ for $x \in S$.

   Nonzero boundary values can be considered part of the input. If we want to solve the equation $\nabla^2\phi = -4\pi\rho$ on D with boundary values $f(x)$ on S, then we have two different Green's functions to compute. For each $y \in D$, we compute $G_1(y,x)$, the solution to $\nabla^2 G_1(y,x) = -4\pi\delta^3(x-y)$ with boundary value zero on S. For each $z \in S$, we compute $G_2(z,x)$, the solution to $\nabla^2 G_2(z,x) = 0$ on D with boundary value $\delta^2(x-z)$ on S. Our solution to the entire problem is then $\phi(x) = \int_D d^3yG_1(y,x)\rho(y) + \int_S d^2zf(z)G_2(z,x)$.
3. *The heat kernel.* In $\mathbb{R}^2$, with variables x and t, let D be the region $t > 0$, so S is the x-axis. We look for solutions to the *heat equation*
$$\frac{\partial f}{\partial t} - \frac{\partial^2 f}{\partial x^2} = 0,$$
with boundary value $f(x,0) = f_0(x)$. Since $G(y,x,t) = \exp(-(x-y)^2/4t)/\sqrt{4\pi t}$ is a solution to (3) and approaches $\delta(x-y)$ as $t \to 0$, the solution to our problem is
$$f(x,t) = \int G(y,x,t)f_0(y)dy = \frac{1}{\sqrt{4\pi t}}\int \exp(-(x-y)^2/4t)f_0(y)dy.$$

66.1 Introduction

Biomolecular modeling is an active research area in computational biology. It studies the structures and functions of biomolecules by using computer modeling and simulation [Sch03]. Proteins are an important class of biomolecules. They are encoded in genes and produced in cells through genetic translation. Proteins are life supporting (or sometimes, destructing) ingredients (Figure 66.1) and are indispensable for almost all biological processes [Boy99]. In order to understand the diverse biological functions of proteins, the knowledge of the three-dimensional structures of proteins is essential. Several structure determination techniques have been used, including x-ray crystallography, nuclear magnetic resonance spectroscopy (NMR), and homology modeling. They all require intensive mathematical computing, ranging from data analysis to model building [Cre93].

As in all other types of scientific computing, linear algebra is one of the most powerful mathematical tools for biological computing. Here we review several subjects in biomolecular modeling, where linear algebra has played a major role, including mapping from distances to coordinates in NMR structure determination (Section 66.2), solving the Procrustes problem for structural comparison (Section 66.3), exploiting the structure of the Karle–Hauptman matrix in protein x-ray crystallography (Section 66.4), computing the fast and slow modes of protein motions (Section 66.5), and solving the flux balancing equations in metabolic network simulation (Section 66.6). The last subject actually involves the modeling of a large biological system, something beyond conventional biomolecular modeling, yet of increased research interests in computational systems biology [Kit99].

FIGURE 66.1 Example proteins: Humans have hundreds of thousands of different proteins (e.g., hemoglobin protein, 1BUW, in blood in 1a) and would not be able to maintain normal life even if short of a single type of protein. On the other hand, with the help of some proteins (e.g., protein, 2PLV, supporting poliovirus in 1b), viruses are able to grow, translate, integrate, and replicate, causing diseases. Some proteins themselves are toxic and even infectious such as the proteins in poisonous plants and in beef causing Mad Cow Disease (e.g., prion protein, 1I4M-D, in human in 1c).

66.2 Mapping from Distances to Coordinates: NMR Protein Structure Determination

A fundamental problem in protein modeling is to find the three-dimensional structure of a protein and its relationship with the protein's biological function. One of the experimental techniques for structure determination is to use nuclear magnetic resonance (NMR) to obtain some information on the distances for certain pairs of atoms in the protein and then find the coordinates of the atoms based on the obtained distance information. Mathematically, the second part of the work requires the solution of a so-called distance geometry problem, i.e., determine the coordinates for a set of points in a given topological space, given the distances for a subset of all pairs of points. We consider such a problem with the distances for all pairs of points assumed to be given.

Definitions:

The **coordinate vector** for atom i is a vector $\mathbf{x}_i = [x_{i,1},\, x_{i,2},\, x_{i,3}]^T$, where $x_{i,1}$, $x_{i,2}$, and $x_{i,3}$ are the first, second, and third coordinates of atom i, respectively.

The **distance** between atoms i and j is defined as $d_{i,,j} = ||\mathbf{x}_i - \mathbf{x}_j||$, where $\mathbf{x}_i$ and $\mathbf{x}_j$ are coordinate vectors of atoms i and j, and $||\cdot||$ is the Euclidean norm.

The **coordinate matrix** for a protein is a matrix of coordinates denoted by $X = [x_{i,j}]$, with $i = 1, \ldots, n$, $j = 1, 2, 3$ where n is the total number of atoms in the protein, and row i of X is the coordinate vector of atom i.

The **distance matrix** for a protein is a matrix of distances denoted by $D = [d_{i,j}]$ where $i, j = 1, \ldots, n$ and $d_{i,j}$ is the distance between atoms i and j.

The problem of computing the coordinates of atoms (X) given a set of distances between pairs of atoms (D) is known as the **molecular distance geometry problem**.

Facts:

1. [Sax79] If the protein structure and, hence, X are known, D can immediately be computed from X°. Conversely, if D is known or even partially known, X can also be obtained from D, but the computation is not as straightforward. The latter is proved to be *NP*-complete for arbitrary sparse distance matrices.
2. [Blu53] Choose a reference system so that the origin is located at the last atom, or in other words, $x_n = (0,\, 0,\, 0)^T$. Let X° be a submatrix of X, $X^\circ = [x_{i,j}], i = 1, \ldots, n -$

$1,\ j = 1,\ 2,\ 3\}$, and D° be a matrix derived from D, $D^{\circ} = [(d_{i,n}^2 - d_{i,j}^2 + d_{j,n}^2)/2] i, j = 1, \ldots, n-1\}$. Then, matrix D° is maximum rank 3 and $X^{\circ} X^{\circ T} = D^{\circ}$.

3. [CH88] Let $D^{\circ} = U \Sigma U^T$ be the singular-value decomposition of D°, where U is an orthogonal matrix and Σ a diagonal matrix with the singular values of D° along the diagonal. If D° is a matrix of rank less than or equal to 3, the decomposition can be obtained with U being $(n-1) \times 3$ and Σ being 3×3, and $X^{\circ} = U \Sigma^{1/2}$ solves the equation $X^{\circ} X^{\circ T} = D^{\circ}$.

Algorithm 1: Computing Coordinates from Distances

Given an $n \times n$ distance matrix D,

```
1. Compute $D^{\circ} = [(d_{i,n}^2 - d_{i,j}^2 + d_{j,n}^2)/2], i, j = 1, \ldots, n-1$.
2. Decompose $D^{\circ} = U \Sigma U^T$ to obtain $X^{\circ} = U[1:n-1, 1:3]\Sigma^{1/2}[1:3, 1:3]$.
3. $X[1:n-1, 1:3] = X^{\circ}[1:n-1, 1:3]$, $X[n, 1:3] = [0, 0, 0]$.
```

Examples:

1. Given the distances among four atoms, D, determine the coordinates of the atoms, X, where

$$D = \begin{bmatrix} 0 & \sqrt{2} & \sqrt{2} & 1 \\ \sqrt{2} & 0 & \sqrt{2} & 1 \\ \sqrt{2} & \sqrt{2} & 0 & 1 \\ 1 & 1 & 1 & 0 \end{bmatrix}.$$

Following Algorithm 1,

$$D^{\circ} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Compute the singular value decomposition of D°. Obviously, $D^{\circ} = U \Sigma U^T$, with

$$U = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \Sigma = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Then,

$$X^{\circ} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

and

$$X = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}.$$

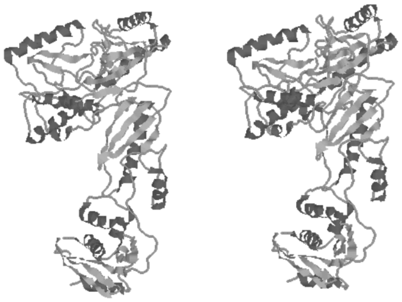

FIGURE 66.2 3D structures of protein 1HMV p66 subunit: The structure on the left was determined by x-ray crystallography, while on the right by solving a distance geometry problem given the distances for all the pairs of atoms. The RMSD for the two structures when compared on all the atoms is around 1.0e–04 Å. (Photo courtesy of Qunfeng Dong.)

2. Figure 66.2 shows two 3D structures of the p66 subunit of the HIV-1 retrotranscriptase (1HMV), one determined experimentally by x-ray crystallography [RGH95] and another computationally by solving a molecular distance geometry problem using the SVD method with the distance data generated from the known crystal structure. The RMSD (see description in Section 66.3) for the two structures when compared on all the atoms is around 1.0e–04 Å, showing that the two structures are almost identical.

66.3 The Procrustes Problem for Protein Structure Comparison

The structural differences between two proteins can be measured by the differences in the coordinates of the atoms for all corresponding atom pairs. The comparison is often required for either structural validation or functional analysis. The calculation can be done by solving a special linear algebra problem called the Procrustes problem [GL89].

Definitions:

Let X and Y be two $n \times 3$ coordinate matrices for two lists of atoms in proteins A and B, respectively, where $\mathbf{x}_i = [x_{i,1}, x_{i,2}, x_{i,3}]^T$ is the coordinate vector of the ith atom selected from protein A to be compared with $\mathbf{y}_i = [y_{i,1}, y_{i,2}, y_{i,3}]^T$, the coordinate vector of the ith atom selected from protein B. Assume that X and Y have been translated so that their centers of geometry are located at the same position, say, at the origin. Then, the structural difference between the two proteins can be measured by using the **root-mean-square deviation** (RMSD) of the structures, $\text{RMSD}(X, Y) = \min_Q \|X - YQ\|_F/\sqrt{n}$, where Q is a 3×3 rotation matrix and $QQ^T = I$, and $|| \cdot ||_F$ is the matrix Frobenius norm.

The RMSD is basically the smallest average coordinate errors of the structures for all possible rotations Q of structure Y to fit structure X. It is called the **Procrustes problem** for its analogy to the Greek story about cutting a person's legs to fit a fixed-sized iron bed. Note that X and Y may be the coordinate matrices for the same ($A = B$) or different ($A \neq B$) proteins and, therefore, each pair of corresponding atoms do not have to be of the same type (when $A \neq B$). However, the number of atoms selected to compare must be the same from A and B (# rows of X = # rows of Y).

Facts:

1. Let A and B be two matrices. Suppose that A is similar to B, then trace(A) = trace(B). In particular, trace(A) = trace(V^TAV), for any orthogonal matrix V.
2. [GL89] Let $C = Y^TX$ and $C = U\Sigma V^T$ be the singular-value decomposition of C. Then, $Q = UV^T$ minimizes $||X - YQ||_F$.

Algorithm 2: Computing the RMSD of Two Protein Structures

1. Compute the geometric centers of X and Y:

$$\mathbf{x}_c[j] = \left(\sum\nolimits_{i=1}^{n} X[i,j]\right)/n, \quad j = 1,\ 2,\ 3;$$
$$\mathbf{y}_c[j] = \left(\sum\nolimits_{i=1}^{n} Y[i,j]\right)/n, \quad j = 1,\ 2,\ 3.$$

2. Translate X and Y to the origin:

$$X = X - \mathbf{1}_n\mathbf{x}_c^T, \quad Y = Y - \mathbf{1}_n\mathbf{y}_c^T, \quad \mathbf{1}_n = [1, \ldots, 1]^T \in \mathbb{R}^n.$$

3. Compute $C = Y^TX$ and $C = U\Sigma V^T$. Then,

$$Q = UV^T, \quad \text{RMSD}(X,Y) = ||X - YQ||_F/\sqrt{n}.$$

Examples:

1. Suppose that X and Y are given as the following.

$$X = \begin{bmatrix} -1 & -1 & -2 \\ -1 & -1 & 0 \\ -1 & 1 & -2 \\ -1 & 1 & 0 \\ 1 & -1 & -2 \\ 1 & -1 & 0 \\ 1 & 1 & -2 \\ 1 & 1 & 0 \end{bmatrix}$$

$$Y = \begin{bmatrix} 1 & 1 & 0 \\ 1 & -1 & 0 \\ -1 & 1 & 0 \\ -1 & -1 & 0 \\ 1 & 1 & 2 \\ 1 & -1 & 2 \\ -1 & 1 & 2 \\ -1 & -1 & 2 \end{bmatrix}.$$

Then $\mathbf{x}_c = [0, 0, -1]^T$ and $\mathbf{y}_c = [0, 0, 1]^T$. Following Step 2 in Algorithm 2, X and $Y$are changed to

$$X = \begin{bmatrix} -1 & -1 & -1 \\ -1 & -1 & 1 \\ -1 & 1 & -1 \\ -1 & 1 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & 1 \\ 1 & 1 & -1 \\ 1 & 1 & 1 \end{bmatrix}$$

$$Y = \begin{bmatrix} 1 & 1 & -1 \\ 1 & -1 & -1 \\ -1 & 1 & -1 \\ -1 & -1 & -1 \\ 1 & 1 & 1 \\ 1 & -1 & 1 \\ -1 & 1 & 1 \\ -1 & -1 & 1 \end{bmatrix}.$$

Let $C = Y^T X$. Then,

$$C = \begin{bmatrix} 0 & -8 & 0 \\ 0 & 0 & -8 \\ 8 & 0 & 0 \end{bmatrix}.$$

Compute the singular value decomposition of C to obtain $C = U\Sigma V^T$, with

$$U = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \text{and} \quad V = \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{bmatrix}.$$

Then,

$$Q = UV^T = \begin{bmatrix} 0 & -1 & 0 \\ 0 & 0 & -1 \\ 1 & 0 & 0 \end{bmatrix}.$$

By calculating $\|X - YQ\|_F \;/\; \sqrt{n}$, we obtain RMSD $(X, Y) = 0$.

2. RMSD calculation has been widely used in structural computing. A straightforward application is for comparing and validating the structures obtained from different (x-ray crystallography, NMR, or homology modeling) sources for the same protein [Rho00]. Even from the same source, such as NMR, multiple structures are often obtained, and the average RSMD for the pairs of the multiple structures has been calculated as an indicator for the consistency and sometimes the flexibility of the structures [SNB03]. It has also been an important tool for structural classification, motif recognition, and structure prediction, where a large number of different proteins need to be aligned and compared [EJT00]. Figure 66.3 gives an example of using RMSD to compare NMR and x-ray crystal structures. Three structures of the second domain of the immunoglobulin-binding protein (2IGG) [LDS92] are displayed in the figure. Two of them are NMR structures. They are compared using RMSD against the x-ray structure (dark line).

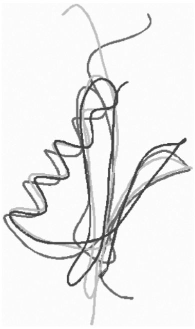

FIGURE 66.3 NMR and x-ray crystal structures of 2IGG: Two NMR structures of 2IGG are superposed to its x-ray crystal structure to find out which one is closer to the x-ray crystal structure (dark line). The RMSD values for the two NMR structures against the x-ray structure are 1.97 Å and 1.75 Å, respectively. (Photo courtesy of Feng Cui.)

66.4 The Karle–Hauptman Matrix in X-Ray Crystallographic Computing

X-ray crystallography has been a major experimental tool for protein structure determination and is responsible for about 80% of 30,000 protein structures thus far determined and deposited in the Protein Data Bank [BWF00]. The structure determination process involves crystallizing the protein, applying x-ray to the protein crystal to obtain x-ray diffractions, and using the diffraction data to deduce the electron density distribution of the crystal (Figure 66.4). Once the electron density distribution of the crystal is known, a 3D structure for the protein can be assigned [Dre94].

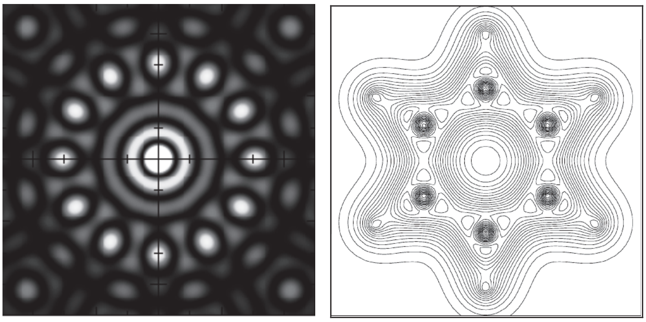

FIGURE 66.4 Example diffraction image and electron density map: The left one is the diffraction image of a 12-atom polygon generated by the program in [PNB01]. The right one is the electron density map of benzene generated by Stewart using program DENSITY in MOPAC [Ste02].

Definitions:

Define ρ: $R^3 \to R$ to be the **electron density distribution function** for a protein and F_H in complex space C to be the structure factor representing the diffraction spot specified by the integral triplet H [Dre94].

A **Karle–Hauptman matrix** [KH52] for a set of structure factors $\{F_H : H = H_0, \ldots, H_{n-1}\}$

is defined as

$$K = \begin{bmatrix} F_{H_0} & F_{H_{n-1}} & \cdots & F_{H_1} \\ F_{H_1} & F_{H_0} & \cdots & F_{H_2} \\ \vdots & \vdots & \ddots & \vdots \\ F_{H_{n-1}} & F_{H_{n-2}} & \cdots & F_{H_0} \end{bmatrix}.$$

Facts:

1. [Dre94] The electron density distribution function ρ can be expanded as a Fourier series with the structure factors F_H as the coefficients. In other words, F_H is a Fourier transform of ρ.

$$\rho(r) = \sum\nolimits_{H \in Z^3} F_H \exp(-2\pi i H^T r),$$

$$F_H = \int_{R^3} \rho(r) \exp(2\pi i H^T r) dr.$$

2. [Bri84] If K is a Karle–Hauptman matrix, then the inverse of K is also a Karle–Hauptman matrix and can be formed directly as

$$K^{-1} = \begin{bmatrix} E_{H_0} & E_{H_{n-1}} & \cdots & E_{H_1} \\ E_{H_1} & E_{H_0} & \cdots & E_{H_2} \\ \vdots & \vdots & \ddots & \vdots \\ E_{H_{n-1}} & E_{H_{n-2}} & \cdots & E_{H_0} \end{bmatrix},$$

where

$$E_{H_j} = \int_{R^3} \rho^{-1}(r) \exp(2\pi i H_j^T r) dr, \quad j = 0,\ 1,\ \ldots,\ n-1.$$

3. [GL89] Suppose that we have a linear system $K\mathbf{x} = \boldsymbol{h}$, where K is an $n \times n$ Karle–Hauptman matrix and $\boldsymbol{h}$ is an n-dimensional complex vector. If a conventional method, such as Gaussian Elimination, is used, the solution of the system usually takes $O(n^3)$ floating-point operations, which is expensive if n is larger than 1000 and if the solution is also required multiple times.
4. [Loa92], [WPT01] Since each element in the inverse matrix can be obtained by doing a Fourier transform for the inverse of ρ and only n distinct elements in the first column are required to form the whole matrix, the calculations can be done in $O(n\log n)$ floating-point operations by using the Fast Fourier Transform.
5. [TML97], [WPT01] The matrix K^{-1} as well as K has only n distinct elements listed repeatedly in the columns of the matrix with each column having the elements in the previous column circulated by one element from top to bottom and then bottom to top. This type of matrix is called the circulant matrix. According to the discrete convolution theory, if h is the Fourier transform of t, then $K^{-1}h$ can be computed by doing a Fourier transform for $\rho^{-1} \cdot t$, where t can be obtained through an inverse Fourier transform for h and the product $\cdot$ is applied component-wise. Therefore, the whole computation for the solution of $K\mathbf{x} = h$ can be done with at most $O(n\log n)$ floating-point operations.

Examples:

1. Let $\rho = [0.1250,\ 0.1250,\ 0.5000,\ 0.1250,\ 0.1250]$ be an electron density distribution. Then $\rho^{-1} = [8,\ 8,\ 2,\ 8,\ 8]$, and the Fourier transforms for ρ and ρ^{-1} are equal to

$$F = [0.2000, -0.0607 + 0.0441\text{i}, 0.0232\text{-}0.0713\text{i}, 0.0232 + 0.0713\text{i}, \text{-}0.0607\text{-}0.0441\text{i}] \text{ and}$$

$$F_{\text{inv}} = [6.8000, 0.9708 - 0.7053\text{i}, -0.3708 + 1.1413\text{i}, -0.3708 - 1.1413\text{i}, 0.9708 + 0.7053\text{i}],$$

   respectively. And it is not hard to verify that the inverse of the Karle–Hauptman matrix $K(F)$ formed by using F is equal to the Karle–Hauptman matrix K_{inv} (F_{inv}) formed by using F_{inv}.
2. The Karle–Hauptman matrix is an important matrix in x-ray crystallography computing, named after two Nobel Laureates, chemist Jerold Karle and mathematician Herbert Hauptman, who received the Nobel Prize in chemistry in 1985 for their work on the phase problem in x-ray crystallography [HK53]. The Karle–Hauptman matrix is frequently used for computing the covariance of the structure factors [KH52] or the electron density distribution that maximizes the entropy of a crystal system [WPT01].

66.5 Calculation of Fast and Slow Modes of Protein Motions

In a reduced model for protein, a residue is represented by a point, in many cases, the position of the backbone atom C_α or the sidechain atom C_β in the residue, and a protein is considered as a sequence of such points connected with strings [HL92]. If the reduced model of a protein is known, a so-called contact map can be constructed to show how the residues in the protein interact with each other. The map is represented by a matrix with its i,j-entry equal to -1 if residues i and j are within, say 7Å distance, and 0 otherwise. The contact matrix can be used to compare different proteins. Similar contact patterns often imply structural or functional similarities between proteins [MJ85]. When a protein reaches its equilibrium state, the residues in contact can be considered as a set of masses connected with springs. A simple energy function can also be defined for the protein using the contact matrix.

Definitions:

Suppose that a protein has n residues with n coordinate vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n$. A **contact matrix** Γ for the protein in its equilibrium state can be defined [HBE97] such that

$$\tilde{A}_{i,j} = \begin{cases} -1, & ||x_i - x_j|| \ \le 7 \ \overset{\circ}{\text{A}} \\ 0, & \text{otherwise} \end{cases} \qquad i \neq j = 1, \ldots, n$$

$$\tilde{A}_{i,i} = -\sum_{j=1}^{n} \tilde{A}_{i,j} \qquad i = 1, \ldots, n$$

A **potential energy function** E for a protein at its equilibrium state can be defined such that for any vector $\Delta\mathbf{x} = (\Delta\mathbf{x}_1, \ldots, \Delta\mathbf{x}_n)^T$ of the displacements of the residues from their equilibrium positions,

$$E(\Delta\mathbf{x}) = \frac{1}{2}\, k\, \Delta\mathbf{x}^T \tilde{A}\, \Delta\mathbf{x},$$

where k is a spring constant.

Facts:

1. [HBE97] Given a potential energy function E, the probability for a protein to have a displacement Δx at temperature T should be subject to the Boltzmann distribution,

$$p_T(\Delta\mathbf{x}) = \frac{1}{Z}\exp(-E(\Delta\mathbf{x})/k_BT) = \frac{1}{Z}\exp(-k\,\Delta\mathbf{x}^T\tilde{\mathbf{A}}\,\Delta\mathbf{x}/2k_BT),$$

   where Z is the normalization factor and k_B the Boltzmann constant.
2. [HBE97] Let the singular-value decomposition of Γ be given as $\Gamma = U\Lambda U^T$. Then, the mean-square residue fluctuations of a protein at its equilibrium state can be estimated as

$$\langle\Delta\mathbf{x}_i, \Delta\mathbf{x}_i\rangle \;\equiv \frac{1}{Z}\int_{R^{3n}} \Delta\mathbf{x}_i^T\Delta\mathbf{x}_i \exp\left(\frac{-E(\Delta\mathbf{x})}{k_BT}\right) d\Delta\mathbf{x} = \sum\nolimits_{j=1}^{n} k_BT\,U_{i,j}\ddot{\mathrm{E}}_{j,j}^{-1}\,U_{i,j}/k.$$

Examples:

1. The energy model defined above for a protein at its equilibrium state is called the Gaussian Network Model. The model can be used to find how the residues in the protein move around their equilibrium positions dynamically and, in particular, to estimate the so-called mean-square fluctuations for the residues $\langle\Delta\mathbf{x}_i, \Delta\mathbf{x}_i\rangle$, $i = 1, \ldots, n$. If the mean-square fluctuation is large, the residue is called hot, and otherwise, is cold, which often correlates with the experimentally detected average atomic fluctuation such as the B-factor in x-ray crystallography [Dre94] and the order parameter in NMR [Gun95]. In fact, the Gaussian Network Model is equivalent to the Normal Mode Analysis for predicting the mean-squares residue fluctuations of a protein, with the energy function defined for the residues instead of the atoms.
2. Figure 66.5 shows the mean-square fluctuations calculated using the Gaussian Network Model for the protein 2KNT and the comparison with the B-factors of the structure determined by x-ray crystallography. The two sets of values appear to be highly correlated. Based on the facts stated above, the calculation of the mean-squares fluctuations requires only a singular-value decomposition of the contact matrix for the protein.

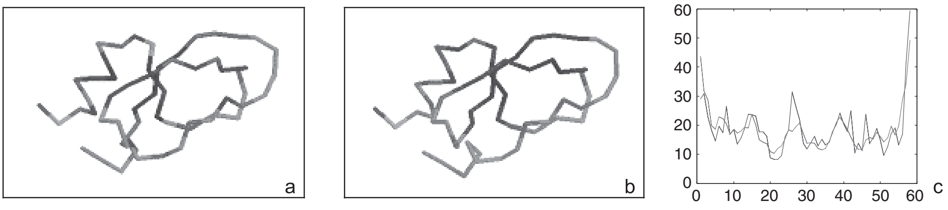

FIGURE 66.5 Mean-square fluctuations: The fluctuations for protein 2KNT based on the mean-square fluctuations calculated with GNM (a) and the B-factors determined by x-ray crystallography (b). The two sets of values show a high correlation (0.82) (c). (Photos courtesy of Di Wu.)

66.6 Flux Balancing Equation in Metabolic Network Simulation

A metabolic system is maintained through constant reactions or interactions among a large number of biological and chemical compounds called metabolites [Fel97]. The reaction network describes the structure of a metabolic system and is key to the study of the metabolic function of the system. Figure 66.6 shows the reaction network for an example metabolic system of five metabolites given in [SLP00].

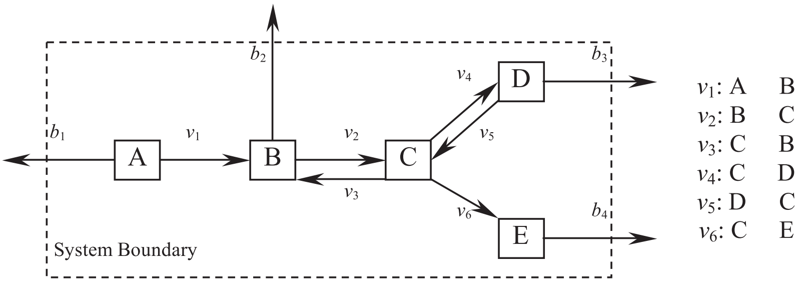

FIGURE 66.6 Example metabolic networks: A, B, C, D, E are metabolites; v_j, $j = 1, \ldots, 6$ are internal fluxes; b_j, $j = 1, \ldots, 4$ are external fluxes. Each flux v_j corresponds to an internal reaction.

Definitions:

Each metabolite has a concentration, which changes constantly. The **rate of the change** is proportional to the amount of the metabolite consumed or produced in all the reactions.

Let C_i be the **concentration of metabolite** i. Let v_j be the **chemical flux** in reaction j, i.e., the amount of metabolites produced in reaction j per mole. Then,

$$\frac{dC_i}{dt} = \sum\nolimits_{j=1}^{n} s_{i,j}\, v_j,$$

where $s_{i,j}$ is the **stoichiometric coefficient of metabolite** i in reaction j, and $s_{i,j} = \pm k$, if $\pm k$ moles of metabolite i are produced (or consumed) in reaction j.

Let $C = (C_1, \ldots, C_m)^T$ be a vector of concentrations of m metabolites, and $v = (v_1, \ldots, v_n)^T$ a vector of fluxes of n reactions. Then, the equations can be written in a compact form,

$$\frac{dC}{dt} = S\, v,$$

where $S = \{s_{i,j} : i = 1, \ldots, m,\ j = 1, \ldots, n\}$ is called the **stoichiometry matrix**, and the equations are called **reaction equations** [HS96].

The fluxes are functions of the concentrations and some other system parameters. Therefore, the above reaction equations are nonlinear equations of C. However, when the system reaches its equilibrium, $d\mathbf{C}/dt = Sv = 0$, and the vector $\mathbf{v}$ becomes constant and is called a solution of the **steady-state flux equation** $Sv = 0$ [HS96].

The steady-state fluxes are important quantities for characterizing metabolic networks. They can be obtained by solving the steady-state flux equation $Sv = 0$. However, since the number of reactions is usually larger than the number of metabolites, the solution to the equation is not unique. Also, because the internal fluxes are nonnegative, the solution set forms a convex cone, called the **steady-state flux cone**.

Usually, a convex cone can be defined in terms of a set of extreme rays such that any vector in the cone can be expressed as a nonnegative linear combination of the extreme rays,

$$\text{cone}\,(S) = \{v = \sum\nolimits_{i=1}^{l} w_i p_i, \quad w_i \geq 0\},$$

where $p = \{p_1, \ldots, p_l\}$ is a set of extreme rays. An **extreme ray** is a vector that cannot be expressed as a nonnegative linear combination of any other vectors in the cone.

A set of vectors is said to be systematically independent if none of them can be expressed as a nonnegative linear combination of others. Since the extreme rays can be used to express all the vectors in a convex cone, they are also called the generating vectors of the cone. For metabolic networks, they are called the **extreme pathways** [PPP02].

Facts:

1. [PPP02] A convex flux cone has a set of systematically independent generating vectors or extreme pathways. They are unique up to positive scalar multiplications. If the extreme pathways of the convex flux cone of a metabolic network are found, all the solutions for the steady-state flux equation can be generated by using the extreme pathways. In other words, the extreme pathways provide a unique description for the solution space of the steady-state flux equation, and can be used to characterize the whole steady-state capacity of the system.
2. [PPP02] Let P be a matrix with each column corresponding to an extreme pathway of a given metabolic network. Let Q be the binary form of P such that $Q_{i,j} = 1$ if $P_{i,j} \neq 0$ and $Q_{i,j} = 0$ otherwise. Then, the diagonal elements of Q^TQ are equal to the lengths of the extreme pathways, while the diagonal elements of QQ^T show the numbers of extreme pathways the reactions participate in.

Examples:

1. Consider the example network in Figure 66.6 and let S be the stoichiometric matrix with 10 columns for the internal ($v_1, \ldots, v_6$) as well as external ($b_1, \ldots, b_4$) fluxes,

$$S = \begin{array}{ccccccccccl} v_1 & v_2 & v_3 & v_4 & v_5 & v_6 & b_1 & b_2 & b_3 & b_4 & \\ -1 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 & \leftarrow A \\ 1 & -1 & 1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & \leftarrow B \\ 0 & 1 & -1 & -1 & 1 & -1 & 0 & 0 & 0 & 0 & \leftarrow C. \\ 0 & 0 & 0 & 1 & -1 & 0 & 0 & 0 & -1 & 0 & \leftarrow D \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 & \leftarrow E \end{array}$$

Then, by using an appropriate algorithm (such as the one given in [SLP00]), a matrix of seven extreme pathways of the system can be found as follows:

$$P^T = \begin{array}{ccccccccccl} v_1 & v_2 & v_3 & v_4 & v_5 & v_6 & b_1 & b_2 & b_3 & b_4 & \\ 1 & 0 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & \leftarrow p_1 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & \leftarrow p_2 \\ 0 & 1 & 0 & 1 & 0 & 0 & 0 & -1 & 1 & 0 & \leftarrow p_3 \\ 0 & 1 & 0 & 0 & 0 & 1 & 0 & -1 & 0 & 1 & \leftarrow p_4 \\ 0 & 0 & 1 & 0 & 1 & 0 & 0 & 1 & -1 & 0 & \leftarrow p_5 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & \leftarrow p_6 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & -1 & 1 & \leftarrow p_7 \end{array},$$

where row i corresponds to extreme pathway p_i, $i = 1, \ldots, 7$.

2. By forming the binary form Q for P and computing

$$Q^TQ = \begin{bmatrix} 3 & 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 2 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 4 & 2 & 2 & 1 & 1 \\ 1 & 1 & 2 & 4 & 1 & 0 & 2 \\ 1 & 1 & 2 & 1 & 4 & 1 & 2 \\ 0 & 0 & 1 & 0 & 1 & 2 & 1 \\ 0 & 0 & 1 & 2 & 2 & 1 & 4 \end{bmatrix}$$

and

$$QQ^T = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 3 & 1 & 1 & 0 & 1 & 0 & 2 & 1 & 1 \\ 0 & 1 & 2 & 0 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 1 & 0 & 2 & 1 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 3 & 1 & 0 & 1 & 2 & 1 \\ 0 & 1 & 0 & 0 & 1 & 2 & 0 & 1 & 1 & 2 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 1 & 2 & 1 & 1 & 1 & 1 & 1 & 4 & 2 & 1 \\ 0 & 1 & 1 & 1 & 2 & 1 & 0 & 2 & 3 & 1 \\ 0 & 1 & 0 & 0 & 1 & 2 & 0 & 1 & 1 & 2 \end{bmatrix},$$

we obtain, from the diagonal elements of the matrices, the lengths of the pathways, p_1: 3, p_2: 2, p_3: 4, p_4: 4, p_5: 4, p_6: 2, p_7: 4, and the participations of the reactions in the extreme pathways, v_1: 1, v_2: 3, v_3: 2, v_4: 2, v_5: 3, v_6: 2, b_1: 1, b_2: 4, b_3: 3, b_4: 2. The off-diagonal elements of Q^TQ show the numbers of common reactions in different extreme pathways. For example, $(Q^TQ)_{3,4} = 2$ means that p_3 and p_4 share two common reactions, and $(Q^TQ)_{3,5} = 1$ means that p_3 and p_5 have one common reaction. The off-diagonal elements of QQ^T show the numbers of extreme pathways in which different reactions participate. For example, $(QQ^T)_{2,3} = 1$ means that v_2 and v_3 participate in one extreme pathway together, and $(QQ^T)_{2,8} = 2$ means that v_2 and b_2 participate in two extreme pathways together.

66.7 Conclusion

In this chapter, we have reviewed several subjects in biomolecular modeling, where linear algebra has played a central role in related computations. The review has focused on simple showcases and demonstrated important applications of linear algebra in biomolecular modeling. The subjects discussed are of great research interest in computational biology and are related directly to the solutions of many critical but challenging computational problems in biology yet to be solved, including the general distance geometry problem in NMR, the phase problem in x-ray crystallography, the structural comparison problem in comparative modeling, molecular dynamics simulation, and biosystems modeling and optimization, which we have not elaborated in detail here, but the interested reader can further explore.

Linear algebra has also been used to support many basic algebraic calculations required for solving other types of mathematical problems in biomolecular modeling, such as the optimization problems in potential energy minimization [WS99], the initial value problem in molecular dynamics simulation [BKP88], and the boundary value problem in simulation of protein conformational transformation [EMO99]. They are usually straightforward or routine linear algebra calculations, so we have not covered them in this chapter, but they should be considered as equally important as the applications we have discussed.

Acknowledgments

I would like to thank my students, Feng Cui, Ajith Gunaratne, Kriti Mukhopadhyay, Rahul Ravindrudu, Andrew Severin, Matthew Studham, Peter Vedell, Di Wu, Eun-Mee YoonAnn, and Rich Wen Zhou, and my colleagues, Dr. Qunfeng Dong and Dr. Wonbin Young, who have read this chapter carefully, helped produce some of the figures, and provided valuable comments and suggestions. The subjects discussed in the chapter have actually been the frequent topics of our research meetings. I would also like to thank the Mathematical Biosciences Institute, Ohio State University, for providing support during my visit to the Institute in Spring 2005 where I completed the writing of this chapter.

Linear algebra is at the core of applications in the computational, mathematical, and statistical sciences. Hence, not surprisingly, linear algebra is central to the study of differential equations. It has provided the mathematical structure required for the study of applications while differential equations have naturally supplied function spaces that have emerged from the study of dynamical processes. It is here that the connections between linear algebra and dynamic biological process come into play. The applications that we will address come from the field of *population biology*, which in our context means the study of the dynamics populations of organisms (size, life history traits, extinction) and the epidemiology of infectious diseases (outbreaks, prevalence, control and extinction). The study of critical questions in population biology and epidemiology is based on the formulation and analysis of nonlinear dynamical systems and therefore the impact of linear algebra in biology is pervasive. We live in a world dominated by nonlinear processes that in general cannot be fully disentangled by analytical approaches. Hence, it is not surprising to see that the study of a large number of classical and timely questions in population biology and epidemiology is tied in to the qualitative study of nonlinear systems of ordinary differential equations. So, the next best thing involves the use of approximate methods tied into the highly useful perspective that *locally* the world is (quite often) approximately linear. A very powerful method tied into the study of approximately linear local phenomena involves the location of equilibria and determination of their stability by the method of "linearization" at each equilibrium state. The characterization of the nature of the local dynamics is achieved through the determination of the eigenvalues of the coefficient matrix of the linearization, a useful and powerful process that will be illustrated in the context of classical applications in population biology and epidemiology. There is no attempt to give a full development of the theory. We just work out a few specific prototypic examples that illustrate the usefulness of linear algebra in population biology and epidemiology. The background on which this theory depends may be found in Chapters 78 and 79.

In this chapter, the focus is on three types of applications that are intimately connected to (i) the study of the dynamics of interacting species, (ii) the approximation of nonlinear systems in the context of the study of disease dynamics, and (iii) the use of discrete linear dynamical systems to capture population structure. The role of "tipping" points as identifiers of critical transitional shifts in dynamical processes is at the cornerstone of the study of many biological systems and the ones introduced here are no exception. In the study of contagion processes, most often described as compartmental models for disease transmission, a transition between the *asymptotic stability* of a disease-free equilibrium and the asymptotic stability of an *endemic* equilibrium, corresponding to a state in which the disease remains established in a population, is commonly highlighted because of its fundamental role in the identification, quantification, evaluation, and implementation of disease intervention or control measures. Determination of these transitions is fundamentally connected to the location of the eigenvalues of the coefficient matrix as functions of disease transmission models parameters. The most common transition shift is determined by the value of a disease's *basic reproduction number or ratio*, which describes the average number of secondary infections that would be produced by the introduction of a single "typical" infectious individual into a completely susceptible population at a demographic steady state. The computation of the basic reproduction number relies on the study of the next generation matrix, which makes use of facts about M-matrices and other aspects of linear algebra. Finding ways of understanding heterogeneity, its causes and consequences, is at the root of most questions in population biology and epidemiology. The introduction of population structure is therefore central to the study of the impact of heterogeneity in biological processes. Here, we highlight its role, in as simple a setting as possible. Hence, we introduce a well-known discrete age-structured population model whose study involve a substantial amount of matrix theory, including the celebrated theorems of Perron/Frobenius (Chapter 10).

67.1 Models for the Populations of Interacting Species

The dynamics of a large class of populations are described by systems of ordinary differential equations often known as Lotka-Volterra systems. In fact, Lotka-Volterra systems emerge from interests in identifying potential mechanisms responsible for either fluctuations or the lack of fluctuations in predator-prey systems in population biology [BC01], [BC12], [Fre80], [HS98], [Kol36], [Mur93], [Tak96], [Vol26], and [Vol31]. If the rates of change (assumed to be known) in these systems of interacting populations are time-independent, the nonlinear systems of differential equations are called *autonomous.* Since Lotka-Volterra systems have been extensively studied under the assumption that the parameters are constant, their analyses have helped expand the theory behind autonomous systems. The study of their qualitative properties of autonomous systems of nonlinear or differential equations starts from identification of constant solutions (equilibria). The linearization about these equilibria is used to characterize the nature of the system dynamics *near* equilibria. Linearization about an equilibrium involves making a linear change of variable, moving the equilibrium to the origin, the expansion in Taylor series of the functions of the state variables describing the rates of change, and the retention of only the linear terms. We highlight the process of linearization after the introduction of two state variables, population densities, a general abstract model that describes the interactions of these two populations, and a few mathematical results.

Definitions:

Let $x(t)$ and $y(t)$ denote the densities of the two populations under consideration. The **classical Kolmogorov system** [Kol36] used to model the interactions is given by the following autonomous system of nonlinear differential equations:

$$\begin{aligned} x' &= F(x,y), \\ y' &= G(x,y) \end{aligned} \tag{67.1}$$

where F and G are sufficiently smooth functions.

An **equilibrium** of a system (67.1) is a constant solution (x_∞, y_∞), that is, a pair of constants satisfying

$$F(x_\infty, y_\infty) = G(x_\infty, y_\infty) = 0.$$

An equilibrium solution is **(locally) asymptotically stable (or l.a.s.)** if every solution starting sufficiently close to the equilibrium remains close to the equilibrium and approaches it as $t \to \infty$.

The **characteristic equation** at an equilibrium is the characteristic polynomial of the matrix of the linearization at the equilibrium.

Facts:

1. [BN69, p. 60] The characteristic equation at an equilibrium is the condition on λ that the linearization at the equilibrium has solutions whose components are constant multiples of $e^{\lambda t}$.
2. [BN69, p. 161] An equilibrium is asymptotically stable if every solution of the linearization at the equilibrium approaches zero as $t \to \infty$.
3. [BN69, p. 161] An equilibrium is asymptotically stable if every solution of the characteristic equation at the equilibrium has negative real part and is unstable if there is a root of the characteristic equation with positive real part.
4. See Section 26.2. The eigenvalues of a matrix are the roots of its characteristic equation, and a necessary and sufficient condition for these roots all to have negative real part is given by the Routh-Hurwitz conditions. For a 2 × 2 matrix, these conditions are that the matrix have negative trace and positive determinant.

Examples:

1. (i) (Types of species interactions) Different kinds of biological interaction can be represented mathematically by the functions F and G. The type is determined by the signs of the rates of change of the growth rates $F(x,y)$ and $G(x,y)$ with respect to the population sizes x and y. It is customarily assumed that an increase in the size of either population tends to inhibit the growth rate of that population, so that whenever x and y are not too close to zero, we have

   $$F_x(x,y) < 0, \quad G_y(x,y) < 0.$$

   Here, the subscripts denote partial derivatives. In *competitive systems*, perhaps describing competition for the same nutrient resource, an increase in the size of either population tends to decrease the growth rate of the other population (interference competition), and in such cases, it is assumed that

   $$F_x(x,y) < 0, \quad F_y(x,y) < 0, \quad G_x(x,y) < 0, \quad G_y(x,y) < 0.$$

   In *predator-prey systems*, an increase in the size of the prey population (x) population size tends to increase the growth rate of the predator population size (y) while an increase in the size of the predator population size tends to decrease the prey population size growth rate, assumptions that translate into the following conditions:

   $$F_x(x,y) < 0, \quad F_y(x,y) > 0, \quad G_x(x,y) > 0, \quad G_y(x,y) < 0.$$

   In *mutualistic systems*, an increase in the size of either population tends to increase the growth rate of the other species, so that

   $$F_x(x,y) < 0, \quad F_y(x,y) \geq 0, \quad G_x(x,y) \geq 0, \quad G_y(x,y) < 0.$$

   These are the basic types of interactions between two populations. Interactions of more than two populations are possible; for example, one might consider two predator populations with a common prey. The possible qualitative behaviors of these types of population interactions are different. We will not describe them in detail here. Instead, we will highlight some examples of two species in competition (for more detailed discussions see, for example, [BC01, BC12, Fre80, Mur93]).

(ii) (Equilibria of a competitive system) In order to highlight the role of linearization, we discuss models where the per capita growth rates are linear. Specifically, we look at per capita growth rates of the form

$$\begin{aligned} x' &= x(\lambda - ax - by), \\ y' &= y(\mu - cx - dy), \end{aligned} \tag{67.2}$$

where λ, μ, a, b, c, d are positive constants. Extensions to models with nonlinear per capita growth rates will be addressed briefly later. The process of linearization around a constant solution in a population system leads to a matrix known in population biology (or ecology) as the *community matrix*

$$\begin{bmatrix} F_x(x,y) & F_y(x,y) \\ G_x(x,y) & G_y(x,y) \end{bmatrix}.$$

Competition models based on linear per capita growth rates support the following four possible equilibria:

I. $(0,0)$, with community matrix

$$\begin{bmatrix} \lambda & 0 \\ 0 & \mu \end{bmatrix},$$

necessarily unstable.

II. $(K,0)$, with $K = \lambda/a$ with community matrix

$$\begin{bmatrix} -\lambda & -\frac{b\lambda}{a} \\ 0 & \mu - \frac{c\lambda}{a} \end{bmatrix},$$

with trace $\frac{1}{a}(a\mu - a\lambda - c\lambda)$ and determinant $\frac{\lambda}{a}(c\lambda - a\mu)$.

III. $(0,M)$, with $M = \frac{\mu}{d}$ with community matrix

$$\begin{bmatrix} \lambda - \frac{b\mu}{d} & 0 \\ -\frac{\mu c}{d} & -\mu \end{bmatrix},$$

with trace $\frac{1}{d}(d\lambda - d\mu - b\mu)$ and determinant $\frac{\mu}{d}(b\mu - d\lambda)$.

IV. (x_∞, y_∞), with $x_\infty > 0$, $y_\infty > 0$, $ax_\infty + by_\infty = \lambda$, $cx_\infty + dy_\infty = \mu$, or

$$x_\infty = \frac{d\lambda - b\mu}{ad - bc}, \qquad y_\infty = \frac{a\mu - c\lambda}{ad - bc}.$$

The corresponding community matrix is

$$\begin{bmatrix} -ax_\infty & -bx_\infty \\ -cy_\infty & -dy_\infty \end{bmatrix},$$

with trace $-ax_\infty - dy_\infty < 0$ and determinant $x_\infty y_\infty (ad - bc)$.

We distinguish four cases, namely those corresponding to the four possible sign combinations for $b\mu - d\lambda$ and $a\mu - c\lambda$ but ignore the possibilities $b\mu - d\lambda = 0$ (which would give $x_\infty = 0$) and $a\mu - c\lambda = 0$ (which would give $y_\infty = 0$). The equilibria $(K,0)$ or $(0,M)$ describe the situation where one species survives but the other loses the struggle for existence, becoming extinct [Gau34a, Gau34b]. An equilibrium (x_∞, y_∞) with $x_\infty > 0, y_\infty > 0$ corresponds to species coexistence.

Case 1. $d\lambda - b\mu > 0$, $a\mu - c\lambda > 0$. In this case $d/b > \mu/\lambda > c/a$, and $ad - bc > 0$. Thus, there is an equilibrium (x_∞, y_∞) in the first quadrant of the phase plane. Because the determinant of the community matrix is positive while the trace is negative, this equilibrium is asymptotically stable. Since the community matrices for the equilibrium $(K, 0)$ and $(0, M)$ both have negative determinants, these equilibria are unstable.
In this case, every orbit tends to (x_∞, y_∞) as $t \to \infty$, indicating coexistence of the two species for all initial population sizes.

Case 2. $c\lambda - a\mu > 0, b\mu - d\lambda > 0$. In this case $c/a > \mu/\lambda > d/b$ and $ad - bc < 0$. There is an equilibrium (x_∞, y_∞) in the first quadrant but because the determinant of the community matrix is negative, this equilibrium is unstable. The equilibria $(K, 0)$ and $(0, M)$ are both asymptotically stable because their community matrices have positive determinant and negative trace. There is a *separatrix*, a curve dividing the first quadrant into two regions, one containing initial points for which orbits tend to $(K, 0)$ and the other, containing initial points for which orbits tend to $(0, M)$. In this case, coexistence of the two species is impossible, and one species will always win the competition for survival. The winner of this competition is determined by the initial population sizes. Although coexistence would be the result of initial population sizes on the separatrix, this possibility is too sensitive to disturbances to be biologically meaningful.

Case 3. $c\lambda - a\mu > 0, d\lambda - b\mu > 0$. In this case, there is no equilibrium in the interior of the first quadrant. It is easy to verify by examination of the community matrix that the equilibrium at $(K, 0)$ is asymptotically stable, while the equilibrium at $(0, M)$ is unstable. All orbits tend to $(K, 0)$ as $t \to \infty$, corresponding to extinction of the y species and survival of the x species for all initial population sizes.

Case 4. $a\mu - c\lambda > 0, b\mu - d\lambda > 0$. Again, there is no equilibrium in the interior of the first quadrant. It is again easy to determine the stability of the equilibria on the axes. Now $(K, 0)$ is unstable while $(0, M)$ is asymptotically stable. All orbits tend to $(0, M)$ as $t \to \infty$, corresponding to extinction of the x species and survival of the y species for all initial population sizes.

(iii) (Qualified and unqualified competition) The numbers K and M are the respective carrying capacities of the x and y species, the equilibrium population size that each species would reach in the absence of the other species. Sometimes, competition between species is described as "qualified" or "unqualified," according to the inhibiting effect of each species on the other (also referred as interference competition). We will say that the competition is *unqualified* if $x_\infty/K + y_\infty/M \leq 1$, that is, if competition tends to reduce the total population size (where the carrying capacities are the units of population size). This is intended to describe a situation in which both species depend on a common source of food and the competition makes survival more difficult for both species.

The condition $x_\infty/K + y_\infty/M \leq 1$ of unqualified competition says geometrically that the equilibrium (x_∞, y_∞) lies below the line $x/K + y/M = 1$ joining the equilibria $(K, 0)$ and $(0, M)$. Because

$$x_\infty = \frac{d\lambda - b\mu}{ad - bc}, \quad y_\infty = \frac{a\mu - c\lambda}{ad - bc},$$

the condition $x_\infty/K + y_\infty/M \leq 1$ is equivalent to

$$\frac{a}{\lambda}\frac{d\lambda - b\mu}{ad - bc} + \frac{d}{\mu}\frac{a\mu - c\lambda}{ad - bc} \leq 1,$$

which is equivalent to

$$a\mu(d\lambda - b\mu) + d\lambda(a\mu - c\lambda) \leq (ad - bc)\lambda\mu.$$

Suppose $ad-bc > 0$. Then it follows that $ab\mu^2-(ad+bc)\lambda\mu+cd\lambda^2 \geq 0$, or $(c\lambda-a\mu)(d\lambda-b\mu) \geq 0$. Thus, the system is in Case 3 or 4. If $ad-bc < 0$ then the above inequalities are reversed, so that $(c\lambda - a\mu)(d\lambda - b\mu) < 0$, which shows that the system is in Case 2. This shows that the assumption of unqualified competition rules out the possibility of coexistence of the two species (Case 1).

The *principle of competitive exclusion*, originally formulated by Gause in 1934 [Gau34a, Gau34b] on the basis of experimental evidence, states that coexistence under unqualified competition is impossible. We have shown that the principle of competitive exclusion is a consequence of the assumption of linear per capita growth rates. The principle itself is quite controversial; in fact, there is experimental evidence suggesting that coexistence under unqualified competition is possible. Our argument shows only that the principle of competitive exclusion is a consequence of the specific model hypothesized, not that the principle has biological validity. It is important to remember that if a mathematical model predicts behavior that contradicts valid observations, one must conclude that there is a flaw in the model.

It may be seen by looking at the phase portraits in Cases 1 and 2 that if the *isoclines* $x' = 0$ and $y' = 0$ are straight lines, then coexistence and unqualified competition are incompatible. However, it is possible to construct models of the form $x' = F(x, y)$, $y' = G(x, y)$ for species in competition for which coexistence and unqualified competition are compatible. An example of such a model that has been proposed [AGL73] is

$$x' = \lambda x\left(1 - \left(\frac{x}{K_1}\right)^{\theta_1} - \frac{b}{\lambda}y\right),$$

$$y' = \mu y\left(1 - \left(\frac{y}{K_2}\right)^{\theta_2} - \frac{c}{\mu}x\right).$$

(iv) (Other models) Predator-prey models and mutualism models may be analyzed by the same methods as those used for competitive systems. Also, models for interaction of more than two species, which would lead to systems of higher dimension than two, may be analyzed by the same methods.

67.2 Compartmental Disease Transmission Models

Kermack and McKendrick [KM27, KM32, KM33] made use of Sir Ronald Ross' modeling ideas [Ros11] to develop one of the first compartmental models aimed at studying the transmission dynamics and control of infectious diseases in humans. The impact of these models has now even reached the popular literature, [Gla96, Gla01, Gla00, CL13]. In a compartmental disease transmission model, the population under consideration is distributed into compartments according to their epidemiological status, that is, according to their relationship with the disease under consideration. Assumptions are made about the rate of birth, or entrance into the population, rate of natural death or departure from the population, the rate of new infections, and the rates of transition between compartments. These assumptions are translated into a system of nonlinear differential equations that is most often analyzed qualitatively by identifying constant equilibria and classifying their (dynamical) stability properties. The prototypical situation requires the existence of a disease-free equilibrium (all individuals susceptible), that is, an equilibrium that must be asymptotically stable for a certain range of model parameter values. This range of parameter values can be formulated in terms of the basic reproduction number $\mathcal{R}_0$.

Definitions:

The basic **compartments** under the Kermack and McKendrick framework [KM27] are S (susceptible), I (infectious), and R (removed), but there may be additional compartments such as E (exposed, meaning infected but not yet infectious), Q (quarantined), T (treated), etc.

The **basic reproduction number** $\mathcal{R}_0$ represents the number of secondary infections that would be caused by a single infected individual inserted into a totally susceptible population, at a demographic steady state, over the duration of his or her infection.

A **disease-free equilibrium** is an equilibrium with no infective individuals.

An **endemic equilibrium** is an equilibrium supporting a positive number of infective individuals.

Facts: A general reference for the following facts is [BDW08, Chap. 2].

1. The condition for asymptotic stability of the disease-free equilibrium is typically $\mathcal{R}_0 < 1$
2. If $\mathcal{R}_0 > 1$, the disease-free equilibrium is unstable and the *usual* situation is that in this case, an endemic equilibrium exists.
3. The endemic equilibrium is (usually) asymptotically stable, at least for values of $\mathcal{R}_0$ close to 1
4. There are situations in which there may be an asymptotically stable endemic equilibrium for parameter values such that $\mathcal{R}_0 < 1$, and such situations are disclosed by the process of locating and analyzing the equilibria of the model.
5. For the $SEIR$ model considered in the example below, the basic reproduction number, where the total population N settles at the constant value K (demographic steady state, Eq. (67.4)), is
$$\mathcal{R}_0 = \frac{\kappa}{\kappa+\mu}\frac{\beta K}{\alpha+\mu}.$$

Examples:

1. We illustrate the prototypical situation using an $SEIR$ (susceptible-exposed-infectious-removed) epidemic model,
$$\begin{aligned} S' &= \Lambda(N) - \beta SI - \mu S \\ E' &= \beta SI - (\kappa+\mu)E \\ I' &= \kappa E - (\alpha+\mu)I \\ R' &= \alpha I - \mu R. \end{aligned} \tag{67.3}$$

   This model arises from the following assumptions:

   (a) There is a birth rate $\Lambda(N)$ which is a function of the total population size $N = S+E+I+R$, and all births are in the susceptible class.

   (b) There is a proportional natural death rate μ in each class and there are no disease deaths.

   (c) The rate of new infections is proportional to the number of susceptibles and to the number of infectives.

   (d) There is a rate κ of movement from the exposed class to the infective class.

   (e) There is a recovery rate α of infectives.

   Since $N' = \Lambda(N) - \mu N$, N approaches a constant limit K with $\Lambda(K) = \mu K$ as $t \to \infty$. The theory of asymptotically autonomous systems [CT93] implies that the asymptotic behavior of system (67.3) is the same as that of the system obtained from Eq. (67.3) by replacing N by the constant K, that is

$$\begin{aligned} S' &= \mu K - \beta S I - \mu S \\ E' &= \beta S I - (\kappa + \mu) E \\ I' &= \kappa E - (\alpha + \mu) I \\ R' &= \alpha I - \mu R. \end{aligned} \tag{67.4}$$

(i) (Equilibria of the $SEIR$ model). Since $S + E + I + R$ is equal to the constant K, the equation for R in Eq. (67.4) can be discarded from the system. An equilibrium of Eq. (67.4) is a solution (S, E, I) of the system

$$\begin{aligned} \beta S I &= \mu(K - S) \\ \beta S I &= (\kappa + \mu) E \\ \kappa E &= (\alpha + \mu) I. \end{aligned}$$

There is a disease-free equilibrium $(K, 0, 0)$ and an endemic equilibrium when $\mathcal{R}_0 > 1$, namely,

$$\left(\frac{(\mu + \kappa)(\alpha + \mu)}{\kappa \beta}, \frac{\mu}{\mu + \kappa} \left[K - \frac{(\alpha + \mu)(\mu + \kappa)}{\kappa \beta} \right], \frac{\mu \kappa}{(\mu + \alpha)(\mu + \kappa)} \left[K - \frac{(\alpha + \mu)(\mu + \kappa)}{\kappa \beta} \right] \right),$$

or

$$\left(\frac{K}{\mathcal{R}_0}, \frac{\mu}{\mu + \kappa} \left[K - S_\infty \right], \frac{\mu \kappa}{(\mu + \alpha)(\mu + \kappa)} \left[K - S_\infty \right] \right),$$

where $S_\infty = \frac{K}{\mathcal{R}_0}$; $I > 0$ if $\kappa \beta K > (\alpha + \mu)(\mu + \kappa)$ or equivalently if $\mathcal{R}_0 > 1$. The matrix of the linearization at an equilibrium (S, E, I) is

$$\begin{bmatrix} -\mu - \beta I & 0 & -\beta S \\ \beta I & -(\mu + \kappa) & \beta S \\ 0 & \kappa & -(\mu + \alpha) \end{bmatrix}.$$

At the disease-free equilibrium, this matrix is

$$\begin{bmatrix} -\mu & 0 & -\beta K \\ 0 & -(\mu + \kappa) & \beta K \\ 0 & \kappa & -(\mu + \alpha) \end{bmatrix}.$$

The eigenvalues of this matrix are $-\mu$ and the eigenvalues of the 2×2 matrix

$$\begin{bmatrix} -(\mu + \kappa) & \beta K \\ \kappa & -(\mu + \alpha) \end{bmatrix}.$$

The trace of this matrix is negative, and the determinant of the matrix is positive if and only if

$$\kappa \beta K < (\alpha + \mu)(\kappa + \mu),$$

or

$$\mathcal{R}_0 = \frac{\kappa}{\kappa + \mu} \frac{\beta K}{\alpha + \mu)} < 1.$$

(ii) (The basic reproduction number) The following heuristic explanation based on the terms involved in the expression for $\mathcal{R}_0$ helps understand its role as the basic reproduction number. Consider the introduction of a single exposed individual into a totally susceptible population at the demographic steady state (that is, the total population is K). The fraction $\kappa/(\kappa + \mu)$

of exposed individuals survives to become infectious. An infectious individual infects βK susceptibles in unit time and remains infective for a time period $1/(\alpha + \mu)$ (the average infectious period). Hence, it follows that the disease-free equilibrium is asymptotically stable if and only if the basic reproduction number is less than 1.

(iii) (The endemic equilibrium) It is not difficult to prove that the endemic equilibrium, which exists if $\mathcal{R}_0 > 1$, is always asymptotically stable. Thus the behavior of the model (67.3) is determined completely by the basic reproduction number. If the basic reproduction number is less than 1, the disease-free equilibrium is asymptotically stable while if the basic reproduction number exceeds 1, the disease-free equilibrium is unstable but there is an asymptotically stable endemic equilibrium. It is possible to prove that in either case the asymptotic stability is global, that is, that all solutions (not only those starting close enough to the equilibrium) approach the equilibrium as $t \to \infty$.

(iv) (General period distributions) If the stays in compartments are not exponentially distributed, compartmental models are no longer sytems of ordinary differential equations. Instead, they become systems of integral or integro-differential equations. We have stated the facts used here in a form that extends to such models. The characteristic equation would become a transcendental equation rather than a polynomial equation, and the asymptotic stability condition becomes a question of the location of the roots of this transcendental equation.

The approach outlined here will help identify the occurrence of phenomena that includes the existence of endemic equilibria when the basic reproduction number is less than 1 or the onset of instability of an endemic equilibrium, usually marked by a Hopf bifurcation and a transition to sustained oscillations in a model (see [BC01, BC12, Het00]).

67.3 The Next Generation Matrix

We have calculated the reproduction number by following the secondary cases caused by a single infective introduced into a fully susceptible population. Often, one encounters subpopulations with different susceptibility to infection and in such cases it becomes necessary to follow the secondary infections in each subpopulation separately, and this approach will not yield the reproduction number. The need for a more general approach that captures the meaning of the reproduction number in heterogenous populations is satisfied by the use of the *next generation matrix* [DH00, DW02]. The method requires the calculation of a matrix whose (i, j) entry is the number of secondary infections caused in compartment i by an infected individual in compartment j.

In a compartmental disease transmission model we sort individuals into compartments.

Definitions:

A compartment is called a **disease compartment** if the individuals therein are infected. Note that this use of the term disease includes stages of infection such as exposed stages in which infected individuals are not necessarily infectious.

We assume there are n disease compartments and m non-disease compartments, and let $\mathbf{x} \in R^n$ and $\mathbf{y} \in R^m$ denote the subpopulations in each of these compartments.

Further, we denote by $\mathcal{F}_i$ the rate at which secondary infections increase the i^{th} disease compartment and by $\mathcal{V}_i$ the rate at which disease progression, death, and recovery decrease the i^{th} compartment.

The compartmental model can then be written in the form

$$\begin{aligned} x_i' &= \mathcal{F}_i(x,y) - \mathcal{V}_i(x,y)\ , \quad i = 1, \ldots, n, \\ y_j' &= g_j(x,y)\ , \quad j = 1, \ldots, m. \end{aligned} \tag{67.5}$$

Under suitable assumptions, the linearized equations for the disease compartments, $\mathbf{x}$, are decoupled from the remaining equations and can be written as

$$\mathbf{x}' = (F - V)\mathbf{x}, \tag{67.6}$$

where F and V are the $n \times n$ matrices with entries

$$F = \frac{\partial \mathcal{F}_i}{\partial x_j}(0, y_o) \qquad \text{and} \qquad V = \frac{\partial \mathcal{V}_i}{\partial x_j}(0, y_o).$$

The **spectral radius** of a matrix K, denoted by $\rho(K)$, is the maximum of the moduli of the eigenvalues of K.

The **spectral bound** (or abscissa) of a matrix A is the maximum real part of all eigenvalues of A.

The matrix $K = FV^{-1}$ is the **next generation matrix** for the system at the disease-free equilibrium [DH00].

The **basic reproduction number** of the system (67.5) is $\mathcal{R}_0 = \rho(FV^{-1})$.

A matrix of the form $A = sI - B$, with $B \geq 0$, is a Z **matrix**. These are matrices whose off-diagonal entries are negative or zero.

An M**-matrix** is a Z-matrix for which $s > \rho(B)$.

An M_0**-matrix** is a Z-matrix for which $s \geq \rho(B)$.

Facts:

1. [BP70] If A is a Z-matrix, then $A^{-1} \geq 0$ if and only if A is an M-matrix.
2. [DW02] If F is nonnegative and V is an M-matrix, then $\mathcal{R}_0 = \rho(FV^{-1}) < 1$ if and only if all eigenvalues of $(F - V)$ have negative real parts.
3. [DW02] If FV^{-1} is irreducible, then $\mathcal{R}_0$ is a simple eigenvalue of FV^{-1} and there is a nonnegative eigenvector ω associated with $\mathcal{R}_0$. If FV^{-1} is reducible, which is often the case for diseases with multiple strains, then FV^{-1} may have several positive real eigenvectors corresponding to reproduction numbers for each competing strain of the disease.
4. [BP70, Theorem 1.3.2] There is a nonnegative eigenvector ω associated with $\mathcal{R}_0$
5. [DW02] The (i, j) entry of FV^{-1} is the expected number of secondary infections in compartment i produced by individuals initially in compartment j, assuming that the environment seen by the individual remains homogeneous for the duration of its infection.

Examples:

1. (Derivation of the basic reproduction number). The next generation matrix approach defines the basic reproduction number in matrix terms and shows the linkage to an epidemiological interpretation. The derivation of the basic reproduction number is based on the linearization of this model about a disease-free equilibrium. The assumptions are (i) that all new infections are secondary infections arising from infected hosts; there is no immigration of individuals into the disease compartments, (ii) that the disease-free set, which consists of all points of the form $(0, y)$, is invariant, so that a solution with no infected individuals at some time

will be free of infection for all time, and (iii) that the disease-free equilibrium is also an equilibrium of the full system.

There are further assumptions that the function $\mathcal{F}$ represents new infections and must be nonnegative, that each component, $\mathcal{V}_i$, represents a net outflow from compartment i and must be negative (inflow only) whenever the compartment is empty, and that the sum $\sum_{i=1}^{n} \mathcal{V}_i(x, y)$ represents the total outflow from all infected compartments. Terms in the model leading to increases in $\sum_{i=1}^{n} x_i$ are assumed to represent secondary infections and therefore belong in $\mathcal{F}$.

The assumption that the disease-free system $\mathbf{y}' = \mathbf{g}(\mathbf{0}, \mathbf{y})$ has a unique asymptotically stable equilibrium implies that the linear stability of the system (67.5) is completely determined by the linear stability of the matrix $(F - V)$ in Eq. (67.6).

If we assume that a single infected person is introduced into a population originally free of disease, then the initial ability of the disease to spread through the population is determined by an examination of the linearization of Eq. (67.5) about the disease-free equilibrium $(\mathbf{0}, \mathbf{y}_0)$, and this is the epidemiological interpretation of the basic reproduction number.

The number of secondary infections produced by a single infected individual is the product of the expected duration of the infectious period and the rate at which secondary infections occur. For the general model with n disease compartments, these are computed for each compartment for a hypothetical index case. The expected time that an index case spends in each compartment is given by the integral $\int_0^\infty \varphi(t, \mathbf{x}_0)\, dt$, where $\varphi(t, \mathbf{x}_0)$ is the solution of Eq. (67.6) with $F = 0$ (no secondary infections) and nonnegative initial conditions, $\mathbf{x}_0$, representing an infected index case:

$$\mathbf{x}' = -V\mathbf{x}, \qquad \mathbf{x}(0) = \mathbf{x}_0. \tag{67.7}$$

In effect, this solution shows the path of the index case through the disease compartments from the initial exposure through to death or recovery with the i^{th} component of $\varphi(t, \mathbf{x}_0)$ interpreted as the probability that the index case (introduced at time $t = 0$) is in disease state i at time t. The solution of Eq. (67.7) is $\varphi(t, \mathbf{x}_0) = e^{-Vt}\mathbf{x}_0$, where the exponential of a matrix is defined by the Taylor series

$$e^A = I + A + \frac{A^2}{2} + \frac{A^3}{3!} + \cdots + \frac{A^k}{k!} + \cdots .$$

(Section 17.2). This series converges for all t (see, for example, [HS74]) and can be integrated term by term. Thus,

$$\int_0^\infty e^{-Vt} dt\mathbf{x}_0 = V^{-1}\mathbf{x}_0 \geq \mathbf{0},$$

and the (i, j) entry of the matrix V^{-1} can be interpreted as the expected time an individual initially introduced into disease compartment j spends in disease compartment i.

The (i, j) entry of the matrix F is the rate at which secondary infections are produced in compartment i by an index case in compartment j. Hence, the expected number of secondary infections produced by the index case is given by

$$\int_0^\infty F e^{-Vt}\mathbf{x}_0\; dt = FV^{-1}\mathbf{x}_0.$$

The (i, j) entry of FV^{-1} is the expected number of secondary infections in compartment i produced by individuals initially in compartment j, assuming, of course, that the environment seen by the individual remains homogeneous for the duration of its infection. Thus, $\mathcal{R}_0$ and the associated eigenvector ω suitably define a "typical" infective and the basic reproduction number can be rigorously defined as the spectral radius of the matrix, FV^{-1}. The facts cited earlier imply that the disease-free equilibrium is asymptotically stable if $\mathcal{R}_0 < 1$ and unstable if $\mathcal{R}_0 > 1$.

These results validate the extension of the definition of the reproduction number to more general situations. There are instances in which the next generation matrix yields a value for the basic reproduction number which is not intuitively appropriate, for example in populations that are divided into subgroups with little or no interaction. However, it remains the main method for calculating reproduction numbers.

2. (The $SEIR$ model). Consider the $SEIR$ model

$$\begin{aligned} S' &= \mu N - \mu S - \beta S I \\ E' &= \beta S I - (\kappa + \mu) E \\ I' &= \kappa E - (\alpha + \mu) I \\ R' &= \alpha I - \mu R. \end{aligned} \tag{67.8}$$

Here the disease states are E and I,

$$\mathcal{F} = \begin{bmatrix} I\beta S \\ 0 \end{bmatrix}, \qquad \mathcal{V} = \begin{bmatrix} (\kappa+\mu)E \\ -\kappa E + (\alpha+\mu) I \end{bmatrix}$$

and

$$F = \begin{bmatrix} 0 & \beta N \\ 0 & 0 \end{bmatrix}, \quad V = \begin{bmatrix} \kappa+\mu & 0 \\ -\kappa & \alpha+\mu \end{bmatrix}, \quad V^{-1} = \begin{bmatrix} \frac{1}{\kappa+\mu} & 0 \\ \frac{\kappa}{(\kappa+\mu)(\alpha+\mu)} & \frac{1}{\alpha+\mu} \end{bmatrix}.$$

Then we may calculate

$$FV^{-1} = \begin{bmatrix} \frac{\kappa}{\kappa+\mu}\frac{\beta N}{\alpha+\mu} & \frac{\beta N}{\alpha+\mu} \\ 0 & 0 \end{bmatrix}.$$

Since FV^{-1} has rank 1, it has only one nonzero eigenvalue, and it is easy to see that

$$\mathcal{R}_0 = \frac{\kappa}{\kappa+\mu}\frac{\beta N}{\alpha+\mu}.$$

If all new infections are in a single compartment, as is the case here, the basic reproduction number is the trace of the matrix FV^{-1}.

67.4 Discrete Age-Structured Population Models

In practice, animal or plant populations are often measured by size with age structure used as an approximation (not always effectively) to size structure. The study of age-structured models is considerably simpler than the study of general size-structured models, primarily because age increases linearly with the passage of time while the linkage of size with time may be less predictable. Age-structured models may be either discrete or continuous. Here, we confine ourselves to the study of linear discrete models, for which total population size generally either increases or decreases exponentially over time. The models described next were pioneered by Leslie [Les45], [Les48] and a wonderful book full of applications is that of Caswell [Cas01]. The population model described in this section is usually known as the *Leslie matrix model*, formulated in 1945, although similar forms appeared in earlier work of Bernardelli [Ber41] and Lewis [Lew42].

Definitions:

Leslie Model

We consider a population that is divided into a finite number of age classes labeled from zero to m, and will describe this population by giving the number of members in each class at a sequence of times.

Let $\rho_{j,n}$ denote the number of members in the jth class at the nth time ($j = 0, 1, \ldots, m$; $n = 0, 1, 2, \ldots$).

We will assume that the length of time spent in each age class is the same and that this length of time is equal to the interval between measurements of population size. Thus, $\rho_{j,n+1}$, the number of members in the jth age class at the $(n+1)$st time, is equal to $\rho_{j-1,n}$, the number of members in the $(j-1)$st age class at the nth time minus the number of members of this age cohort who die before entering the next age class.

We will assume that the probability of survival from one age class to the next depends only on age, that is, that there are constants $p_0, p_1, \ldots, p_{m-1}$ such that

$$\rho_{1,n+1} = p_0\rho_{0,n}, \quad \rho_{2,n+1} = p_1\rho_{1,n}, \quad \ldots, \quad \rho_{m,n+1} = p_{m-1}\rho_{m-1,n},$$

for $n = 0, 1, 2, \ldots$. Thus, p_j is the probability that a member of the jth age class survives to the $(j+1)$st age class ($j = 0, 1, 2, \ldots, m-1$); it is assumed that no member survives beyond the mth age class.

All recruitment of new members into the population is assumed to come from a **birth process**, with fecundity depending only on age. Thus, we assume that there are constants $\beta_0, \beta_1, \ldots, \beta_m$ such that

$$\rho_{0,n+1} = \beta_0\rho_{0,n} + \beta_1\rho_{1,n} + \cdots + \beta_m\rho_{m,n}.$$

The fecundities of the various age classes need not all be different from zero.

We assume that the survival probabilities $p_0, p_1, \ldots, p_{m-1}$ are positive and that the fecundity coefficients $\beta_0, \beta_1, \ldots, \beta_m$ are nonnegative and not all zero.

We define the $(m+1)$-dimensional column vector

$$\boldsymbol{\rho}_n = \begin{bmatrix} \rho_{0,n} \\ \rho_{1,n} \\ \vdots \\ \rho_{m,n} \end{bmatrix}$$

and the **Leslie matrix**

$$A = \begin{bmatrix} \beta_0 & \beta_1 & \beta_2 & \ldots & \beta_{m-1} & \beta_m \\ p_0 & 0 & 0 & \ldots & 0 & 0 \\ 0 & p_1 & 0 & \ldots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \ldots & p_{m-1} & 0 \end{bmatrix}.$$

Facts: A general reference for the following facts is [Les45].

1. The Leslie model is a population model described by a system of $(m+1)$ linear difference equations

$$\begin{aligned}
\rho_{0,n+1} &= \beta_0\rho_{0,n} + \beta_1\rho_{1,n} + \cdots + \beta_m\rho_{m,n},\\
\rho_{1,n+1} &= p_0\rho_{0,n},\\
\rho_{2,n+1} &= p_1\rho_{1,n},\\
\vdots\ &\ \ \vdots\\
\rho_{m,n+1} &= p_{m-1}\rho_{m-1,n},
\end{aligned}$$

to which we must add an initial condition and specify $\rho_{0,0}, \rho_{1,0}, \ldots, \rho_{m,0}$.

2. The Leslie model may be written in vector-matrix form: The model consists of the vector difference equation

$$\boldsymbol{\rho}_{n+1} = A\boldsymbol{\rho}_n,$$

together with the specification of the initial vector $\boldsymbol{\rho}_0$, which has the solution

$$\boldsymbol{\rho}_n = A^n\boldsymbol{\rho}_0. \qquad (67.9)$$

3. Let A be any matrix all of whose elements are nonnegative, and such that for some positive integer k every element of the matrix A^k is positive. Then A has a simple positive eigenvalue λ_0 with a corresponding eigenvector having all components positive, and $|\lambda_j| < \lambda_0$ for every other eigenvalue λ_j. In this case, $\frac{1}{\sum_{i=1}^m \rho_{i,n}}\boldsymbol{\rho}_n \to \mathbf{v}_0$ as $n \to \infty$, where $\mathbf{v}_0$ is a positive eigenvector for λ_0 whose entries sum to one. See also Example 1 below.

Examples:

1. (The solution of the Leslie matrix model) The formal solution of Eq. (67.9) in Fact 2 is of little use without an understanding of the nature of the matrix A^n for a given Leslie matrix A; such an understanding requires knowledge of the eigenvalues and eigenvectors of the matrix A, and is related to the power method for finding eigenvalues and eigenvectors (see Section 55.1).

In the simplest case, in which the $(m+1)\times(m+1)$ matrix A has $(m+1)$ linearly independent eigenvectors $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_m$ corresponding to the eigenvalues $\lambda_0, \lambda_1, \ldots, \lambda_m$, respectively, we may expand

$$\boldsymbol{\rho}_n = \sum_{j=0}^{m} c_{j,n}\mathbf{v}_j,$$

because $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_m$ span the space $\mathbb{R}^{m+1}$ of $(m+1)$-dimensional vectors with real components. Then

$$\boldsymbol{\rho}_{n+1} = \sum_{j=0}^{m} c_{j,n+1}\mathbf{v}_j = A\boldsymbol{\rho}_n = \sum_{j=0}^{m} c_{j,n}A\mathbf{v}_j = \sum_{j=0}^{m} c_{j,n}\lambda_j\mathbf{v}_j,$$

and therefore

$$\sum_{j=0}^{m}(c_{j,n+1} - c_{j,n}\lambda_j)\mathbf{v}_j = \mathbf{0}.$$

Because the vectors $\mathbf{v}_0, \mathbf{v}_1, \ldots, \mathbf{v}_m$ are linearly independent, $c_{j,n+1} = \lambda_j c_{j,n}$ for $j = 0, 1, \ldots, m;\ n = 0, 1, 2, \ldots$, and this implies $c_{j,n} = \lambda_j^n c_{j,0}$ for $j = 0, 1, \ldots, m;\ n = 0, 1, 2, \ldots$. Now we may write

$$\boldsymbol{\rho}_n = \sum_{j=0}^{m} c_{j,0}\lambda_j^n\mathbf{v}_j, \qquad n = 0, 1, 2, \ldots.$$

We now suppose that the eigenvalues can be arranged in decreasing order, or at least that λ_0 is a real simple eigenvalue that is *dominant* in the sense that $|\lambda_j| < \lambda_0$ for $j = 1, 2, \ldots, m$. Then we may write

$$\boldsymbol{\rho}_n = c_{0,0}\lambda_0^n \mathbf{v}_0 + \mathbf{u}_n,$$

where $\lambda_0^{-n}\mathbf{u}_n \to \mathbf{0}$ as $n \to \infty$. In other words, $\boldsymbol{\rho}_n$ is λ_0^n multiplied by an eigenvector of A corresponding to λ_0 plus terms that are negligible compared to this term as $n \to \infty$. We define

$$P_n = \sum_{j=0}^{m} \rho_{j,n} \qquad \text{(total population at time } n\text{)},$$

$$B_n = \sum_{j=0}^{m} \beta_j \rho_{j,n} = \rho_{0,n+1} \quad \text{(births into population at time } n\text{)}.$$

Then we have

$$P_n = c_{0,0}\lambda_0^n \sum_{j=0}^{m} v_{0,j} + \sum_{j=0}^{m} u_{n,j},$$

and

$$\frac{\boldsymbol{\rho}_n}{P_n} = \frac{c_{0,0}\mathbf{v}_0 + \lambda_0^{-n}\mathbf{u}_n}{c_{0,0}\sum_{j=0}^{m} v_{0,j} + \lambda_0^{-n}\sum_{j=0}^{m} u_{n,j}}.$$

Because $\lambda_0^{-n}\mathbf{u}_n \to \mathbf{0}$ as $n \to \infty$, we have

$$\frac{\boldsymbol{\rho}_n}{P_n} \sim \frac{\mathbf{v}_0}{\sum_{j=0}^{m} v_{0,j}}.$$

Thus, the fraction of the population in each age class approaches a limit, and these limits are proportional to the components of the eigenvector $\mathbf{v}_0$. Thus, there is a *stable age distribution.* If the matrix A does not have $(m+1)$ linearly independent eigenvectors, the above reasoning must be modified, but we can still show that if there is a positive simple dominant eigenvalue λ_0 with corresponding eigenvector $\mathbf{v}_0$, then

$$\boldsymbol{\rho}_n = c\lambda_0^n \mathbf{v}_0 + \mathbf{u}_n$$

with $\lim_{n\to\infty} \lambda_0^{-n}\mathbf{u}_n = \mathbf{0}$. This suffices to show that there is a stable age distribution. Of course, the result makes no sense biologically unless every component of the eigenvector $\mathbf{v}_0$ is positive.

By examining the particular form of the Leslie matrix, we may show that the characteristic equation is

$$\lambda^{m+1} - \beta_0\pi_0\lambda^m - \beta_1\pi_1\lambda^{m-1} - \cdots - \beta_m\pi_m = 0,$$

where $\pi_0 = 1, \pi_1 = p_0, \pi_2 = p_0p_1, \ldots, \pi_m = p_0p_1\cdots p_{m-1}$. Thus, $\pi_j > 0$ is the probability of survival from birth to entry into the jth age class. Division by λ^{m+1} gives the equivalent characteristic equation

$$\sum_{j=0}^{m} \beta_j\pi_j\lambda^{-(j+1)} = 1.$$

Because $\sum_{j=0}^{m} \beta_j\pi_j\lambda^{-(j+1)}$ is unbounded as $\lambda \to 0^+$, tends to zero as $\lambda \to \infty$, and is monotone decreasing, there is a unique positive real root λ_0. If $\mathbf{v}_0$ is the corresponding eigenvector, with components $(v_0, v_1, \ldots, v_m)$, we may again use the form of the Leslie matrix to write the equations

$$
\begin{aligned}
\beta_0 v_0 + \beta_1 v_1 + \ldots + \beta_m v_m &= \lambda_0 v_0,\\
p_0 v_0 &= \lambda_0 v_1,\\
p_1 v_1 &= \lambda_0 v_2,\\
p_{m-1} v_{m-1} &= \lambda_0 v_m.
\end{aligned}
$$

If we take $v_0 = 1$, then from these equations we obtain

$$
\begin{aligned}
v_1 &= \frac{p_0}{\lambda_0} = \frac{\pi_1}{\lambda_0},\\
v_2 &= \frac{p_1 v_1}{\lambda_0} = \frac{p_0 p_1}{\lambda_0^2} = \frac{\pi_2}{\lambda_0^2},\\
&\vdots\\
v_m &= \frac{p_{m-1} v_{m-1}}{\lambda_0} = \frac{p_0 \cdots p_{m-1}}{\lambda_0^m} = \frac{\pi_m}{\lambda_0^m}.
\end{aligned}
$$

Thus, the components of $\mathbf{v}_0$ are proportional to π_j/λ_0^j $(j = 0, 1, \ldots, m)$, and these are the proportions in the stable age distribution, obviously positive. If $\lambda_0 > 1$, or equivalently if $\sum_{j=0}^m \beta_j \pi_j > 1$ (because then the value of λ that makes $\sum_{j=0}^m \pi_j \beta_j \lambda_j^{-(j+1)} = 1$ must be greater than one), the total population size grows like λ_0^n. If $\sum_{j=0}^m \beta_j \pi_j < 1$, so that $\lambda_0 < 1$, the total population size decreases like λ_0^n. If $\sum_{j=0}^m \beta_j \pi_j = 1$, so that $\lambda_0 = 1$, the total population size remains constant. In each case, the proportion of the population in each age class tends to a limit.

2. (More properties of the solution of the Leslie matrix model) While we have shown that for the Leslie matrix model there is a unique real simple eigenvalue λ_0 with a corresponding eigenvector whose components are all positive, we have *not* shown that this eigenvalue is dominant. In fact, additional conditions are needed to ensure the dominance of the eigenvalue λ_0.

   The conclusions of the classical Perron–Frobenius Theorem (see Fact 3) are exactly what we need, but the hypothesis is unsuitable for our purposes. Fortunately, it is possible to show that for a Leslie matrix model with two consecutive β_j different from zero, some power of the matrix has all elements positive, and thus the conclusion of the Perron–Frobenius theorem holds [Cas01]. Under these conditions we have as $n \to \infty$,

$$
\begin{aligned}
\boldsymbol{\rho}_n &\sim c\lambda_0^n \mathbf{v}_0,\\
P_n &\sim c \sum_{j=0}^{m} \lambda_0^n \frac{\pi_j}{\lambda_0^j} = c\lambda_0^n \sum_{l=0}^{m} \frac{\pi_j}{\lambda_0^j},
\end{aligned}
$$

   so that $P_n \sim c\lambda_0^n$ if $\lambda_0 > 1$, but $P_n \sim c\pi_m \lambda_0^{n-m}$ if $\lambda_0 < 1$ and

$$
B_n = c \sum_{j=0}^{m} \lambda_0^n \frac{\pi_j}{\lambda_0^j} \sim c \sum_{j=0}^{m} \beta_j \lambda_0^n \frac{\pi_j}{\lambda_0^j} = c\lambda_0^{n+1} \sum_{j=0}^{m} \beta_j \frac{\pi_j}{\lambda_0^{j+1}} = c\lambda_0^{n+1},
$$

   because $\sum_{j=0}^m \beta_j \frac{\pi_j}{\lambda_0^{j+1}} = 1$.

   There are age-structured populations for which the Perron–Frobenius result does not hold. The simplest example of a two-stage model with immature (non-reproducing) members and adults corresponds to a Leslie matrix of the form

$$
A = \begin{bmatrix} 0 & \beta \\ \rho & 0 \end{bmatrix}
$$

   having two eigenvalues of equal absolute value and opposite sign.

If $\lambda = re^{i\theta}$ is a complex eigenvalue, then $\lambda^n = r^n e^{in\theta} = r^n \cos n\theta + ir^n \sin n\theta$. Corresponding to the pair of complex conjugate eigenvalues $re^{\pm i\theta}$ there is a pair of real solutions of the difference equation containing terms $r^n \cos n\theta$ and $r^n \sin n\theta$ representing oscillations. If the absolute value r of this pair of eigenvalues is as large as λ_0, then these terms cannot be neglected in the asymptotic expression for the solution vector $\boldsymbol{\rho}_n$. An extreme case arises if the fertility is concentrated in a single age class, so that the birth rate might be periodic in time. A periodic age structure is known as a *Bernardelli population wave* [Ber41]. Such population waves have been observed in human populations. A simple example is given by the 3×3 Leslie matrix

$$A = \begin{bmatrix} 0 & 0 & \beta_2 \\ p_0 & 0 & 0 \\ 0 & p_1 & 0 \end{bmatrix}$$

with characteristic equation $\lambda^3 - \beta_2 p_0 p_1 = 0$. This equation has three roots, one real and positive and two nonreal, all having the same absolute value. The three cube roots of 1 are $-\frac{1}{2} + i\frac{\sqrt{3}}{2}$, $-\frac{1}{2} - i\frac{\sqrt{3}}{2}$, and 1. Letting $w = -\frac{1}{2} - i\frac{\sqrt{3}}{2}$, we have $w^2 = -\frac{1}{2} + i\frac{\sqrt{3}}{2}$, and $w^3 = 1$. Then the eigenvalues are $\sqrt[3]{\beta_2 p_0 p_1}w$, $\sqrt[3]{\beta_2 p_0 p_1}w^2$, and $\sqrt[3]{\beta_2 p_0 p_1}$.

3. (Choice of model) The approach described here is most commonly used in demographic studies (see [KC05]). Dynamic population models are more commonly continuous, described as partial differential equations, because these may be generalized to nonlinear models that may be better descriptions of population behavior (see [BC01], [BC12]). The approach described here does not lend itself to extensions to nonlinear situations.

68.1 What Is Linear Programming?

Definitions:

Optimization is maximization or minimization of a real-valued function, called the **objective function,** on a set, called the **feasible region** or the set of **feasible solutions**.

The values of function on the set are called **feasible values**.

An **optimal solution** (optimizer) is a feasible solution where the objective function reaches an **optimal value** (optimum), i.e., maximal or minimal value, respectively.

An optimization problem is **infeasible** if there are no feasible solutions, i.e., the feasible region is empty.

It is **unbounded** if the feasible values are arbitrary large, in the case of a maximization problem, or arbitrary small, in the case of a minimization problem.

A **mathematical program** is an optimization problem where the feasible region is a subset of $\mathbb{R}^n$, a finite dimensional real space; i.e., the objective function is a function of one or several real variables.

A **linear form** in variables $x_1, \ldots, x_n$ is $c_1x_1 + \cdots + c_nx_n$, where c_i are given numbers.

An **affine function** is a linear form plus a given number.

The term *linear function*, which is not used here, means a linear form in some textbooks and an affine function in others.

A **linear constraint** is one of the following three constraints: $f \leq g, f = g, f \geq g$, where f and g are affine functions. In standard form, f is a linear form and g is a given number.

A **linear program** is a mathematical program where the objective function is an affine function and the feasible region is given by a finite system of linear constraints, all of them to be satisfied.

Facts:

For background reading on the material in this section, see [Vas03].

1. Linear constraints with equality signs are known as linear equations. The main tool of simplex method, pivot steps, allows us to solve any system of linear equations.
2. In some textbooks, the objective function in a linear program is required to be a linear form. Dropping a constant in the objective function does not change optimal solutions, but the optimal value changes in the obvious way.
3. Solving an optimization problem usually means finding the optimal value and an optimal solution or showing that they do not exist. By comparison, solving a system of linear equations usually means finding all solutions. In both cases, in real life we only find approximate solutions.
4. Linear programs with one and two variables can be solved graphically. In the case of one variable x, the feasible region has one of the following forms: Empty, a point $x = a$, a finite interval $a \leq x \leq b$, with $a < b$, a ray $x \geq a$ or $x \leq a$, the whole line. The objective function $f = cx + d$ is represented by a straight line. Depending on the sign of c and whether we want to maximize or minimize f, we move in the feasible region to the right or to the left as far as we can in search for an optimal solution.

   In the case of two variables, the feasible region is a closed convex set with finitely many vertices (corners). Together with the feasible region, we can draw in plane levels of the objective function. Unless the objective function is constant, every level (where the function takes a certain value) is a straight line. This picture allows us to see whether the program is feasible and bounded. If it is, the picture allows us to find a vertex which is optimal.
5. Linear programming is about formulating, collecting data, and solving linear programs, and also about analyzing and implementing solutions in real life.
6. Linear programming is an important part of mathematical programming. In its turn, mathematical programming is a part of *operations research. Systems engineering* and *management science* are engineering and business versions of operations research.
7. Every linear program is either infeasible, or unbounded, or has an optimal solution.

Examples:

1. Here are 3 linear forms in $x, y, z : 2x - 3y + 5z, x + z, y$.
2. Here are 3 affine functions of $x, y, z : 2x - 3y + 5z - 1, x + z + 3, y$.
3. Here are 3 functions of x, y, z that are not affine: $xy, x^2 + z^3, \sin z$.
4. The constraint $|x| \leq 1$ is not linear, but it is equivalent to a system of two linear constraints, $x \leq 1, x \geq -1$.
5. (An infeasible linear program) Here is a linear program:
   Maximize $x + y$ subject to $x \leq -1, x \geq 0$.

   It has two variables and two linear constraints. The objective function is a linear form. The program is infeasible.
6. (An unbounded linear program) Here is a linear program:
   Maximize $x + y$.

   This program has two variables and no constraints. The objective function is a linear form. The program is unbounded.

7. Here is a linear program:
   Minimize $x + y$ subject to $x \geq 1, y \geq 2$.

   This program has two variables and two linear constraints. The objective function is a linear form. The optimal value (the minimum) is 3. An optimal solution is $x = 1, y = 2$. It is unique.

68.2 Setting Up (Formulating) Linear Programs

Examples:

1. Finding the maximum of n given numbers $c_1, \ldots, c_n$ does not look like a linear program. However, it is equivalent to the following linear program with n variables x_i and $n+1$ linear constraints:
   $c_1x_1 + \cdots + c_nx_n \to \max$, all $x_i \geq 0$, $x_1 + \cdots + x_n = 1$.

   An equivalent linear program with one variable y and n linear constraints is $y \to \min$, $y \geq c_i$ for all i.
2. (Diet problem [Vas03, Ex. 2.1]). The general idea is to select a mix of different foods in such a way that basic nutritional requirements are satisfied at minimum cost. Our example is drastically simplified.

   According to the recommendations of a nutritionist, a person's daily requirements for protein, vitamin A, and calcium are as follows: 50 grams of protein, 4000 IUs (international units) of vitamin A, 1000 milligrams of calcium. For illustrative purposes, let us consider a diet consisting only of apples (raw, with skin), bananas (raw), carrots (raw), dates (domestic, natural, pitted, chopped), and eggs (whole, raw, fresh) and let us, if we can, determine the amount of each food to be consumed in order to meet the recommended dietary allowances (RDA) at minimal cost.

Food	Unit	Protein (g)	Vit. A (IU)	Calcium (mg)
Apple	1 medium (138 g)	0.3	73	9.6
Banana	1 medium (118 g)	1.2	96	7
Carrot	1 medium (72 g)	0.7	20,253	19
Dates	1 cup (178 g)	3.5	890	57
Egg	1 medium (44 g)	5.5	279	22

Since our goal is to meet the RDA with minimal cost, we also need to compile the costs of these foods:

Food		Cost (in cents)
1	Apple	10
1	Banana	15
1	Carrot	5
1 cup	Dates	60
1	Egg	8

Using these data, we can now set up a linear program. Let a, b, c, d, e be variables representing the quantities of the five foods we are going to use in the diet. The objective function to be minimized is the total cost function (in cents),

$$C = 10a + 15b + 5c + 60d + 8e,$$

where the coefficients represent cost per unit of the five items under consideration.

What are the constraints? Obviously,

$$a, b, c, d, e \geq 0. \qquad (i)$$

These constraints are called *nonnegativity constraints.*

Then, to ensure that the minimum daily requirements of protein, vitamin A, and calcium are satisfied, it is necessary that

$$\begin{cases} 0.3a + 1.2b + 0.7c + 3.5d + 5.5e \geq 50 \\ 73a + 96b + 20253c + 890d + 279e \geq 4000 \\ 9.6a + 7b + 19c + 57d + 22e \geq 1000, \end{cases} \qquad (ii)$$

where, for example, in the first constraint, the term $0.3a$ expresses the number of grams of protein in each apple multiplied by the quantity of apples needed in the diet, the second term $1.2b$ expresses the number of grams of protein in each banana multiplied by the quantity of bananas needed in the diet, and so forth.

Thus, we have a linear program with 5 variables and 8 linear constraints.

3. (Blending problem [Vas03, Ex. 2.2]). Many coins in different countries are made from cupronickel (75% copper, 25% nickel). Suppose that the four available alloys (scrap metals) A, B, C, D to be utilized to produce the coin contain the percentages of copper and nickel shown in the following table:

Alloy	A	B	C	D
% copper	90	80	70	60
% nickel	10	20	30	40
$/lb	1.2	1.4	1.7	1.9

The cost in dollars per pound of each alloy is given as the last row in the same table.

Notice that none of the four alloys contains the desired percentages of copper and nickel. Our goal is to combine these alloys into a new blend containing the desired percentages of copper and nickel for cupronickel while minimizing the cost. This lends itself to a linear program.

Let a, b, c, d be the amounts of alloys A, B, C, D in pounds to make a pound of the new blend. Thus,

$$a,\ b,\ c,\ d \geq 0. \qquad (i)$$

Since the new blend will be composed exclusively from the four alloys, we have

$$a + b + c + d = 1. \qquad (ii)$$

The conditions on the composition of the new blend give

$$\begin{cases} .9a + .8b + .7c + .6d = .75 \\ .1a + .2b + .3c + .4d = .25. \end{cases} \qquad (iii)$$

For example, the first equality states that 90% of the amount of alloy A, plus 80% of the amount of alloy B, plus 70% of the amount of alloy C, plus 60% of the amount of alloy D will give the desired 75% of copper in a pound of the new blend. Likewise, the second equality gives the desired amount of nickel in the new blend.

Taking the preceding constraints into account, we minimize the cost function

$$C = 1.2a + 1.4b + 1.7c + 1.9d.$$

In this problem, all the constraints, except (i), are *equalities.* In fact, there are three linear equations and four unknowns. However, the three equations are not independent. For example, the sum of the equations in (iii) gives (ii). Thus, (ii) is redundant.

In general, a constraint is said to be *redundant* if it follows from the other constraints of our system. Since it contributes no new information regarding the solutions of the linear program, it can be dropped from consideration without changing the feasible set.

4. (Manufacturing problem [Vas03, Ex. 2.3]). We are now going to state a program in which the objective function, a profit function, is to be maximized. A factory produces three products: P1, P2, and P3. The unit of measure for each product is the standard-sized boxes into which the product is placed. The profit per box of P1, P2, and P3 is \$2, \$3, and \$7, respectively. Denote by x_1, x_2, x_3 the number of boxes of P1, P2, and P3, respectively. So the profit function we want to maximize is

$$P = 2x_1 + 3x_2 + 7x_3.$$

The five resources used are raw materials R1 and R2, labor, working area, and time on a machine. There are 1200 lb of R1 available, 300 lb of R2, 40 employee-hours of labor, 8000 m^2 of working area, and 8 machine-hours on the machine.

The amount of each resource needed for a box of each of the products is given in the following table (which also includes the aforementioned data):

Resource	Unit	P1	P2	P3	Available
R1	lb	40	20	60	1200
R2	lb	4	1	6	300
Labor	hour	.2	.7	2	40
Area	m^2	100	100	800	8000
Machine	hour	.1	.3	.6	8
Profit	\$	2	3	7	→ max

As we see from this table, to produce a box of P1 we need 40 lb of R1, 4 lb of R2, 0.2 hours of labor, 100 m^2 of working area, and 0.1 hours on the machine. Also, the amount of resources needed to produce a box of P2 and P3 can be deduced from the table. The constraints are

$$x_1, x_2, x_3 \geq 0, \qquad (i)$$

and

$$\left\{\begin{array}{rcrcrcrc} 40x_1 & + & 20x_2 & + & 60x_3 & \leq & 1200 & \text{(pounds of R1)} \\ 4x_1 & + & x_2 & + & 6x_3 & \leq & 300 & \text{(pounds of R2)} \\ .2x_1 & + & .7x_2 & + & 2x_3 & \leq & 40 & \text{(hours of labor)} \\ 100x_1 & + & 100x_2 & + & 800x_3 & \leq & 8000 & \text{(area in m}^2\text{)} \\ .1x_1 & + & .3x_2 & + & .8x_3 & \leq & 8 & \text{(machine).} \end{array}\right. \qquad (ii)$$

5. (Transportation problem [Vas03, Ex. 2.4]). Another concern that manufacturers face daily is *transportation costs* for their products. Let us look at the following hypothetical situation and try to set it up as a linear program. A manufacturer of widgets has warehouses in Atlanta, Baltimore, and Chicago. The warehouse in Atlanta has 50 widgets in stock, the warehouse in Baltimore has 30 widgets in stock, and the warehouse in Chicago has 50 widgets in stock. There are retail stores in Detroit, Eugene, Fairview, Grove City, and Houston. The retail stores in Detroit, Eugene, Fairview, Grove City, and Houston need at least 25, 10, 20, 30, and 15 widgets, respectively. Obviously, the manufacturer needs to ship widgets to all five stores from the three warehouses and he wants to do this in the cheapest possible

way. This presents a perfect backdrop for a linear program to minimize shipping cost. To start, we need to know the cost of shipping one widget from each warehouse to each retail store. This is given by a shipping cost table.

	1.D	2.E	3.F	4.G	5.H
1. Atlanta	55	30	40	50	40
2. Baltimore	35	30	100	45	60
3. Chicago	40	60	95	35	30

Thus, it costs \$30 to ship one unit of the product from Baltimore to Eugene (E), \$95 from Chicago to Fairview (F), and so on.

In order to set this up as a linear program, we introduce variables that represent the number of units of product shipped from each warehouse to each store. We have numbered the warehouses according to their alphabetical order and we have enumerated the stores similarly. Let x_{ij}, for all $1 \leq i \leq 3$, $1 \leq j \leq 5$, represent the number of widgets shipped from warehouse $\#i$ to store $\#j$. This gives us 15 unknowns. The objective function (the quantity to be minimized) is the shipping cost given by

$$\begin{aligned} C = {} & 55x_{11} + 30x_{12} + 40x_{13} + 50x_{14} + 40x_{15} \\ & +35x_{21} + 30x_{22} + 100x_{23} + 45x_{24} + 60x_{25} \\ & +40x_{31} + 60x_{32} + 95x_{33} + 35x_{34} + 30x_{35}, \end{aligned}$$

where $55x_{11}$ represents the cost of shipping one widget from the warehouse in Atlanta to the retail store in Detroit (D) multiplied by the number of widgets that will be shipped, and so forth.

What are the constraints? First, our 15 variables satisfy the condition that

$$x_{ij} \geq 0, \qquad \text{for all } 1 \leq i \leq 3,\ 1 \leq j \leq 5, \tag{i}$$

since shipping a negative amount of widgets makes no sense. Second, since the warehouse $\#i$ cannot ship more widgets than it has in stock, we get

$$\begin{cases} x_{11} + x_{12} + x_{13} + x_{14} + x_{15} \leq 50 \\ x_{21} + x_{22} + x_{23} + x_{24} + x_{25} \leq 30 \\ x_{31} + x_{32} + x_{33} + x_{34} + x_{35} \leq 50. \end{cases} \tag{ii}$$

Next, working with the amount of widgets that each retail store needs, we obtain the following five constraints:

$$\begin{cases} x_{11} + x_{21} + x_{31} \geq 25 \\ x_{12} + x_{22} + x_{32} \geq 10 \\ x_{13} + x_{23} + x_{33} \geq 20 \\ x_{14} + x_{24} + x_{34} \geq 30 \\ x_{15} + x_{25} + x_{35} \geq 15. \end{cases} \tag{iii}$$

The problem is now set up. It is a linear program with 15 variables and 23 linear constraints.

6. (Job assignment problem [Vas03, Ex. 2.5]). Suppose that a production manager must assign n workers to do n jobs. If every worker could perform each job at the same level of skill and efficiency, the job assignments could be issued arbitrarily. However, as we know, this is seldom the case. Thus, each of the n workers is evaluated according to the time he or she takes to perform each job. The time, given in hours, is expressed as a number greater

than or equal to zero. Obviously, the goal is to assign workers to jobs in such a way that the total time is as small as possible. In order to set up the notation, we let c_{ij} be the time it takes for worker $\# i$ to perform job $\# j$. Then the times naturally could be written in a table. For example, take $n = 3$ and let the times be given as in the following table:

	a	b	c
A	10	70	40
B	20	60	10
C	10	20	90

We can examine all six assignments and find that the minimum value of the total time is 40. So, we conclude that the production manager would be wise to assign worker **A** to job **a**, worker **B** to job **c**, and worker **C** to job **b**.

In general, this method of selection is not good. The total number of possible ways of assigning jobs is $n! = n \times (n-1) \times (n-2) \times \cdots \times 2 \times 1$. This is an enormous number even for moderate n. For $n = 70$,

$$n! = 1197857166996989179607278372168909873645893814 25$$
$$464258575553628646280095827898453196800000000000000000.$$

It has been estimated that if a Sun Workstation computer had started solving this problem at the time of the Big Bang, by looking at all possible job assignments, then by now it would not yet have finished its task.

Although it is not obvious, the job assignment problem (with any number n of workers and jobs) can be solved by linear programming. Namely, we set

$$x_{ij} = 0 \quad \text{or} \quad 1 \tag{i}$$

depending on whether the worker i is assigned to do the job j. The total time is then

$$\sum_i \sum_j c_{ij} x_{ij} (\text{to be minimized}). \tag{ii}$$

The condition that every worker i is assigned to exactly one job is

$$\sum_j x_{ij} = 1 \quad \text{for all} \quad i. \tag{iii}$$

The condition that exactly one worker is assigned to every job j is

$$\sum_i x_{ij} = 1 \quad \text{for all} \quad j. \tag{iv}$$

The constraints (i) are not linear. If we replace them by linear constraints $x_{i,j} \geq 0$, then we obtain a linear program with n^2 variables and $n^2 + 2n$ linear constraints. Mathematically, it is a transportation problem with every demand and supply equal to 1. As such, it can be solved by the simplex method (see below). (When $n = 70$ it takes seconds.)

The simplex method for the transportation problem does not involve any divisions. Therefore, for any optimal solution it gives, we have integral values for all components $x_{i,j}$ (we used that every supply and every demand is an integer). Thus, the conditions (i) hold, and the simplex method solves the job assignment problem. (Another way to express this is that all vertices of the feasible region (iii) to (iv) satisfy (i).)

68.3 Standard and Canonical Forms for Linear Programs

Definitions:

LP in **canonical form** [Vas03] is $\mathbf{c}^T\mathbf{x}+d \to \min, \mathbf{x} \geq 0, A\mathbf{x} \leq \mathbf{b}$, where $\mathbf{x}$ is a column of distinct (decision) variables, $\mathbf{c}^T$ is a given row, d is a given number, A is a given matrix, and $\mathbf{b}$ is a given column.

LP in **standard form** [Vas03] is $\mathbf{c}^T\mathbf{x}+d \to \min, \mathbf{x} \geq 0, A\mathbf{x} = \mathbf{b}$, where $\mathbf{x}, \mathbf{c}, d, A$, and $\mathbf{b}$ are as in the previous paragraph.

The **slack variable** for a constraint $f \leq c$ is $s = c - f \geq 0$. The **surplus variable** for a constraint $f \geq c$ is $s = f - c \geq 0$.

Facts:

For background reading on the material in this section, see [Vas03].

1. Every LP can be written in normal as well as standard and canonical forms using the following five little tricks (*normal* is a term used by some texts):
   (a) Maximization and minimization problems can be converted to each other. Namely, the problems $f(\mathbf{x}) \to \min, \mathbf{x} \in S$ and $-f(\mathbf{x}) \to \max, \mathbf{x} \in S$ are equivalent in the sense that they have the same optimal solutions and max = −min.
   (b) The equation $f = g$ is equivalent to the system of two inequalities, $f \geq g, g \leq f$.
   (c) The inequality $f \leq g$ is equivalent to the inequality $-f \geq -g$.
   (d) The inequality $f \leq g$ is equivalent to $f + x = g, x \geq 0$, where $x = g - f$ is a new variable called a *slack variable.*
   (e) A variable x unconstrained in sign can be replaced in our program by two new nonnegative variables, $x = x' - x''$, where $x', x'' \geq 0$.
2. The same tricks are sufficient for rewriting any linear program in different standard, canonical, and normal forms used in different textbooks and software packages. In most cases, all decision variables in these forms are assumed to be nonnegative.

Examples:

1. The canonical form $\mathbf{c}^T\mathbf{x}+d \to \min, \mathbf{x} \geq 0, A\mathbf{x} \leq \mathbf{b}$ can be rewritten in the following standard form:

$$\mathbf{c}^T\mathbf{x} + d \to \min,\ \mathbf{x}\ \geq 0,\ \mathbf{y} \geq 0,\ A\mathbf{x} + \mathbf{y} = \mathbf{b}.$$

2. The standard form $\mathbf{c}^T\mathbf{x}+d \to \min, \mathbf{x} \geq 0, A\mathbf{x} = \mathbf{b}$ can be rewritten in the following canonical form:

$$\mathbf{c}^T\mathbf{x} + d \to \min,\ \mathbf{x}\ \geq 0,\ A\mathbf{x} \leq \mathbf{b},\ -A\mathbf{x} \leq -\mathbf{b}.$$

3. The diet problem (Example 68.2.2) can be put in canonical form by replacing (ii) with

$$\begin{cases} -0.3a & - & 1.2b & - & 0.7c & - & 3.5d & - & 5.5e & \geq & -50 \\ -73a & - & 96b & - & 20253c & - & 890d & - & 279e & \geq & -4000 \\ -9.6a & + & 7b & - & 19c & - & 57d & - & 22e & \geq & -1000. \end{cases} \qquad (ii)$$

4. The blending problem (Example 68.2.3) is in standard form.

68.4 Standard Row Tableaux

Definitions:

A **standard row tableau** (of [Vas03]) is

$$\begin{array}{cc|l} \mathbf{x}^T & 1 & \\ \end{array}$$
$$\begin{bmatrix} A & \mathbf{b} \\ \mathbf{c}^T & d \end{bmatrix} \begin{array}{l} = \mathbf{u} \\ \to \min, \ \mathbf{x} \geq 0, \ \mathbf{u} \geq 0 \end{array} \tag{SRT}$$

with given matrix A, columns $\mathbf{b}$ and $\mathbf{c}$, and number d, where all decision variables in $\mathbf{x}, \mathbf{u}$ are distinct.

This tableau means the following linear program:

$$A\mathbf{x} + \mathbf{b} = \mathbf{u} \geq 0, \ \mathbf{x} \geq 0, \ \mathbf{c}^T\mathbf{x} + d \to \min.$$

The **basic solution** for the standard tableau (SRT) is $\mathbf{x} = 0, \mathbf{u} = \mathbf{b}$. The corresponding value for the objective function is d.

A standard tableau (SRT) is **row feasible** if $\mathbf{b} \geq 0$, i.e., the basic solution is feasible. Graphically, a feasible tableau looks like

$$\begin{array}{cc} \oplus & 1 \end{array}$$
$$\begin{bmatrix} * & \oplus \\ * & * \end{bmatrix} \begin{array}{l} = \oplus \\ \to \min, \end{array}$$

where $\oplus$ stands for nonnegative entries or variables.

A standard tableau (SRT) is **optimal** if $\mathbf{b} \geq \mathbf{0}$ and $\mathbf{c} \geq \mathbf{0}$. Graphically, an optimal tableau looks like

$$\begin{array}{cc} \oplus & 1 \end{array}$$
$$\begin{bmatrix} * & \oplus \\ \oplus & * \end{bmatrix} \begin{array}{l} = \oplus \\ \to \min. \end{array}$$

A **bad row** in a standard tableau is a row of the form $[\ominus -] = \oplus$, where $\ominus$ stands for nonpositive entries, $-$ stands for a negative number, and $\oplus$ stands for a nonnegative variable.

A **bad column** in a standard tableau is a column of the form $\begin{array}{c} \oplus \\ \begin{bmatrix} \oplus \\ - \end{bmatrix} \end{array}$, where $\oplus$ stands for a nonnegative variable and nonnegative numbers and $-$ stands for a negative number.

Facts:

For background reading on the material in this section, see [Vas03].

1. Standard row tableaux are used in simplex method; see Section 68.6.
2. The canonical form above can be written in a standard tableau as follows:

$$\begin{array}{cc} \mathbf{x}^T & 1 \end{array}$$
$$\begin{bmatrix} -A & \mathbf{b} \\ \mathbf{c}^T & d \end{bmatrix} \begin{array}{l} = \mathbf{u} \\ \to \min, \ \mathbf{x} \geq 0, \ \mathbf{u} \geq 0 \end{array}$$

   where $\mathbf{u} = \mathbf{b} - A\mathbf{x} \geq 0$.
3. The standard form above can be transformed into canonical form $\mathbf{c}^T\mathbf{x}+d \to \min, \mathbf{x} \geq 0, -A\mathbf{x} \leq -\mathbf{b}, A\mathbf{x} \leq \mathbf{b}$, which gives the following standard tableau:

$$\begin{array}{cc} \mathbf{x}^T & 1 \end{array}$$
$$\begin{bmatrix} -A & \mathbf{b} \\ A & -\mathbf{b} \\ \mathbf{c}^T & d \end{bmatrix} \begin{array}{l} = \mathbf{u} \\ = \mathbf{v} \\ \to \min, \ \mathbf{x} \geq 0; \ \mathbf{u}, \mathbf{v} \geq 0. \end{array}$$

To get a smaller standard tableau, we can solve the system of linear equations $A\mathbf{x} = \mathbf{b}$. If there are no solutions, the linear program is infeasible. Otherwise, we can write the answer in the form $\mathbf{y} = B\mathbf{z} + \mathbf{b}'$, where the column $\mathbf{y}$ contains some variables in $\mathbf{x}$ and the column $\mathbf{z}$ consists of the rest of the variables. This gives the standard tableau

$$\begin{array}{cc} \mathbf{z}^T & 1 \\ \left[\begin{array}{c} B \\ \mathbf{c}'^T \end{array}\right. & \left.\begin{array}{c} \mathbf{b}' \\ d' \end{array}\right] \end{array} \begin{array}{l} \\ = \mathbf{y} \\ \to \min, \ \mathbf{y} \ge 0, \, \mathbf{z} \ge 0, \end{array}$$

where ${\mathbf{c}'}^T\mathbf{z} + d'$ is the objective function $\mathbf{c}^T\mathbf{x} + \mathbf{b}$ expressed in the terms of $\mathbf{z}$.

4. The basic solution of an optimal tableau is optimal.
5. An optimal tableau allows us to describe all optimal solutions as follows. The variables on top with nonzero last entries in the corresponding columns must be zeros. Crossing out these columns and the last row, we obtain a system of linear constraints on the remaining variables describing the set of all optimal solutions. In particular, the basic solution is the only optimal solution if all entries in the $\mathbf{c}$-part are positive.
6. A bad row shows that the linear program is infeasible.
7. A bad column in a feasible tableau shows that the linear program is unbounded.

Examples:

1. The linear programs in Example 68.2.1 are written in an SRT and in an SCT in Example 68.8.1.
2. Consider the blending problem, Example 68.2.3. We solve the system of linear equations for a, b and the objective function f and, hence, obtain the standard tableau

$$\begin{array}{ccc} c & d & 1 \\ \end{array}$$
$$\begin{bmatrix} 1 & 2 & -0.5 \\ -2 & -3 & 1.5 \\ 0.1 & 0.1 & 1.5 \end{bmatrix} \begin{array}{l} = a \\ = b \\ = f \to \min . \end{array}$$

The tableau is not optimal and has no bad rows or columns. The associated LP can be solved graphically, working in the (c, d)-plane. In Example 68.6.1, we will solve this LP by the simplex method.

68.5 Pivoting

Definitions:

Given a system of linear equations $\mathbf{y} = A\mathbf{z} + \mathbf{b}$ solved for m variables, a **pivot step** solves it for a subset of m variables which differs from $\mathbf{y}$ in one variable.

Variables in $\mathbf{y}$ are called **basic variables.** The variables in $\mathbf{z}$ are called **nonbasic variables.**

Facts:

For background reading on the material in this section, see [Vas03].

1. Thus, a pivot step switches a basic and a nonbasic variable. In other words, one variable leaves the basis and another variable enters the basis.
2. Here is the pivot rule:

$$\begin{array}{cc} x & y \\ \end{array} \qquad\qquad \begin{array}{cc} u & y \\ \end{array}$$
$$\begin{bmatrix} \alpha^* & \beta \\ \gamma & \delta \end{bmatrix} \begin{array}{l} = u \\ = v \end{array} \mapsto \begin{bmatrix} 1/\alpha & -\beta/\alpha \\ \gamma/\alpha & \delta - \beta\gamma/\alpha \end{bmatrix} \begin{array}{l} = x \\ = v. \end{array}$$

We switch the two variables x and u. The pivot entry α marked by $*$ must be nonzero, β represents any entry in the pivot row that is not the pivot entry, γ represents any entry in the pivot column that is not the pivot entry, and δ represents any entry outside the pivot row and column.

3. A way to solve any of linear equations $A\mathbf{x} = \mathbf{b}$ is to write it in the row tableau

$$\begin{array}{c} \mathbf{x}^T \\ [A] = \mathbf{b} \end{array}$$

and move as many constants from the right margin to the top margin by pivot steps. After this, we drop the rows that read $c = c$ with a constant c. If one of the rows reads $c_1 = c_2$ with distinct constants c_1, c_2, the system is infeasible. The terminal tableau has no constants remaining at the right margin. If no rows are left, the answer is $0 = 0$ (every $\mathbf{x}$ is a solution). If no variables are left at the right margin, we obtain the unique solution $\mathbf{x} = \mathbf{b}'$. Otherwise, we obtain the answer in the form $\mathbf{y} = B\mathbf{z} + \mathbf{b}'$ with nonempy disjoint sets of variables $\mathbf{y}, \mathbf{z}$.

This method requires somewhat more computations than the Gauss elimination, but it solves the system with parametric $\mathbf{b}$.

Examples:

1. Here is a way to solve the system $\begin{cases} x + 2y = 3 \\ 4x + 7y = 5 \end{cases}$ by two pivot steps:

$$\begin{array}{cc} x & y \\ \end{array} \qquad \begin{array}{cc} 3 & y \end{array} \qquad \begin{array}{cc} 3 & 5 \end{array}$$

$$\begin{bmatrix} 1^* & 2 \\ 4 & 7 \end{bmatrix} \begin{matrix} = 3 \\ = 5 \end{matrix} \quad \mapsto \quad \begin{bmatrix} 1 & -2 \\ 4 & -1^* \end{bmatrix} \begin{matrix} = x \\ = 5 \end{matrix} \quad \mapsto \quad \begin{bmatrix} -7 & 2 \\ 4 & -1 \end{bmatrix} \begin{matrix} = x \\ = y \end{matrix},$$

i.e., $x = -11, y = 7$.

68.6 Simplex Method

The simplex method is the most common method for solving linear programs. It was suggested by Fourier for linear programs arising from linear approximation (see below). Important early contributions to linear programming were made by Walras and Kantorovich. The fortuitous synchronization of the advent of the computer and Dantzig's reinvention of the simplex method in 1947 contributed to the explosive development of linear programming with applications to economics, business, industrial engineering, actuarial sciences, operations research, and game theory. For their work in linear programming, Samuelson (b. 1915) was awarded the Nobel Prize in Economics in 1970, and Kantorovich (1912–1986) and Koopmans (1910–1985) received the Nobel Prize in Economics in 1975.

Now we give the simplex method in terms of standard tableaux. The method consists of finitely many pivot steps, separated in two phases (stages). In Phase 1, we obtain either a feasible tableau or a bad row. In Phase 2, we work with feasible tableaux. We obtain either a bad column or an optimal tableau. Following is the scheme of the simplex method, where LP stands for the linear program:

$$\left[\begin{tikzcd}[column sep=small]
& & (\textit{bad row}),\ \text{LP is infeasible} & & \\
\begin{pmatrix}\textit{initial}\\ \textit{tableau}\end{pmatrix} \arrow[urr, "\text{Phase 1}"] \arrow[drr, "\text{pivot steps}"'] & & & & (\textit{bad column}),\ \text{LP is unbounded} \\
& & \begin{pmatrix}\textit{feasible}\\ \textit{tableau}\end{pmatrix} \arrow[urr, "\text{Phase 2}"] \arrow[drr, "\text{pivot steps}"'] & & \\
& & & & \begin{pmatrix}\textit{optimal}\\ \textit{tableau}\end{pmatrix}.
\end{tikzcd}\right]$$

Both phases are similar and can be reduced to each other. We start Definitions with Phase 2 and Phase 1 in detail, dividing a programming loop (including a pivot step) for each phase into four substeps.

Definitions:

Phase 2 of simplex method. We start with a feasible tableau (SRT).

1. Is the tableau optimal? If yes, we write the answer: min $= d$ at $\mathbf{x} = 0, \mathbf{u} = \mathbf{b}$.
2. Are there any bad columns? If yes, the linear program is unbounded.
3. (Choosing a pivot entry) We choose a negative entry in the **c**-part, say, c_j in column j. Then we consider all negative entries $a_{i,j}$ above to choose our pivot entry. For every $a_{i,j} < 0$ we compute $b_i/a_{i,j}$ where b_i is the last entry in the row i. Then we maximize $b_i/a_{i,j}$ to obtain our pivot entry $a_{i,j}$.
4. Pivot and go to Substep 1.

Phase 1 of simplex method. We start with a standard tableau (SRT).

1. Is the tableau feasible? If yes, go to Phase 2.
2. Are there bad rows? If yes, the LP is infeasible.
3. (Choosing a pivot entry) Let the first negative number in the **b**-part be in the row i. Consider the subtableau consisting of the first i rows with the ith row multiplied by -1, and choose the pivot entry as in Substep 3 of Phase 2.
4. Pivot and go to Substep 1.

A pivot step (in Phase 1 or 2) is **degenerate** if the last entry in the pivot row is 0, i.e., the (basic) feasible solution stays the same.

A **cycle** in the simplex method (Phase 1 or 2) is a finite sequence of pivot steps which starts and ends with the same tableau.

Facts:

For background reading on the material in this section, see [Vas03].

1. In Phase 2, the current value of the objective function (the last entry in the last row) either improves (decreases) or stays the same (if and only if the pivot step is degenerate).
2. In Phase 1, the first negative entry in the last column increases or stays the same (if and only if the pivot step is degenerate).
3. Following this method, we either terminate in finitely many pivot steps or, after a while, all our steps are degenerate, i.e., the basic solution does not change and we have a cycle.

4. The basic solutions in a cycle are all the same.
5. To prevent cycling, we can make a perturbation (small change in the **b**-part) such that none of the entries in this part of the tableau is ever 0 (see [Vas03] for details).
6. Another approach was suggested by Bland. We can make an ordered list of our variables, and then whenever there is a choice we choose the variable highest on the list (see [Vas03] for a reference and the proof that this rule prevents cycling). Bland's rule also turns the simplex method into a deterministic algorithm, i.e., it eliminates freedom of choices allowed by the simplex method. Given an initial tableau and an ordered list of variables, Bland's rule dictates a unique finite sequence of pivot steps resulting in a terminal tableau.
7. With Bland's rule, the simplex method (both phases) terminates in at most $\binom{m+n}{n}-1$ pivot steps where m is the number of basis variables and n is the number of nonbasic variables (so the tableau has $m+1$ rows and $n+1$ columns). The number $\binom{m+n}{n}$ here is an upper bound for the number of all standard tableaux that can be obtained from the initial tableau by pivot steps, up to permutation of the variables on the top (between themselves) and permutation of the variables at the right margin (between themselves).
8. If all data for an LP are rational numbers, then all entries of all standard tableaux are rational numbers. In particular, all basic solutions are rational. If the LP is feasible and bounded, then there is an optimal solution in rational numbers. However, like for a system of linear equations, the numerators and denominators could be so large that finding them could be impractical.

Examples:

1. Consider the blending problem, Example 68.2.3.
   We start with the standard tableau in Example 68.3.2. The simplex method allows two choices for the first pivot entry, namely, 1 or 2 in the first row. We pick 1 as the pivot entry:

$$\begin{array}{ccc} c & d & 1 \\ \end{array} \qquad\qquad \begin{array}{ccc} a & d & 1 \\ \end{array}$$

$$\begin{bmatrix} 1^* & 2 & -0.5 \\ -2 & -3 & 1.5 \\ 0.1 & 0.1 & 1.5 \end{bmatrix} \begin{matrix} = a \\ = b \\ = f \to \min \end{matrix} \quad \mapsto \quad \begin{bmatrix} 1 & -2 & 0.5 \\ -2 & 1 & 0.5 \\ 0.1 & -0.1 & 1.55 \end{bmatrix} \begin{matrix} = c \\ = b \\ = f \to \min . \end{matrix}$$

   Now the tableau is feasible, and we can proceed with Phase 2:

$$\begin{array}{ccc} a & d & 1 \\ \end{array} \qquad\qquad \begin{array}{ccc} a & c & 1 \\ \end{array}$$

$$\begin{bmatrix} 1 & -2^* & 0.5 \\ -2 & 1 & 0.5 \\ 0.1 & -0.1 & 1.55 \end{bmatrix} \begin{matrix} = c \\ = b \\ = f \to \min \end{matrix} \quad \mapsto \quad \begin{bmatrix} 0.5 & -0.5 & 0.25 \\ -1.5 & -0.5 & 0.75 \\ 0.15 & 0.05 & 1.525 \end{bmatrix} \begin{matrix} = d \\ = b \\ = f \to \min \end{matrix} .$$

   The tableau is optimal, so min = 1.525 at $a = 0, b = 0.75, c = 0$, and $d = 0.25$.

68.7 Geometric Interpretation of Phase 2

Definitions:

A subset S of $\mathbf{R}^N$ is **closed** if S contains the limit of any convergent sequence in S.

A **convex linear combination** or **mixture** of two points $\mathbf{x}, \mathbf{y}$, is $\alpha\mathbf{x}+(1-\alpha)\mathbf{y}$, where $0 \le \alpha \le 1$. A particular case of a mixture is the **halfsum** $\mathbf{x}/2 + \mathbf{y}/2$.

The **line segment** connecting distinct points **x, y** consists of all mixtures of **x, y**.

A set S is **convex** if it contains all mixtures of its points.

An **extreme point** in a convex set is a point that is not the halfsum of any two distinct points in the set, i.e., the set stays convex after removing the point.

In the case of a closed convex set with finitely many extreme points, the extreme points are called **vertices**.

Two extreme points in a convex set are **adjacent** if the set stays convex after deleting the line segment connecting the points.

Facts:

For background reading on the material in this section, see [Vas03].

1. The feasible region for any linear program is a closed convex set with finitely many extreme points (vertices).
2. Consider a linear program and the associated feasible tableaux. The vertices of the feasible region are the basic solutions of the feasible tableaux. Permutation of rows or columns does not change the basic solution.
3. A degenerate pivot step does not change the basic solution. Any nondegenerate pivot step takes us from a vertex to an adjacent vertex with a better value for the objective function.
4. The set of optimal solutions for any linear program is a closed convex set with finitely many extreme points.
5. The number of pivot steps in Phase 2 without cycles (say, with Bland's rule) is less than the number of vertices in the feasible region.
6. For (SRT) with $m+1$ rows and $n+1$ columns, the number of vertices in the feasible region is at most $\binom{m+n}{m}$. When $n=1$, this upper bound can be improved to 2. When $n=2$, this upper bound can be improved to $m+2$.
7. The total number of pivot steps in both phases (with Bland's rule) is less than $\binom{m+n}{m}$. The adjacency gives a graph structure on the set of vertices of the feasible region. The number of pivot steps in Phase 2 in the worst case is at least the diameter of the graph decreased by 1. It is unknown (in 2012) whether, for arbitrary m, n, an upper bound for the diameter exists that is a polynomial in $m+n$.

68.8 Duality

Definitions:

A **standard column tableau** has the form

$$\begin{array}{rc} \begin{matrix} -y \\ 1 \end{matrix} & \left[\begin{matrix} A & b \\ c^T & d \end{matrix}\right] \\ & \begin{matrix} \| & \downarrow \\ \mathbf{v}^T & \max. \end{matrix} \end{array} \quad y \geq 0,\ v \geq 0 \tag{SCT}$$

The **associated LP** is $-\mathbf{y}^T\mathbf{b} + d \to \max$, $-\mathbf{y}^T A + \mathbf{c}^T = \mathbf{v}^T \geq 0$, $\mathbf{y} \geq 0$.

The **basic solution** associated with (SCT) is $\mathbf{y} = 0$, $\mathbf{v} = \mathbf{c}$.

The tableau (SCT) is **column feasible** if $\mathbf{c} \geq 0$, i.e., the basic solution is feasible. (So, a tableau is optimal if and only if it is both row and column feasible.)

The linear program in (SCT) is **dual** to that in (SRT). We can write both as the row and the column problem with the same matrix:

$$\begin{array}{rccll} & \mathbf{x}^T & 1 & & \\ -\mathbf{y} & A & \mathbf{b} & = \mathbf{u} & \mathbf{x} \geq 0,\ \mathbf{u} \geq 0 \\ 1 & \mathbf{c}^T & d & = z \to \min & \mathbf{y} \geq 0,\ \mathbf{v} \geq 0 \\ & = \mathbf{v}^T & = w & \to \max & \end{array} \tag{ST}$$

Facts:

For background reading on the material in this section, see [Vas03].

1. The linear program in the standard row tableau (SRT) can be written in the following standard column tableau:
$$\begin{array}{r} -\mathbf{x} \\ 1 \\ \\ \\ \end{array}\begin{array}{c} \left[\begin{array}{cc} -A^T & \mathbf{c} \\ \mathbf{b}^T & -d \end{array}\right] \\ \begin{array}{cc} \| & \downarrow \\ \mathbf{u}^T & \max. \end{array} \end{array} \quad \mathbf{x} \geq \mathbf{0}, \mathbf{u} \geq \mathbf{0}$$
Then the dual problem becomes the row problem with the same matrix. This shows that the dual of the dual is the primal program.
2. The pivot rule for column and row tableaux is the same inside tableaux:
$$\begin{array}{r} -x \\ -u \\ \\ \\ \end{array}\begin{array}{c} \left[\begin{array}{cc} \alpha^* & \beta \\ \gamma & \delta \end{array}\right] \\ \begin{array}{cc} \| & \| \\ u & v \end{array} \end{array} \to \begin{array}{r} -u \\ -u \\ \\ \\ \end{array}\begin{array}{c} \left[\begin{array}{cc} 1/\alpha & -\beta/\alpha \\ \gamma/\alpha & \delta-\beta\gamma/\alpha \end{array}\right] \\ \begin{array}{cc} \| & \| \\ x & v \end{array} \end{array}.$$
3. If a linear program has an optimal solution, then the simplex method produces an optimal tableau. This tableau is also optimal for the dual program, hence both programs have the same optimal values (the duality theorem).
4. The duality theorem is a deep fact with several interpretations and applications. Geometrically, the duality theorem means that certain convex sets can be separated from points outside them by hyperplanes. We will see another interpretation of the duality theorem in the theory of matrix games (see below). For problems in economics, the dual problems and the duality theorem also have important economic interpretations (see examples below).
5. If a linear program is unbounded, then (after writing it in a standard row tableau) the simplex method produces a row feasible tableau with a bad column. The bad column shows that the dual problem is infeasible.
6. There is a standard tableau that has both a bad row and a bad column, hence there is an infeasible linear program such that the dual program is also infeasible.
7. Here is another way to express the duality theorem: Given a feasible solution for a linear program and a feasible solution for the dual problem, they are both optimal if and only if the feasible values are the same.
8. Given a feasible solution for a linear program and a feasible solution for the dual problem, they are both optimal if and only if for every pair of dual variables at least one value is 0, i.e., the *complementary slackness* condition $\mathbf{v}^T\mathbf{x} + \mathbf{y}^T\mathbf{u} = 0$ in terms of (ST) holds.
9. More precisely, given a feasible solution $(\mathbf{x}, \mathbf{u})$ for the row program in (ST) and a feasible solution $(\mathbf{y}, \mathbf{v})$ for the column program, the difference $(\mathbf{c}^T\mathbf{x}+d) - (-\mathbf{y}^T\mathbf{u}+d)$ between the corresponding feasible values is $\mathbf{v}^T\mathbf{x} + \mathbf{y}^T\mathbf{u}$.
10. All pairs $(\mathbf{x}, \mathbf{u}), (\mathbf{y}, \mathbf{v})$ of optimal solutions for the row and column programs in (ST) are described by the following system of linear constraints: $A\mathbf{x} + \mathbf{b} = \mathbf{u} \geq 0, \mathbf{x} \geq 0, -\mathbf{y}^T A + \mathbf{c} = \mathbf{v} \geq 0, \mathbf{y} \geq 0, \mathbf{v}^T\mathbf{x} + \mathbf{y}^T\mathbf{u} = 0$. This is a way to show that solving a linear program can be reduced to finding a feasible solution for a finite system of linear constraints.

Examples:

(Generalizations of Examples 68.2.1–4 above and their duals):

1. The linear programs $c_1x_1 + \cdots + c_nx_n \to \max$, all $x_i \geq 0$, $x_1 + \cdots + x_n = 1$, and $y \to \min$, $y \geq c_i$ for all i in Example 1 are dual to each other. To see this, we use the standard tricks: $y = y' - y''$ with $y', y'' \geq 0$; $x_1 + \cdots + x_n = 1$ is equivalent to $x_1 + \cdots + x_n \leq 1, -x_1 - \cdots - x_n \leq -1$.

We obtain the following standard tableau:

$$\begin{array}{cl} & \begin{array}{ccc} y' & y'' & 1 \end{array} \\ \begin{array}{c} -\mathbf{x} \\ 1 \end{array} & \left[\begin{array}{ccc} \mathbf{J} & -\mathbf{J} & -\mathbf{c} \\ 1 & -1 & 0 \end{array}\right] \begin{array}{l} = \oplus \\ = y \to \min \end{array} \\ & \begin{array}{ccc} = \oplus & = \oplus & \to \end{array} \quad \max, \end{array}$$

where $\mathbf{J}$ is the column of n ones, $\mathbf{c} = [c_1, \ldots, c_n]^T$, and $\mathbf{x} = [x_1, \ldots, x_n]^T$.

2. Consider the general diet problem (a generalization of Example 2):

$$A\mathbf{x} \geq \mathbf{b},\ \mathbf{x} \geq 0,\ C = \mathbf{c}^T\mathbf{x} \to \min,$$

where m variables in $\mathbf{x}$ represent different foods and n constraints in the system $A\mathbf{x} \geq \mathbf{b}$ represent ingredients. We want to satisfy given requirements $\mathbf{b}$ in ingredients using given foods at minimal cost C.

On the other hand, we consider a warehouse that sells the ingredients at prices $y_1, \ldots, y_n \geq 0$. Its objective is to maximize the profit $P = \mathbf{y}^T\mathbf{b}$ while matching the price for each food: $\mathbf{y}^T A \leq \mathbf{c}^T$.

We can write both problems in a standard tableau using slack variables $\mathbf{u} = A\mathbf{x} - \mathbf{b} \geq 0$ and $\mathbf{v}^T = \mathbf{c}^T - \mathbf{y}^t A \geq 0$:

$$\begin{array}{cl} & \begin{array}{cc} \mathbf{x}^T & 1 \end{array} \\ \begin{array}{c} -\mathbf{y} \\ 1 \end{array} & \left[\begin{array}{cc} A & -\mathbf{b} \\ \mathbf{c}^T & 0 \end{array}\right] \begin{array}{ll} = \mathbf{u} & \qquad \mathbf{x} \geq 0,\ \mathbf{u} \geq 0 \\ = C \to \min & \qquad \mathbf{y} \geq 0,\ \mathbf{v} \geq 0 \end{array} \\ & \begin{array}{cc} = \mathbf{v}^T & = P \end{array} \quad \to\ \max. \end{array}$$

So, these two problems are dual to each other. In particular, the simplex method solves both problems and if both problems are feasible, then $\min(C) = \max(P)$.

The optimal prices for the ingredients in the dual problem are also called *dual* or *shadow* prices. These prices tell us how the optimal value reacts to small changes in $\mathbf{b}$; see Section 68.9.

3. Consider the general mixing problem (a generalization of Example 3):

$$A\mathbf{x} = \mathbf{b}, \mathbf{x} \geq 0,\ C = \mathbf{c}^T\mathbf{x} \to \min,$$

where m variables in $\mathbf{x}$ represent different alloys and n constraints in $A\mathbf{x} = \mathbf{b}$ represent elements. We want to satisfy given requirements b in elements using given alloys at minimal cost C.

On the other hand, consider a dealer who buys and sells the elements at prices $y_1, \ldots, y_n$. A positive price means that the dealer sells, and negative price means that the dealer buys. Dealer's objective is to maximize the profit $P = \mathbf{y}^T\mathbf{b}$ while matching the price for each alloy: $\mathbf{y}^T A \leq c$.

To write the problems in standard tableaux, we use the standard tricks and artificial variables:

$$\mathbf{u}' = A\mathbf{x} - \mathbf{b} \geq 0,\ \mathbf{u}'' = -A\mathbf{x} + \mathbf{b} \geq 0;$$
$$\mathbf{v}^T = \mathbf{c}^T - \mathbf{y}^T A \geq 0;\ \mathbf{y} = \mathbf{y}' - \mathbf{y}'',\ \mathbf{y}' \geq 0,\ \mathbf{y}'' \geq 0.$$

Now we manage to write both problems in the same standard tableau:

$$\begin{array}{cl} & \begin{array}{cc} \mathbf{x}^T & 1 \end{array} \\ \begin{array}{c} -\mathbf{y}' \\ -\mathbf{y}'' \\ 1 \end{array} & \left[\begin{array}{cc} A & -\mathbf{b} \\ -A & \mathbf{b} \\ \mathbf{c}^T & 0 \end{array}\right] \begin{array}{l} = \mathbf{u}' \\ = \mathbf{u}'' \\ = C \to \min \end{array} \quad \begin{array}{l} \mathbf{x} \geq 0;\ \mathbf{u}', \mathbf{u}'' \geq 0 \\ \mathbf{y}', \mathbf{y}'' \geq 0;\ \mathbf{v} \geq 0 \end{array} \\ & \begin{array}{cc} = \mathbf{v}^T & = P \end{array} \ \to \max. \end{array}$$

4. Consider a generalization of the manufacturing problem in Example 4:

$$P = \mathbf{c}^T\mathbf{x} \to \max,\ A\mathbf{x} \le \mathbf{b},\ \mathbf{x} \ge 0,$$

where the variables in $\mathbf{x}$ are the amounts of products, P is the profit (or revenue) you want to maximize, constraints $A\mathbf{x} \le \mathbf{b}$ correspond to resources (e.g., labor of different types, clean water you use, pollutants you emit, scarce raw materials), and the given column $\mathbf{b}$ consists of amounts of resources you have. Then the dual problem

$$\mathbf{y}^T\mathbf{b} \to \min,\ \mathbf{y}^T A \ge \mathbf{c}^T,\ \mathbf{y} \ge 0$$

admits the following interpretation. Your competitor, Bob, offers to buy you out at the following terms: You go out of business and he buys all resources you have at price $\mathbf{y}^T \ge 0$, matching your profit for every product you may want to produce, and he wants to minimize his cost.

Again, Bob's optimal prices are your resource shadow prices by the duality theorem. The shadow price for a resource shows the increase in your profit per unit increase in the quantity b_0 of the resource available or decrease in the profit when the limit b_o decreases by one unit. While changing b_0, we do not change the limits for the other resources and any other data for our program. There are only finitely many values of b_0 for which the downward and upward shadow prices are different. One of these values could be the borderline between the values of b_0 for which the corresponding constraint is binding or nonbinding (in the sense that dropping of this constraint does not change the optimal value).

The shadow price of a resource cannot increase when supply b_0 of this resource increases (the law of diminishing returns, see the next section).

5. (General transportation problem and its dual). We have m warehouses and n retail stores. The warehouse $\#i$ has a_i widgets available and the store $\#j$ needs b_j widgets.

It is assumed that the following *balance condition* holds:

$$\sum_{i=1}^{m} a_i = \sum_{j=1}^{n} b_j.$$

If total supply is greater than total demand, the problem can be reduced to the one with the balance condition by introducing a fictitious store where the surplus can be moved at zero cost. If total supply is less than total demand, the program is infeasible.

The cost of shipping a widget from warehouse $\#i$ to store $\#j$ is denoted by c_{ij} and the number of widgets shipped from warehouse $\#i$ to store $\#j$ is denoted by x_{ij}. The linear program can be stated as follows:

$$\begin{cases} \text{minimize} & C(x_{11},\dots,x_{mn}) = \displaystyle\sum_{i=1}^{m}\sum_{j=1}^{n} c_{ij}\, x_{ij} \\ \text{subject to} & \displaystyle\sum_{i=1}^{n} x_{ij} \ge b_j, \quad j = 1,\dots,m \\ & \displaystyle\sum_{j=1}^{m} x_{ij} \le a_i, \quad i = 1,\dots,n \\ & x_{ij} \ge 0,\ i = 1,\dots,n,\ j = 1,\dots,m. \end{cases}$$

The dual program is

$$-\sum_{i=1}^{m} a_i u_i + \sum_{j=1}^{n} b_j v_j \to \max,\ w_{ij} = c_{ij} + u_i - v_j \ge 0 \quad \text{for all} \quad i, j; u \ge 0, v \ge 0.$$

So, what is a possible meaning of the dual problem? The control variables u_i, v_j of the dual problem are called *potentials* or "zones." While the potentials correspond to the constraints on each retail store and each warehouse (or to the corresponding slack variables), there are other variables w_{ij} in the dual problem that correspond to the decision variable x_{ij} of the primal problem.

Imagine that you want to be a mover and suggest a simplified system of tariffs. Instead of mn numbers $c_{i,j}$, we use $m+n$ "zones." Namely, you assign a "zone" $u_i \geq 0$ $i = 1, 2$ to each of the warehouses and a "zone" $v_j \geq 0$ $j = 1, 2$ to each of the retail stores. The price you charge is $v_j - u_i$ instead of $c_{i,j}$. To beat competition, you want $v_j - u_i \leq c_{i,j}$ for all i, j. Your profit is $-\sum a_i u_i + \sum b_j v_j$ and you want to maximize it.

The simplex method for any transportation problem can be implemented using m by n tables rather than $mn+1$ by $m+n+1$ tableaux. Since all pivot entries are ± 1, no division is used. In particular, if all a_i, b_j are integers, we obtain an optimal solution with integral $x_{i,j}$.

Phase 1 is especially simple. If $m, n \geq 2$, we choose any position and write down the maximal possible number (namely, the minimum of supply and demand). Then we cross out the row or column and adjust the demand or supply, respectively. If $m = 1 < n$, we cross out the column. If $n = 1 < m$, we cross out the row. If $m = n = 1$, then we cross out both the row and column. Thus, we find a feasible solution in $m+n-1$ steps, which correspond to pivot steps, and the $m+n-1$ selected positions correspond to the basic variables.

Every transportation problem with the balance condition has an optimal solution. (See [Vas03] for details.)

68.9 Sensitivity Analysis and Parametric Programming

Sensitivity analysis is concerned with how small changes in data affect the optimal value and optimal solutions, while large changes are studied in parametric programming.

Consider the linear program given by (SRT) with the last column being an affine function of a parameter t, i.e., we replace b, d by affine functions $b + b_1 t, d + d_1 t$ of a parameter t. Then the optimal value becomes a function $f(t)$ of t.

Facts:

For background reading on the material in this section, see [Vas03].

1. The function $f(t)$ is defined on a closed convex set S on the line, i.e., S is one of the following "intervals": empty set, a point, an interval $a \leq t \leq b$ with $a < b$, a ray $t \geq a$, a ray $t \leq a$, the whole line.
2. The function $f(t)$ is piece-wise linear, i.e., the interval S is a finite union of subintervals S_k with $f(t)$ being an affine function on each subinterval.
3. The function $f(t)$ is *convex* in the sense that the set of points in the plane below the plot is a convex set. In particular, the function $f(t)$ is continuous.
4. In parametric programming, there are methods for computing $f(t)$. The set S is covered by a finite set of tableaux optimal for various values of t. The number of these tableaux is at most $\binom{m+n}{m}$.
5. Suppose that the LP with $t = 0$ (i.e., the LP given by (SRT)) has an optimal tableau T_0. Let $\mathbf{x} = \mathbf{x}^{(0)}, \mathbf{u} = \mathbf{u}^{(0)}$ be the corresponding optimal solution (the basic solution), and let $\mathbf{y} = \mathbf{y}^{(0)}, \mathbf{v} = \mathbf{v}^{(0)}$ be the corresponding optimal solution for the dual problem (see (ST) for notation). Assume that the $\mathbf{b}$-part of T_0 has no zero entries. Then the function $f(t)$ is affine in an interval containing 0. Its slope, i.e., derivative $f'(0)$ at $t = 0$, is $f'(0) = d_1 + \mathbf{b_1}^T \mathbf{v}^{(0)}$. Thus, we can easily compute $f'(0)$ from T_0. In other words, the optimal tableau gives the partial derivatives of the optimal value with respect to the components of given $\mathbf{b}$ and d.

6. If we pivot the tableau with a parameter, the last column stays an affine function of the parameter and the rest of the tableau stays independent of parameter.
7. Similar facts are true if we introduce a parameter into the last row rather than into the last column.
8. If both the last row and the last column are affine functions of parameter t, then after pivot steps, the A-part stays independent of t, the **b**-part and **c**-part stay affine functions of t, but the d-part becomes a quadratic polynomial in t. So the optimal value is a piece-wise quadratic function of t.
9. If we want to maximize, say, profit (rather than minimize, say, cost), then the optimal value is concave (convex upward), i.e., the set of points below the graph is convex. The fact that the slope is nonincreasing is referred to as the *law of diminishing returns.*

68.10 Matrix Games

Matrix games are very closely related with linear programming.

Definitions:

A matrix game is given by a matrix A, the **payoff matrix,** of real numbers.

There are two players. The players could be humans, teams, computers, or animals. We call them *He* and *She*. He chooses a row, and she chooses a column. The corresponding entry in the matrix represents what she pays to him (the payoff of the row player). Games like chess, football, and blackjack can be thought of as (very large) matrix games. Every row represents a strategy, i.e., his decision what to do in every possible situation. Similarly, every column corresponds to a strategy for her. The rows are his **(pure) strategies** and columns are her (pure) strategies.

A **mixed strategy** is a mixture of pure strategies. In other words, a mixed strategy for him is a probability distribution on the rows and a mixed strategy for her is a probability distribution on the columns.

We write his mixed strategy as columns $\mathbf{p} = (p_i)$ with $\mathbf{p} \geq 0, \sum p_i = 1$. We write her mixed strategy as rows $\mathbf{q}^T = (q_j)$ with $\mathbf{q} \geq 0, \sum q_j = 1$.

The corresponding payoff is $\mathbf{p}^T A\mathbf{q}$, the mathematical expectation.

A pair of strategies (his strategy, her strategy) is an **equilibrium** or a **saddle point** if neither player can gain by changing his or her strategy. In other words, no player can do better by a unilateral change. (The last sentence can be used to define the term "equilibrium" in any game, while "saddle point" is used only for zero-sum two-player games; sometimes it is restricted to the pure joint strategies.)

In other words, at an equilibrium, the payoff $\mathbf{p}^T A\mathbf{q}$ reaches its maximum as a function of $\mathbf{p}$ and its minimum as a function of q.

His mixed strategy p is **optimal** if his worst case payoff $\min(\mathbf{p}^T A)$ is maximal. The maximum is the **value of the game** (for him). Her mixed strategy $\mathbf{q}^T$ is **optimal** if her worst case payoff $\min(-A\mathbf{q})$ is maximal. The maximum is the value of the game for her.

If the payoff matrix is skew-symmetric, the matrix game is called **symmetric.**

Facts:

For background reading on the material in this section, see [Vas03].

1. A pair (i, j) of pure strategies is a saddle point if and only if the entry $a_{i,j}$ of the payoff matrix $A = a_{i,j}$ is both largest in its column and the smallest in its row.
2. Every matrix game has an equilibrium.
3. A pair (his strategy, her strategy) is an equilibrium if and only if both strategies are optimal.

4. His payoff $\mathbf{p}^T A\mathbf{q}$ at any equilibrium $(\mathbf{p}, \mathbf{q})$ equals his value of the game and equals the negative of her value of the game (the *minimax theorem).*
5. To solve a matrix game means to find an equilibrium and the value of the game.
6. Solving a matrix game can be reduced to solving the following dual pair of linear programs written in a standard tableau:

$$\begin{array}{r|cccc|l}
 & \mathbf{q}^T & \mu' & \mu'' & 1 & \\
\hline
-\mathbf{P} & -A & 1_m & -1_m & 0 & = * \geq 0 \\
-\lambda' & 1_n^T & 0 & 0 & -1 & = * \geq 0 \\
-\lambda'' & -1_n^T & 0 & 0 & 1 & = * \geq 0 \\
1 & 0 & 1 & -1 & 0 & = \mu \to \min \\
\hline
 & \| & \| & \| & \| & \\
 & * & * & * & \lambda \to & \max.
\end{array}$$

Here, A is the m by n payoff matrix, $\mathbf{1}_n^T$ is the row of n ones, $\mathbf{1}_m$ is the column of m ones, $\mathbf{p}$ is his mixed strategy, $\mathbf{q}^T$ is her mixed strategy. Note that her problem is the row problem and his problem is the column problem. Their problems are dual to each other. Since both problems have feasible solutions (take, for example, $\mathbf{p} = \mathbf{1}_m/m, \mathbf{q} = \mathbf{1}_n/n$), the duality theorem says that $\min(f) = \max(g)$. That is,

$$\text{his value of the game} = \max(\lambda) = \min(\mu) = -\text{her value of the game.}$$

Thus, the minimax theorem follows from the duality theorem.

7. We can save two rows and two columns and get a row feasible tableau as follows:

$$\begin{array}{r|cc|l}
 & \mathbf{q}/(\mu + c) & 1 & \\
\hline
-\mathbf{p}/(\lambda + c) & -A - c\mathbf{1}_m\mathbf{1}_n^T & \mathbf{1}_m & = * \geq 0 \\
1 & -\mathbf{1}_n^T & 0 & = -1/(\mu + c) \to \min \\
\hline
 & \| & \| & \\
 & * & -1/(\lambda + c) & \to \max.
\end{array}$$

Here we made sure that the value of the game is positive by adding a number c to all entries of A, i.e., replacing A by $A + c\mathbf{1}_m\mathbf{1}_n^T$. For example, $c = 1 - \min(A)$. Again his and her problems are dual to each other, since they share the same standard tableau. Since the tableau is feasible, we bypass Phase 1.

8. An arbitrary dual pair (ST) of linear programs can be reduced to a symmetric matrix game, with the following payoff matrix:

$$M = \begin{bmatrix} 0 & -A & -\mathbf{b} \\ A^T & 0 & -\mathbf{c} \\ \mathbf{b}^T & \mathbf{c}^T & 0 \end{bmatrix}.$$

Its size is $(m + n + 1) \times (m + n + 1)$, where $m \times n$ is the size of the matrix A.

9. The definition of equilibria makes sense for any game (not only for two-player zero-sum games). However, finding equilibria is not the same as solving the game when there are equilibria with different payoffs or when cooperation between players is possible and makes sense.
10. For any symmetric game, the value is 0, and the optimal strategies for the row and column players are the transposes of each other.

Examples:

1. [Vas03, Ex. 19.3] Solve the matrix game

$$A = \begin{bmatrix} 5 & 0 & 6 & 1 & -2 \\ 2 & 1 & 2 & 1 & 2 \\ -9 & 0 & 5 & 2 & -9 \\ -9 & -8 & 0 & 4 & 2 \end{bmatrix}.$$

   We mark the maximal entries in every column by *. Then we mark the minimal entries in each row by $'$. The positions marked by both * and $'$ are exactly the saddle points:

$$A = \begin{bmatrix} 5^* & 0 & 6^* & 1 & -2' \\ 2 & 1^{*\prime} & 2 & 1' & 2^* \\ -9' & 0 & 5 & 2 & -9' \\ -9' & -8 & 0 & 4^* & 2^* \end{bmatrix}.$$

   In this example, the position $(i, j) = (2, 2)$ is the only saddle point. The corresponding payoff (the value of the game) is 1.
2. This small matrix game is known as Heads and Tails or Matching Pennies. We will call the players *He* and *She*. He chooses: heads (H) or tails (T). Independently, she chooses: H or T. If they choose the same, he pays her a penny. Otherwise, she pays him a penny. Here is his payoff in cents:

$$\begin{array}{ccc} & & \textit{She} \\ & & \begin{array}{cc} H & T \end{array} \\ \textit{He} & \begin{array}{c} H \\ T \end{array} & \begin{bmatrix} -1 & 1 \\ 1 & -1 \end{bmatrix}. \end{array}$$

   There is no equilibrium in pure strategies. The only equilibrium in mixed strategies is $([1/2, 1/2]^T,\ [1/2, 1/2])$. The value of game is 0. The game is not symmetric in the usual sense. However, the game is symmetric in the following sense: if we switch the players and also switch H and T for a player, then we get the same game.
3. Another game is Rock, Paper, Scissors. In this game, two players simultaneously choose *Rock*, *Paper*, or *Scissors*, usually by a show of hand signals on the count of three, and the payoff function is defined by the rules *Rock breaks Scissors, Scissors cuts Paper, Paper covers Rock*, and every strategy ties against itself. Valuing a win at 1, a tie at 0, and a loss at -1, we can represent the game with the following matrix, where, for both players, strategy 1 is *Rock*, strategy 2 is *Scissors*, and strategy 3 is *Paper*:

$$A = \begin{bmatrix} 0 & 1 & -1 \\ -1 & 0 & 1 \\ 1 & -1 & 0 \end{bmatrix}.$$

   The only optimal strategy for the column player is $\mathbf{q}^T = [1/3, 1/3, 1/3]$. Since the game is symmetric, the value is 0, and $\mathbf{q}$ is the only optimal strategy for the row player.

68.11 Linear Approximation

Definitions:

An l^p**-best linear approximation** (fit) of a given column $\mathbf{w}$ with n entries by the columns of a given m by n matrix A is $A\mathbf{x}$, where $\mathbf{x}$ is an optimal solution for $\|\mathbf{w} - A\mathbf{x}\|_p \to \min$. (See Chapter 50 for information about $\|\cdot\|_p$.)

In other words, we want the vector $\mathbf{w} - A\mathbf{x}$ of **residuals** (offsets, errors) to be smallest in a certain sense.

Facts:

For background reading on the material in this section, see [Vas03].

1. Most common values for p are $2, 1, \infty$. In statistics, usually $p = 2$ and the first column of the matrix A is the column of ones. In simple regression analysis, $n = 2$. In multiple regression, $n \geq 3$. In time series analysis, the second column of A is an arithmetic progression representing time; typically, this column is $[1, 2, ..., m]^T$. (See Chapter 70 for more information.)
2. If $n = 1$ and the matrix A is a column of ones, we want to approximate given numbers w_i by one number Y. When $p = 2$, the best fit is the arithmetic mean $(\sum w_i)/m$. When $p = 1$, the best fits are the medians. When $p = \infty$, the best fit is the midrange $(\min(w_i) + \max(w_i))/2$.
3. When $p = 2$, the l^2-norm is the usual Euclidean norm, the most common way to measure the size of a vector, and this norm is used in Euclidean geometry. The best fit is known as the least squares fit. To find it, we drop a perpendicular from w onto the column space of A. In other words, we want the vector $\mathbf{w} - A\mathbf{x}$ to be orthogonal to all columns of A; that is, $A^T(\mathbf{w} - A\mathbf{x}) = 0$. This gives a system of n linear equations $A^T A\mathbf{x} = A^T\mathbf{w}$ for n unknowns in the column $\mathbf{x}$. The system always has a solution. Moreover, the best fit $A\mathbf{x}$ is the same for all solutions $\mathbf{x}$. In the case when w belongs to the column space, the best fit is w (this is true for all p). Otherwise, $\mathbf{x}$ is unique. (See Section 5.8 or Chapter 52 for more information about least squares methods.)
4. The best l^∞-fit is also known as the least-absolute-deviation fit and the Chebyshev approximation.
5. When $p = 1$, finding the best fit can be reduced to a linear program. Namely, we reduce the optimization problem with the objective function $\|\mathbf{e}\|_1 \to \min$, where $\mathbf{e} = (e_i) = \mathbf{w} - A\mathbf{x}$, to a linear program using m additional variables u_i such that $|e_i| \leq u_i$ for all i. We obtain the following linear program with $m + n$ variables a_j, u_i and $2m$ linear constraints:

$$\sum u_i \to min, \ -u_i \leq w_i - A_i\mathbf{x} \leq u_i \quad \text{for} \quad i = 1, \ldots, m,$$

   where A_i is the ith row of the given matrix A.
6. When $p = \infty$, finding the best fit can also be reduced to a linear program. Namely, reduce the optimization problem with the objective function $\|e\|_\infty \to \min$, where $\mathbf{e} = (e_i) = \mathbf{w} - A\mathbf{x}$, to a linear program using an additional variable u such that $e_i| \leq u$ for all i. A similar trick was used when we reduced solving matrix games to linear programming. We obtain the following linear program with $n+1$ variables a_j, u and $2m$ linear constraints:

$$t \to \min, \ -u \leq w_i - A_i\mathbf{x} \leq u \quad \text{for} \quad i = 1, \ldots, m,$$

   where A_i is the ith row of the given matrix A.
7. Any linear program can be reduced to finding a best l^∞-fit as well as to finding a best l^1-fit. Any linear program can be reduced to finding an optimal strategy for a symmetric game. All three reductions can be done in polynomial (even linear) time in the sense or real computational complexity [Vas10]. It is unknown whether linear programming has a polynomial complexity in this sense.

Examples:

1. [Vas03, Prob. 22.7] Find the best l^p-fit $w = ch^2$ for $p = 1, 2, \infty$ given the following data:

i	1	2	3
Height h in m	1.6	1.5	1.7
Weight w in kg	65	60	70

Compare the optimal values for c with those for the best fits of the form $w/h^2 = c$ with the same p (the number w/h^2 in kg/m^2 is known as BMI, body mass index). Compare the minimums with those for the best fits of the form $w = b$ with the same p.

Solution

Case $p = 1$. We could convert this problem to a linear program with four variables and then solve it by the simplex method (see Fact 6 above). But we can just solve graphically the nonlinear program with the objective function

$$f(c) = |65 - 1.6^2c| + |60 - 1.5^2c| + |70 - 1.7^2c|$$

to be minimized and no constraints. The function $f(c)$ is piece-wise affine and convex. The optimal solution is $c = x_1 = 65/1.6^2 \approx 25.39$. This c equals the median of the three observed BMIs $65/1.6^2, 60/1.5^2$, and $70/1.7^2$. The optimal value is

$$\min = |65 - c_1 1.6^2| + |60 - c_1 1.5^2| + |70 - c_1 1.7^2| = 6.25.$$

To compare this with the best l^1-fit for the model $w = b$, we compute the median $b = x_1 = 65$ and the corresponding optimal values:

$$\min = |65 - x_1| + |60 - x_1| + |70 - x_1| = 10.$$

So the model $w = ch^2$ is better than $w = b$ for our data with the l^1-approach.

Case $p = 2$. Our optimization problem can be reduced to solving a linear equation for c (see Fact 3 above). Also, we can solve the problem using calculus, taking advantage of the fact that our objective function

$$f(c) = (65 - 1.6^2c)^2 + (60 - 1.5^2c)^2 + (70 - 1.7^2c)^2$$

is differentiable. The optimal solution is $c = x_2 = 2518500/99841 \approx 25.225$. This x_2 is not the mean of the observed BMIs, which is about 25.426. The optimal value is $\min \approx 18$.

The mean of w_i is 65, and the corresponding minimal value is $5^2 + 0^2 + 5^2 = 50$. So, again the model $w = ch^2$ is better than $w = b$.

Case $p = \infty$. We could reduce this problem to a linear program with two variables and then solve it by graphical method or simplex method (see Fact 7 above). But we can do a graphical method with one variable. The objective function to minimize now is

$$f(c) = \max(|65 - 1.6^2c|, |60 - 1.5^2c|, |70 - 1.7^2c|).$$

This objective function $f(c)$ is piecewise affine and convex. The optimal solution is

$$c_\infty = 6500/257 \approx 25.29.$$

It differs from the midrange of the BMIs, which is about 25.44. The optimal value is ≈ 3.

On the other hand, the midrange of the weights w_i is 65, which gives $\min = 5$ for the model $w = b$ with the best l^∞-fit. So, again, the model $w = ch^2$ is better than $w = b$.

2. [Vas03, Ex. 2, p. 255] A student is interested in the number w of integer points $[x, y]$ in the disc $x^2 + y^2 \leq r^2$ of radius r. He computed w for some r:

r	1	2	3	4	5	6	7	8	9
w	5	13	29	45	81	113	149	197	253

The student wants to approximate w by a simple formula $w = ar + b$ with constants a, b. But you feel that the area of the disc, πr^2 would be a better approximation and, hence, the best l^2-fit of the form $w = ar^2$ should work even better for the numbers above.

Compute the best l^2-fit (the least squares fit) for both models, $w = ar + b$ and $w = ar^2$, and find which is better. Also, compare both optimal values with

$$\sum_{i=1}^{9} (w_i - \pi i^2)^2.$$

Solution

For our data, the equation $w = ar + b$ is the system of linear equations $A\mathbf{x} = \mathbf{w}$, where

$$\mathbf{w}{=}[5, 13, 29, 45, 81, 113, 149, 197, 253]^T,$$

$$A{=}\begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \\ 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}^T, \text{ and } \mathbf{x} = \begin{bmatrix} a \\ b \end{bmatrix}.$$

The least-squares solution is the solution to $A^T A\mathbf{x} = A^T w$, i.e.,

$$\begin{bmatrix} 285 & 45 \\ 45 & 9 \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix} = \begin{bmatrix} 6277 \\ 885 \end{bmatrix}.$$

So, $a = 463/15, b = -56$. The error

$$\sum_{i=1}^{9} (w_i - 463i/15 + 56)^2 = 48284/15 \approx 3218.93.$$

For $w = ar^2$, the system is $Ba = w$, where w is as above and

$$B = [1^2, 3^2, 3^2, 4^2, 5^2, 6^2, 7^2, 8^2, 9^2]^T.$$

The equation $B^T Ba = B^T w$ is $415398a = 47598$, hence $a = 23799/7699 \approx 3.09118$. The error

$$\sum_{i=1}^{9} (w_i - 23799i^2/7699)^2 = 2117089/7699 \approx 274.982.$$

So, the model $w = ar^2$ gives a much better least-squares fit than the model $w = ar + b$ although it has one parameter instead of two.

The model $w = \pi r^2$ without parameters gives the error

$$\sum_{i=1}^{9} (w_i - \pi i)^2 = 147409 - 95196\pi + 15398\pi^2 \approx 314.114.$$

It is known that $w_i/h_i^2 \to \pi$ as $i \to \infty$. Moreover, $|w_i - \pi r_i^2|/r_i$ is bounded as $i \to \infty$. It follows that $a \to \pi$ for the the best L_p-fit $w = ar^2$ for any $p \geq 1$ as we use data for $r = 1, 2, \ldots n$ with $n \to \infty$.

68.12 Interior Point Methods

Definitions:

A point $\mathbf{x}$ in a convex subset $X \subset \mathbf{R}^n$ is **interior** if

$$\{\mathbf{x} + (\mathbf{x} - \mathbf{y})\delta/\|\mathbf{y} - \mathbf{x}\|_2 : \mathbf{y} \in X,\, \mathbf{y} \neq \mathbf{x}\} \subset X$$

for some $\delta > 0$.

The **boundary** of X is the points in X, which are not interior.

An **interior solution** for a linear program is an interior point of the feasible region.

An **interior point method** for solving bounded linear programs starts with given interior solutions and produces a sequence of interior solutions which converges to an optimal solution.

An **exterior point method** for linear programs starts with a point outside the feasible region and produces a sequence of points which converges to feasible solution (in the case when the LP is feasible).

Facts:

For background reading on the material in this section, see [Vas03].

1. In linear programming, the problem of finding a feasible solution (i.e., Phase 1) and the problem of finding an optimal solution starting from a feasible solution (i.e., Phase 2) can be reduced to each other. So, the difference between interior point methods and exterior point methods is not so sharp.
2. The simplex method, Phase 1, can be considered as an exterior point method which (theoretically) converges in finitely many steps. The ellipsoid method [Ha79] is truly an exterior point method. Hačijan proved an exponential convergence for the method.
3. In the simplex method, Phase 2, we travel from a vertex to an adjacent vertex and reach an optimal vertex (if the LP is bounded) in finitely many steps. The vertices are not interior solutions unless the feasible region consists of single point. If an optimal solution for a linear program is interior, then all feasible solutions are optimal.
4. The first interior point method was given by Brown in the context of matrix games. The convergence was proved by Robinson. von Neumann suggested a similar method with better convergence.
5. Karmarkar suggested an interior point method with exponential convergence. After him, many similar methods were suggested. They can be interpreted as follows. We modify our objective function by adding a penalty for approaching the boundary. Then we use Newton's method. The recent progress is related to understanding of properties of convex functions which make minimization by Newton's method efficient. Recent interior methods beat simplex methods for very large problems.
6. [Vas03, Sect. A8] On the other hand, it is known that for LPs with small numbers of variables (or, by duality, with a small number of constraints), there are faster methods than the simplex method.

   For example, consider an (SRT) with only two variables on top and m variables at the right margin (basis variables). The feasible region S has at most $m + 2$ vertices. Phase 2, starting with any vertex, terminates in at most $m + 1$ pivot steps.

   At each pivot step, it takes at most two comparisons to check whether the tableau is optimal or to find a pivot column. Then in m sign checks, at most m divisions, and at most $m - 1$ comparisons we find a pivot entry or a bad column.

   Next, we pivot to compute the new $3m + 3$ entries of the tableau. In one division, we find the new entry in the pivot row that is not the last entry (the last entry was computed before) and in $2m$ multiplications and $2m$ additions, we find the new entries outside the pivot row and column. Finally, we find the new entries in the pivot column in $m + 1$ divisions. So a pivot step, including finding a pivot entry and pivoting, can be done in $8m + 3$ *operations*— arithmetic operations and comparisons.

Thus, Phase 2 can be done in $(m + 1)(8m + 3)$ operations. While small savings in this number are possible (e.g., at the $(m + 1)$-th pivot step we need to compute only the last column of the tableau), it is unlikely that any substantial reduction of this number for any modification of the simplex method can be achieved (in the worst case). Concerning the number of pivot steps, for any $m \geq 1$ it is clearly possible for S to be a bounded convex $(m + 2)$-gon, in which case for any vertex there is a linear objective function such that the simplex method requires exactly $\lfloor 1 + n/2 \rfloor$ pivot steps with only one choice of pivot entry at each step. It is also possible to construct an $(m + 2)$-gon, an objective point, and an initial vertex such that m pivot steps, with unique choice of pivot entry at each step, are required. There is an example with two choices at the first step such that the first choice leads to the optimal solution while the second choice leads to m additional pivot steps with unique choice.

Using a fast median search instead of the simplex method, it is possible to have Phase 2 done in $\leq 100m + 100$ operations.

69.1 Introduction

Semidefinite programming (SDP) refers to optimization problems where variables X in the objective function or constraints can be symmetric matrices restricted to the cone of positive semidefinite matrices. (We restrict ourselves to real symmetric matrices, $\mathcal{S}_n$, since the vast majority of applications are for the real case. The complex case requires using the complex inner-product space.) An example of a *simple linear SDP* is

$$\text{(SDP)} \qquad \begin{array}{rll} p^* = & \min & \operatorname{tr} CX \\ & \text{subject to} & TX = \mathbf{b} \\ & & X \succeq 0, \end{array}$$

where $T : \mathcal{S}_n \to \mathbb{R}^m$. The details are given in the definitions in Section 69.2; the SDP relaxation of the Max-Cut problem is given in Example 1 in this section. The linear SDP is a generalization of the standard *linear programming problem* (see Chapter 68), (LP) $\min \mathbf{c}^{\mathrm{T}}\mathbf{x}$, s.t. $A\mathbf{x} = b$, $\mathbf{x} \geq \mathbf{0}$, where $A \in \mathbb{R}^{m \times n}$, and the element-wise nonnegativity constraint $\mathbf{x} \geq \mathbf{0}$ is replaced by the positive semidefinite constraint, $X \succeq 0$. These cone constraints are the *hard constraints* for these linear problems, i.e., they introduce a combinatorial element into the problem. In the LP case, this refers to finding the *active constraints*, i.e., finding the *active set* at the optimum $\{j : x_j^* = 0\}$. For SDP, this translates to finding the set of zero eigenvalues of the optimum X^*. However, for SDP this is further complicated by the unknown eigenvectors.

But there are surprisingly many parallels between semidefinite and linear programming as well as interesting differences. The parallels include: elegant and strong duality theory, many important applications, and the successful interior-point approaches for handling the hard constraints. The differences include possible existence of duality gaps, as well as possible failure of strict complementarity. Since LP is such a well-known area, we emphasize the similarities and differences between LP and SDP as we progress through this chapter.

The study of SDP, or linear matrix inequalities (LMI), dates back to the work of Lyapunov on the stability of trajectories from differential equations in 1890, [Lya47]. More recently, applications in control theory appear in the work of [Yak62]. More details are given in [BEF94].

Cone programming, also called *generalized linear programming*, is a generalization of SDP [BF63]. Other books dealing with problems over cones that date back to the 1960s are [Lue69], [Hol75], and [Jah86]. More recently, SDP falls into the class of *symmetric or homogeneous cone programming* [Fay97], [SA01], which includes optimization over combinations of the nonnegative orthant, the cone of positive semidefinite matrices, and the Lorentz (or second-order) cone.

Positive definite and Euclidean matrix completion problems are feasibility questions in SDP. Research dates back to the early 1980s [DG81], [GJM84]. This continues to be an active area of research [Lau98], [Joh90]. (More recently, positive definite completion theory is being used to solve large scale instances of SDP [BMZ02], [FKM01].)

Combinatorial optimization applications fueled the popularity of SDP in the 1980s, [Lov79] and the strong approximation results in [GW95] and Example 1 in this section. A related survey paper is [Ren99]. SDP continues to attract new applications in, e.g., molecular conformation [AKW99], sensor localization [Jin05], [SY07], and optimization over polynomials [HL03].

The fact that SDP is a convex program that can be solved to any desired accuracy in polynomial time follows from the seminal work in [NN94].

Examples:

1. Suppose that we are given the weighted undirected graph $G = (V, E)$ with vertex set $V = \{1, \dots, n\}$ and nonnegative edge weights $w_{ij},\ ij \in E$ (with $w_{ij} = 0,\ ij \notin E$). The Max-Cut problem finds the partition of the vertices into two parts so as to maximize the sum of the weights on the edges that are cut (vertices in different parts). This problem arises in, e.g., physics and VLSI design. We can model this problem as a ±1 program with quadratic functions.

$$\text{(MC)}\qquad \begin{array}{rcc} \mu^* = & \max & \frac{1}{4}\sum_{ij=1}^{n} w_{ij}(1 - x_i x_j) = \frac{1}{4}\mathbf{x}^T L \mathbf{x} \\ & \text{subject to} & x_j^2 = 1, \quad j = 1, \dots, n, \end{array}$$

where L is the Laplacian matrix of the graph, $L_{ij} = \begin{cases} \sum\limits_{k \neq i} w_{ik} & \text{if } i = j; \\ -w_{ij} & \text{if } i \neq j. \end{cases}$ We consider the simple example with vertex set $V = \{1, 2, 3\}$ and nonnegative edge weights $w_{12} = 1, w_{13} = 2, w_{23} = 2$. Here, the Laplacian matrix $L = \begin{bmatrix} 3 & -1 & -2 \\ -1 & 3 & -2 \\ -2 & -2 & 4 \end{bmatrix}$. The optimal solution places vertices 1 and 2 in one part and vertex 3 in the other; thus, it cuts the edges 13 and 23. An optimal solution is $\mathbf{x}^* = \begin{bmatrix} 1 \\ 1 \\ -1 \end{bmatrix}$ with optimal value $\mu^* = 4$.

The well-known semidefinite relaxation for the Max-Cut problem is obtained using the commutativity of the trace $\mathbf{x}^T L \mathbf{x} = \mathrm{tr}\, \mathrm{L}\mathbf{x}\mathbf{x}^{\mathrm{T}} = \mathrm{tr}\, \mathrm{LX}$ and discarding the (hard) rank one constraint on X.

$$\text{(MCSDP)}\qquad \begin{array}{rcl} \mu^* \ \leq \ \nu^* = & \max & \frac{1}{4}\mathrm{tr}\, \mathrm{LX} \\ & \text{subject to} & \mathrm{diag}\,(\mathrm{X}) = \mathrm{e} \\ & & X \succeq 0, \end{array}$$

where the linear transformation $\mathrm{diag}\,(\mathrm{X}) : \mathcal{S}_{\mathrm{n}} \to \mathbb{R}^{\mathrm{n}}$ denotes the diagonal of X, and e is the vector of ones. The optimal solution to MCSDP is $X^* = \begin{bmatrix} 1 & 1 & -1 \\ 1 & 1 & -1 \\ -1 & -1 & 1 \end{bmatrix}$. (This is verified using duality; see Example 69.4.3.) In fact, here X^* is rank one, and column one of X^* provides the optimal solution $\mathbf{x}^*$ of MC and the optimal value $\mu^* = \nu^* = 4$.

For this simple example, X^* was rank one and the SDP relaxation obtained the exact solution of the NP-hard MC problem. This is not true in general. However, the MCSDP relaxation is a surprisingly strong relaxation for MC. A randomized approximation algorithm based on MCSDP provides a ±1 vector $\mathbf{x}$ with objective value at least .87856 times the optimal value μ^* [GW94]. Empirical tests obtain even stronger results.

69.2 Specific Notation and Preliminary Results

Note that in this section all matrices are real.

Definitions:

For general $m \times n$ matrices $M, N \in \mathbb{R}^{m \times n}$, we use the matrix inner product $\langle M, N \rangle = \mathrm{tr}\, N^T M$. The corresponding norm is $\|M\|_F = \sqrt{\mathrm{tr}\, M^T M}$, the **Frobenius norm**.

$\mathcal{S}_n$ denotes the space of **symmetric $n \times n$ matrices**.

The set of **positive semidefinite (respectively, definite) matrices** is denoted by PSD (respectively, PD); $X \succeq 0$ means $X \in$ PSD.

The **linear SDP** is

$$\text{(SDP)} \qquad \begin{array}{rcl} p^* = & \min & \mathrm{tr}\, CX \\ & \text{subject to} & TX = \mathbf{b} \\ & & X \succeq 0, \end{array}$$

where the variable $X \in \mathcal{S}_n$, the linear transformation $T : \mathcal{S}_n \to \mathbb{R}^m$, the vector $\mathbf{b} \in \mathbb{R}^m$, and the matrix $C \in \mathcal{S}_n$ are (given) problem parameters. The constraint $TX = \mathbf{b}$ can be written concretely as $\mathrm{tr}\, A_k X = b_k$, for some given $A_k \in \mathcal{S}_n$, $k = 1, \ldots, m$. Thus, SDP can be expressed explicitly as

$$\text{(SDP)} \qquad \begin{array}{rcl} p^* = & \min & \sum_{ij} C_{ij} X_{ij} \\ & \text{subject to} & \sum_{ij} A_{ijk} X_{ij} = b_k, \quad k = 1, \ldots, m \\ & & X \succeq 0, \end{array}$$

where A_{ijk} denotes the ij element of the symmetric matrix A_k.

For $M \in \mathbb{R}^{m \times n}$, $\mathrm{vec}\,(M) \in \mathbb{R}^{mn}$ is the vector formed from the columns of M.

For $S \in \mathcal{S}_n$, $\mathrm{svec}\,(S) \in \mathbb{R}^{\frac{n(n+1)}{2}}$ is the vector formed from the upper triangular part of S, taken column-wise, with the strict upper triangular part multiplied by $\sqrt{2}$. The inverse of svec is denoted sMat.

For $U \in \mathcal{S}_n$, the **symmetric Kronecker product** is defined by

$$(M \overset{s}{\otimes} N)\mathrm{svec}\,(U) = \mathrm{svec}\left(\frac{1}{2}(NUM^T + MUN^T)\right).$$

For a linear transformation between two vector spaces $T : V \to W$, the **adjoint linear transformation** is denoted $T^* : W \to V$, i.e., it is the unique linear transformation that satisfies the adjoint equation for the inner products in the respective vector spaces

$$\langle T\mathbf{v}, \mathbf{w} \rangle_W = \langle \mathbf{v}, T^*\mathbf{w} \rangle_V, \quad \forall\ \mathbf{v} \in V,\ \mathbf{w} \in W.$$

(this is the definition given in Section 5.3).

We follow the standard notation used in SDP: for $\mathbf{y} \in \mathbb{R}^n$, Diag $(\mathbf{y})$ denotes the diagonal matrix formed using the vector $\mathbf{y}$, while the adjoint linear transformation is $\mathrm{diag}\,(\mathrm{X}) = \mathrm{Diag}^*(\mathrm{X}) \in \mathbb{R}^{\mathrm{n}}$.

For an inner product space V, the **polar cone** of $S \subseteq V$ is

$$S^+ = \{\phi : \langle \phi, \mathbf{s} \rangle \geq 0,\ \forall \mathbf{s} \in S\}.$$

Given a set $K \subseteq \mathbb{R}^n$, we let cone (K) denote the convex cone generated by K. (See Section 10.1 for more information on cones.) A set K is a convex cone if it is closed under nonnegative scalar multiplication and addition, i.e.,

$$\alpha K \subseteq K,\ \forall \alpha \geq 0, \quad K + K \subseteq K.$$

For a convex cone K, the convex cone $\mathcal{F} \subseteq K$ is a **face** of K (denoted $\mathcal{F} \lhd K$) if

$$\mathbf{x}, \mathbf{y} \in K, \mathbf{z} = \alpha \mathbf{x} + (1-\alpha)\mathbf{y} \in \mathcal{F}, 0 < \alpha < 1 \quad \text{implies} \quad \mathbf{x}, \mathbf{y} \in \mathcal{F}.$$

Facts:

1. In the space of real, symmetric matrices, $\mathcal{S}_n$, the matrix inner product reduces to $\langle X, Y \rangle = \mathrm{tr}\,\mathrm{XY}$.
2. For general compatible matrices M, N, the trace is commutative, i.e., $\mathrm{tr}\,\mathrm{MN}^{\mathrm{T}} = \mathrm{tr}\,\mathrm{N}^{\mathrm{T}}\mathrm{M} = \sum_{\mathrm{i}=1}^{\mathrm{n}} \sum_{\mathrm{j}=1}^{\mathrm{n}} \mathrm{M}_{\mathrm{ij}}\mathrm{N}_{\mathrm{ij}}$.
3. svec (and sMat) is an isometry between $\mathcal{S}_n$ (equipped with the Frobenius norm) and $\mathbb{R}^{\frac{n(n+1)}{2}}$ (equipped with the Euclidean norm). The svec transformation is used in algorithms when solving symmetric matrix equations. Using the isometry (rather than the ordinary vec) provides additional robustness.
4. PSD is a closed convex cone and the interior of PSD consists of the positive definite matrices. The following are equivalent: (a) $A \succeq 0 \quad (A \succ 0)$, (b) the vector of eigenvalues $\lambda(A) \geq 0 \quad (\lambda(A) > 0)$, and (c) all principal minors ≥ 0 (all leading principal minors > 0).
5. The Kronecker product $K \otimes L$ is easily formed using the blocks $K_{ij}L$. It is useful in changing matrix equations into vector equations (see [HJ94]), (here K is the unknown matrix) $\mathrm{vec}\,(\mathrm{NKM}^{\mathrm{T}}) = (\mathrm{M} \otimes \mathrm{N})\mathrm{vec}\,(\mathrm{K})$. Similarly, the symmetric Kronecker product $M \overset{s}{\otimes} N$ changes matrix equations with symmetric matrix variables $U \in \mathcal{S}_n$ to vector equations. (See the definition in this section.) By extending the definition from $\mathcal{S}_n$ to $\mathbb{R}^{n \times n}$, the symmetric Kronecker product can be expressed explicitly using the standard Kronecker product (see [TW05]),

   $$8M \overset{s}{\otimes} N = (I + A)(N \otimes M^T + M \otimes N^T) + (N \otimes M^T + M \otimes N^T)(I + A),$$

   where A is the matrix representation of the transpose transformation. Matrix equations with symmetric matrix variables arise when finding the search direction in interior-point methods for SDP; see Section 69.6. Surprisingly (see [TW05]), for $A, B \in \mathcal{S}_n$,

   $$A \overset{s}{\otimes} B \succeq 0 \iff A \otimes B \succeq 0;$$

   $$A \overset{s}{\otimes} B \succ 0 \iff A \otimes B \succ 0.$$

6. If $A \in \mathbb{R}^{m \times n}$ and the linear transformation $T\mathbf{v} = A\mathbf{v}$, then $T^* \cong A^T$.
7. The polar cone is a closed convex cone and the second polar $(K^+)^+ = K$ if and only if K is a closed convex cone.

Examples:

1.

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 5 \\ 3 & 5 & 6 \end{bmatrix}, \mathbf{v} = \begin{bmatrix} 1 \\ 2\sqrt{2} \\ 4 \\ 3\sqrt{2} \\ 5\sqrt{2} \\ 6 \end{bmatrix}, \qquad \begin{array}{c} \operatorname{svec}(\mathrm{A}) = \mathbf{v} \\ \|A\|_F = \|\mathbf{v}\|_2 = \sqrt{129}. \end{array}$$

2. The polars: (a) $(\mathbb{R}^n)^+ = \{\mathbf{0}\}$; $\{\mathbf{0}\}^+ = \mathbb{R}^n$, (b) for the unit vector $\mathbf{e}_i \in \mathbb{R}^n$, $\{\mathbf{e_i}\}^+ = \{\mathbf{v} \in \mathbb{R}^n : v_i \geq 0\}$, (c) $(\text{cone}\,\{\begin{bmatrix}1 & 1\end{bmatrix}^{\mathrm{T}}, \begin{bmatrix}1 & 0\end{bmatrix}^{\mathrm{T}}\})^+ = \text{cone}\,\{[0 \quad 1]^{\mathrm{T}}, [1 \quad -1]^{\mathrm{T}}\}$; (d) let $\mathcal{I} = \{\mathbf{v} \in \mathbb{R}^3 : v_3^2 \leq v_1 v_2, v_1 \geq 0, v_2 \geq 0\}$ be the so-called ice-cream cone [Ber73], i.e., the cone of vectors that makes an angle at most 45 degrees with the vector $\begin{bmatrix}1 & 1 & 1\end{bmatrix}^T$. Then $\mathcal{I} = \mathcal{I}^+$.

69.3 Geometry

Extending LP to SDP can be thought of as replacing a polyhedral cone (the nonnegative orthant $(\mathbb{R}^+)^n$) by the nonpolyhedral cone PSD. We now see that many of the geometric properties follow through from $K = (\mathbb{R}^+)^n$ to $K = \text{PSD}$.

Definitions:

A cone K is called **self-polar** if it equals its polar $K = K^+$

A face $\mathcal{F} \lhd K$ is called **facially exposed** if $\mathcal{F} = K \cap \phi^\perp$, for some $\phi \in K^+$.

A face $\mathcal{F} \lhd K$ is called **projectionally exposed** if $\mathcal{F}$ is the image of K under an orthogonal projection, $\mathcal{F} = \mathcal{P}(\mathcal{K})$.

Facts:

1. Both $(\mathbb{R}^+)^n$ and PSD are closed convex cones with nonempty interior. And both are self-polar cones, i.e., $((\mathbb{R}^+)^n)^+ = (\mathbb{R}^+)^n$, $(\text{PSD})^+ = \text{PSD}$. (See [Ber73].)
2. Suppose that $\hat{X} \in \operatorname{relint} \mathcal{F} \subseteq \text{PSD}$ and $\operatorname{rank} \hat{\mathrm{X}} = \mathrm{r}$. Then $\hat{X} = PD_rP^T$, where P is the $n \times r$ matrix with orthonormal columns of eigenvectors corresponding to nonzero (positive) eigenvalues. We get that $\mathcal{F} \lhd \text{PSD}$ if and only if $\mathcal{F} = P\mathcal{S}_+^r P^T$. Equivalently, faces $\mathcal{F} \lhd \text{PSD}$ are characterized by $\{Y \in \text{PSD} : \mathcal{R}(Y) \subseteq \mathcal{R}(\hat{X})\}$, where $\hat{X}$ is any matrix in the relative interior of $\mathcal{F}$ and $\mathcal{R}$ denotes the range. Equivalently, we could use $\mathcal{N}(Y) \supset \mathcal{N}(\hat{X})$, where $\mathcal{N}$ denotes nullspace. (See [Boh48], [BC75].)
3. Both $(\mathbb{R}^+)^n$ and PSD are facially and projectionally exposed, i.e., all faces are both facially and projectionally exposed [BW81b], [BLP87], [ST90].
4. The following relates to closure conditions that are needed for strong duality results. Suppose that $\mathcal{F} \lhd \text{PSD}$. Then (see [RTW97]),

$$\text{PSD} + \mathcal{F}^\perp \text{ is closed}; \text{PSD} + \operatorname{Span} \mathcal{F} \text{ is not closed}.$$

Examples:

1. Consider the face $\mathcal{F} = \{X \in \text{PSD} : X\mathbf{e} = 0\}$, i.e., the face of PSD of centered matrices, positive semidefinite matrices with row and column sums equal to 0. Let $P = \begin{bmatrix}\mathbf{e} & V\end{bmatrix}$ be an orthogonal matrix, i.e., $V^Te = 0, V^TV = I$. Then we get $\mathcal{F} = V\{X \in \mathcal{S}_{n-1} : X \succeq 0\}V^T$,

i.e., a one-to-one mapping between the face $\mathcal{F}$ and the semidefinite cone in $\mathcal{S}_{\backslash-\infty}$. This relationship is used in [AKW99] to map Euclidean distance matrices to positive semidefinite matrices of full rank.

69.4 Duality and Optimality Conditions

Duality lies behind efficient algorithms in optimization. Unlike LP , strong duality can fail for SDP if a *constraint qualification* does not hold. We consider duality the linear *primal* SDP introduced above a game-theoretic approach.

Definitions:

The corresponding **Lagrangian function** (or payoff function from primal player X, who plays matrix X, to dual player Y, who plays vector y) is $L(X, \mathbf{y}) = \operatorname{tr} \mathrm{CX} + \mathbf{y}^{\mathrm{T}}(\mathbf{b} - \mathrm{TX})$.
The **dual problem** is

$$\begin{array}{llll} & d^* = & \text{maximize} & \mathbf{b}^T\mathbf{y} \\ \text{DSDP} & & \text{subject to} & T^*\mathbf{y} \preceq C \\ & & (\text{equivalently} & T^*\mathbf{y} + Z = C, \quad Z \succeq 0). \end{array}$$

Weak duality $p^* \geq d^*$ holds. If $p^* = d^*$ and d^* is attained, then **Strong duality** holds.
Complementary slackness holds if $\operatorname{tr} \mathrm{ZX} = 0$; **strict complementarity** holds if, in addition, $Z + X \succ 0$.

Facts:

1. The optimal strategy of player X over all possible strategies by the dual player Y has optimal value greater or equal to that of the optimal strategy for player Y over all strategies for player X, i.e.,

$$p^* = \min_{X \succeq 0} \max_{\mathbf{y}} L(X, \mathbf{y}) \geq d^* = \max_{\mathbf{y}} \min_{X \succeq 0} b^T\mathbf{y} + \operatorname{tr} \mathrm{X}(\mathrm{C} - \mathrm{T}^*\mathbf{y}).$$

   The first equality in the min–max problem can be seen from the *hidden constraint* for the inner maximization problem. The inequality follows from interchanging min and max. The hidden constraint in the inner minimization of the max–min problem yields our dual problem and weak duality. However, *strong duality* can fail. (See [RTW97].)
2. For $X, Z \succeq 0$, complementary slackness $\operatorname{tr} \mathrm{ZX} = 0$ is equivalent to $ZX = 0$.
3. *Characterization of Optimality Theorem*
   The primal-dual pair $X, (\mathbf{y}, Z)$, with $X \succeq 0, Z \succeq 0$, is primal-dual optimal for SDP and DSDP if and only if

$$\begin{array}{rrl} & T^*\mathbf{y} + Z - C = 0 & \text{(dual feasibility)} \\ (\text{OPT}) & TX - \mathbf{b} = 0 & \text{(primal feasibility)} \\ & ZX = 0 & \text{(complementary slackness).} \end{array}$$

4. The theorem in the previous fact is used to derive efficient primal-dual interior-point methods.
5. Again we note the similarity between the above optimality conditions and those for LP, where Z, X are diagonal matrices. However, in contrast to LP, the Goldman–Tucker theorem [GT56] can fail, i.e., a strict complementary solution may not exist. This means that there may be no optimal solution with $X + Z \succ 0$ positive definite;

see [Sha00], [WW10]. This can result in loss of superlinear convergence for numerical algorithms for SDP. Moreover, in LP, Z, X are diagonal matrices and so is ZX. This means that the optimality conditions OPT are a square system. However, for SDP, the product of two symmetric matrices ZX is not necessarily symmetric. Therefore, the optimality conditions are an overdetermined nonlinear system of equations. This gives rise to many subtle algorithmic difficulties.

Examples:

1. The lack of closure noted in Fact 69.3.4 is illustrated by the sequence
$$\begin{bmatrix}\frac{1}{i} & 1\\ 1 & i\end{bmatrix} + \begin{bmatrix}0 & 0\\ 0 & -i\end{bmatrix} \to \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix} \notin \mathrm{PSD} + \mathrm{Span}\left\{\begin{bmatrix}0 & 0\\ 0 & 1\end{bmatrix}\right\}.$$
This gives rise to an SDP with a duality gap. Let $C = \begin{bmatrix}0 & 1\\ 1 & 0\end{bmatrix}$ and $A_1 = \begin{bmatrix}0 & 0\\ 0 & 1\end{bmatrix}$. Then a primal SDP is $0 = \min \mathrm{tr\,CX}$ s.t. $\mathrm{tr\,A_1X} = 0, \mathrm{X} \succeq 0$. But the dual program has optimal value $-\infty = \max 0\mathbf{y}$ s.t. $\mathbf{y}A_1 \preceq C$, i.e., it is infeasible.
2. For fixed $\alpha > 0$, we use parameters $\mathbf{b} = \begin{bmatrix}0\\ 1\end{bmatrix}$ and $C = \begin{bmatrix}\alpha & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & 0\end{bmatrix}$, $A_1 = \begin{bmatrix}0 & 0 & 0\\ 0 & 1 & 0\\ 0 & 0 & 0\end{bmatrix}$, $A_2 = \begin{bmatrix}1 & 0 & 0\\ 0 & 0 & 1\\ 0 & 1 & 0\end{bmatrix}$. Then we get the primal and dual SDP pair with a finite duality gap: $\alpha = \min \alpha U_{11}$ s.t.$U_{22} = 0$, $U_{11} + 2U_{23} = 1$, $U \succeq 0; 0 = \max y_2$ s.t. $\begin{bmatrix}y_2 & 0 & 0\\ 0 & y_1 & y_2\\ 0 & y_2 & 0\end{bmatrix} \preceq \begin{bmatrix}\alpha & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & 0\end{bmatrix}$.
3. We now verify that $X^* = \begin{bmatrix}1 & 1 & -1\\ 1 & 1 & -1\\ -1 & -1 & 1\end{bmatrix}$ is optimal for MCSDP in Example 69.1.1. The dual of MCSDP is $\min e^T\mathbf{y}$ s.t. $\mathrm{Diag}\,(\mathbf{y}) \succeq \frac{1}{4}\mathrm{L}$. Since $\mathbf{y} = \begin{bmatrix}1 & 1 & 2\end{bmatrix}^T$ is feasible for this dual, optimality follows from checking strong duality $\mathrm{tr\,LX^*} = \mathrm{e^Ty} = 4$. Equivalently, one can check complementary slackness $(\mathrm{Diag}\,(\mathbf{y}) - \mathrm{L})\mathrm{X}^* = 0$.

69.5 Strong Duality without a Constraint Qualification

Definitions:

A **constraint qualification**, CQ, is a condition on the constraints that guarantees that strong duality holds at an optimum point.

Slater's Constraint Qualification (strict feasibility) is defined as: $\exists X \succ 0,\ TX = \mathbf{b}$.

Facts:

1. Suppose that Slater's CQ holds. Then strong duality holds for SDP and DSDP, i.e., $p^* = d^*$ and d^* is attained.
2. [BW81a] *Duality Theorem*: Suppose that p^* is finite. Let $\mathcal{F}_{\mathrm{e}}$ denote the minimal face of PSD that contains the feasible set of SDP. Consider the extended dual program
$$\begin{array}{lrll} & d^*_{\mathrm{e}} = & \text{maximize} & \mathbf{b}^T\mathbf{y} \\ \mathrm{DSDP}_{\mathrm{e}} & & \text{subject to} & T^*\mathbf{y} + Z = C \\ & & & Z \in \mathcal{F}_{\mathrm{e}}^+. \end{array}$$

Then $p^* = d^*_{\mathrm{e}}$ and d^*_{e} is attained, i.e., strong duality holds between SDP and DSDP$_{\mathrm{e}}$.

3. An algorithm for finding the minimal face $\mathcal{F}_{\mathrm{e}}$ defined above is given in [BW81b].

Examples:

We can apply the strong duality results to the two examples given in Section 69.4.

1. For the first example, replace PSD in the primal with the minimal face $\mathcal{F} = \mathrm{PSD} \cap \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}^{\perp} = \mathrm{cone}\{A_1\}$; so $\mathcal{F}^+ = \{A_1\}^+$ and the dual is now feasible.
2. For the second example, replace PSD in the primal with the minimal face $\mathcal{F} = \mathrm{PSD} \cap \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}^{\perp}$; so U_{23} is no longer restricted to be 0 in the dual.
3. The strong duality results are needed in many SDP applications to combinatorial problems where Slater's constraint qualification (strict feasibility) fails, e.g., [WZ99], [ZKR98].

69.6 A Primal-Dual Interior-Point Algorithm

As mentioned above, it was the development of efficient polynomial-time algorithms for SDP at the end of the 1980s that spurred the increased interest in the field. We look at the specific method derived in [HRV96]. (See also [KSH97], [Mon97].)

We assume that Slater's constraint qualification (strict feasibility) holds for both primal and dual problems.

Definitions:

For each $\mu > 0$, the log-barrier approach applied to DSDP requires the solution of the **log-barrier problem**

$$\mathrm{DSDP}_{\mu} \qquad \begin{array}{lll} d^*_{\mu} = & \text{maximize} & \mathbf{b}^T\mathbf{y} + \mu \log\det Z \\ & \text{subject to} & T^*\mathbf{y} + Z = C, \quad Z \succ 0. \end{array}$$

The **Lagrangian** is $L(X, \mathbf{y}, Z) = \mathbf{b}^T\mathbf{y} + \mu \log\det Z + \operatorname{tr} \mathrm{X}(\mathrm{C} - \mathrm{T}^*\mathbf{y} - \mathrm{Z})$, where we use X for the Lagrange multiplier vector.

Facts:

1. The derivative, with respect to $(X, \mathbf{y}, Z)$ of the Lagrangian, yields the optimality conditions for the barrier problem:

$$\mathrm{OPT}_{\mu} \qquad \begin{array}{rl} T^*\mathbf{y} + Z - C = 0 & \text{(dual feasibility)} \\ TX - b = 0 & \text{(primal feasibility)} \\ \mu Z^{-1} - X = 0 & \text{(perturbed complementary slackness).} \end{array}$$

   We let $X_{\mu}, \mathbf{y}_{\mu}, Z_{\mu}$ denote the unique solution of OPT_{μ}, i.e., the unique optimum of the log-barrier problem. The set $\{X_{\mu}, \mathbf{y}_{\mu}, Z_{\mu} : \mu \downarrow 0\}$ is called the *central path.* Successful primal-dual interior-point methods are actually path-following methods, i.e., they follow the central path to the optimum at $\mu = 0$.
2. The last equation in the optimality conditions OPT_{μ} is very nonlinear and leads to ill-conditioning as μ gets close to zero. Therefore, it is replaced by the more familiar

$$\mathrm{OPT}_{\mu} \qquad \mathrm{ZX} - \mu\mathrm{I} = 0 \quad \text{(perturbed complementary slackness).}$$

We denote the resulting optimality conditions using

$$F_\mu(X, \mathbf{y}, Z) = 0.$$

This system has the same appearance as the one used in LP . However, it is an overdetermined nonlinear system, i.e., $F_\mu : \mathcal{S}_n \times \mathbb{R}^m \times \mathcal{S}_n \to \mathcal{S}_n \times \mathbb{R}^m \times \mathbb{R}^{n \times n}$, since the product ZX is not necessarily symmetric. Therefore, the successful application of Newton's method done in LP must be modified. A Gauss–Newton method is used in [KMR01]. Another approach is to symmetrize the last equation of OPT_μ . A general symmetrization scheme is presented in [MZ98].

3. We derive and present (arguably) the most popular algorithm for SDP, the *HKM method* [HRV96], [KSH97], [Mon97].

   We consider a current estimate X, y, Z of the optimum of the log-barrier problem DSDP $_\mu$, where both $X \succ 0,\ Z \succ 0$. Since we want $ZX = \mu I$, we set $\mu = \frac{1}{n}\mathrm{tr}\,\mathrm{ZX}$. We use a centering parameter $0 < \sigma$ that is adaptive in that it decreases (respectively, increases) according to the decrease (respectively, increase) in the duality gap estimate at each iteration. Small σ signifies an aggressive step in decreasing μ to 0. We replace $\mu \leftarrow \sigma\mu$ in the optimality conditions. We denote the optimality conditions using $F_\mu = F_\mu(X, \mathbf{y}, Z) = \begin{bmatrix} R_d \\ \mathbf{r_p} \\ R_c \end{bmatrix}$, i.e., using three residuals. To derive the HKM method, we solve for the Newton direction $d_N = \begin{bmatrix} \Delta X \\ \mathbf{\Delta y} \\ \Delta Z \end{bmatrix}$ in the Newton equation

$$F'_\mu(X, \mathbf{y}, Z) = \begin{bmatrix} 0 & T^*\cdot & I\cdot \\ T\cdot & 0 & 0 \\ Z\cdot & 0 & \cdot X \end{bmatrix} d_N = -\begin{bmatrix} R_d \\ \mathbf{r_p} \\ R_c \end{bmatrix} = -F_\mu.$$

   To solve the above linearized system efficiently, we use block elimination. We use the first equation to solve for

$$\Delta Z = -R_d - T^*\Delta \mathbf{y}.$$

   We then substitute into the third equation and solve for

$$\Delta X = Z^{-1}\left((R_d + T^*\mathbf{\Delta y})X - R_c\right).$$

   We then substitute this into the second equation and obtain the so-called *Schur complement* system, which is similar to the normal equation in LP:

$$\begin{aligned} TZ^{-1}T^*\mathbf{\Delta y}X &= -TZ^{-1}\left(R_dX - R_c\right) - \mathbf{r_p} \\ &= -TZ^{-1}\left(R_dX - ZX + \mu I\right) - TX + \mathbf{b} \\ &= \mathbf{b} - TZ^{-1}\left(R_dX + \mu I\right). \end{aligned}$$

   This is a positive definite linear system. Once $\mathbf{\Delta y}$ is found, we can backsolve for $\Delta X, \Delta Z$.

   We now observe another major difference with LP and a major difficulty for SDP. Though ΔZ is now symmetric, this is not true, in general, for ΔX, since the product of symmetric matrices is not necessarily symmetric. Therefore, we symmetrize $\Delta X \leftarrow \frac{1}{2}(\Delta X + \Delta X^T)$. We have now obtained the search direction $(\Delta X, \mathbf{\Delta y}, \Delta Z)$.

   Next, a line search is performed that maintains X, Z positive definite, i.e., we find the next iterate (X, y, Z) using the primal and dual steplengths $X \leftarrow X + \alpha_p\Delta X \succ 0, Z \leftarrow Z + \alpha_d\Delta Z \succ 0$ and set $\mathbf{y} \leftarrow \mathbf{y} + \alpha_d\mathbf{\Delta y}$. We then update σ, μ and repeat the iteration, i.e., we go back to Fact 3 above.

4. See [HRV96] for more details on the HKM algorithm, including a predictor-corrector approach. Details on different symmetrization schemes that lead to various search directions and convergence proofs can be found in [MT00]. Algorithms based on bundle methods that handle large-scale SDP can be found in [HO00].

69.7 Applications of SDP

There are a surprising number of important applications for SDP, several of which have already been mentioned. Early applications in engineering involved solutions of linear matrix inequalities, LMIs, e.g., Lyapunov and Riccati equations; see [BEF94]. Semidefinite programming plays an important role in combinatorial optimization where it is used to solve nonlinear convex relaxations of NP-hard problems [Ali95], [WZ99], [ZKR98]. This includes strong theoretical results that characterize the quality of the bounds; see [GR00]. Matrix completion problems have been mentioned above. This includes Euclidean Distance Matrix completion problems with applications to, e.g., molecular conformation; see [AKW99]. Further applications to control theory, finance, nonlinear programming, etc. can be found in [BEF94] and [WSV00].

Facts:

1. SDP arises naturally when finding relaxations for hard combinatorial problems. We saw one simple case, the Max-Cut problem, MC, in the introduction in Example 1, i.e., MC was modeled as a quadratic maximization problem and the binary ± 1 variables were modeled using the quadratic constraints $x_j^2 = 1$.
2. In addition to ± 1 binary variables in Fact 1, we can model $0, 1$ variables using the quadratic constraints $x_j^2 - x_j = 0$. Linear constraints $A\mathbf{x} - \mathbf{b} = 0$ can be modeled using the quadratic constraint $\|A\mathbf{x} - \mathbf{b}\|^2 = 0$. Thus, in general, many hard combinatorial optimization problems are equivalent to a quadratically constrained quadratic program, QQP . Denote the quadratic function $q_i(\mathbf{y}) = \frac{1}{2}\mathbf{y}^T Q_i \mathbf{y} + \mathbf{y}^T b_i + c_i, \mathbf{y} \in \mathbb{R}^n, i = 0, 1, \ldots, m$. Then we have
$$\text{(QQP)} \qquad \begin{array}{rcl} q^* = & \min & q_0(\mathbf{y}) \\ & \text{subject to} & q_i(\mathbf{y}) = 0, \quad i = 1, \ldots m. \end{array}$$
(For simplicity, we restrict to equality constraints.)
3. SDP arises naturally from the Lagrangian relaxation of QQP in Fact 2 above. We write the Lagrangian $L(\mathbf{y}, \mathbf{x})$, with Lagrange multiplier vector $\mathbf{x}$.
$$L(\mathbf{y},\mathbf{x}) = \overbrace{\tfrac{1}{2}y^T(Q_0 - \textstyle\sum_{i=1}^m x_i Q_i)y}^{\text{quadratic in } \mathbf{y}} + \overbrace{y^T(b_0 - \textstyle\sum_{i=1}^m x_i b_i)}^{\text{linear in } \mathbf{y}} + \overbrace{(c_0 - \textstyle\sum_{i=1}^m x_i c_i)}^{\text{constant in } y}.$$
Weak duality follows from the primal-dual pair relationship
$$q^* = \min_y \max_x L(y,x) \geq d^* = \max_x \min_y L(y,x).$$
We now homogenize the Lagrangian by adding y_0 to the linear term: $y_0 y^T(b_0 - \sum_{i=1}^m x_i b_i)$, $y_0^2 = 1$. Then, after moving the constraint on y_0 into the Lagrangian, the dual program becomes
$$\begin{array}{rcll} d^* & = & \max\limits_x \min\limits_y & L(y,x) \\ & = & \max\limits_{x,t} \min\limits_y & \frac{1}{2}y^T\left(Q_0 - \sum_{i=1}^m x_i Q_i\right)y(+ty_0^2) \\ &&& \quad + y_0 y^T\left(b_0 - \sum_{i=1}^m x_i b_i\right) \\ &&& \quad + \left(c_0 - \sum_{i=1}^m x_i c_i\right)(-t). \end{array}$$

We now exploit the *hidden constraint* from the inner minimization of a homogeneous quadratic function, i.e., the Hessian of the Lagrangian must be positive semidefinite. This gives rise to the SDP

$$(\mathbf{D}) \qquad \begin{array}{rll} d^* = & \sup & -t - \sum_{i=1}^m x_i c_i \\ & \text{s.t.} & T\begin{bmatrix} t \\ x \end{bmatrix} \preceq B \\ & & x \in \mathbb{R}^m, \quad t \in \mathbb{R}, \end{array}$$

where the linear transformation $T : \mathbb{R}^{m+1} \to \mathcal{S}_{n+1}$ and the matrix B are defined by

$$B = \begin{bmatrix} 0 & b_0^T \\ b_0 & Q_0 \end{bmatrix}, \quad T\begin{bmatrix} t \\ x \end{bmatrix} = \begin{bmatrix} -t & \sum_{i=1}^m x_i b_i^T \\ \sum_{i=1}^m x_i b_i & \sum_{i=1}^m x_i Q_i \end{bmatrix}.$$

The dual, DD, of the program D gives rise to the SDP relaxation of QQP .

$$(\mathbf{DD}) \qquad \begin{array}{rll} p^* = & \inf & \operatorname{tr} BU \\ & \text{s.t.} & T^* U = \begin{bmatrix} -1 \\ -c \end{bmatrix} \\ & & U \succeq 0. \end{array}$$

70.1 Introduction and Mise-En-Scène

Linear algebra is used extensively in statistical science, in particular in linear statistical models, see, e.g., Christensen [Chr11], Graybill [Gra01], Puntanen, Styan, and Isotalo [PSI11], Ravishanker and Dey [RD02], Rencher and Schaalje [RS08], Searle [Sea97], Seber and Lee [SL03], Sengupta and Jammalamadaka [SJ03], and Stapleton [Sta09]; as well as in applied economics, see, e.g., Searle and Willett [SW01]; econometrics, see, e.g., Davidson and MacKinnon [DM04], Magnus and Neudecker [MN99], and Rao and Rao [RR98]; Markov chain theory, see, e.g., Chapter 72 or Kemeny and Snell [KS83]; multivariate statistical analysis, see, e.g., Anderson [And03], Kollo and von Rosen [KvR05], and Seber [Seb04]; psychometrics, see, e.g., Takane [Tak04] and Takeuchi, Yanai, and Mukherjee [TYM82]; and random matrix theory, see, e.g., Bleher and Its [BI01] and Mehta [Meh04]. Moreover, there are several books on linear algebra and matrix theory written by (and mainly for) statisticians, see, e.g., Bapat [Bap00], Graybill [Gra83], Hadi [Had96], Harville [Har97], [Har01], Healy [Hea00], Rao and Rao [RR98], Schott [Sch05], Searle [Sea82], and Seber [Seb08].

As Miller and Miller [MM04, p. 1] and Wackerly, Mendenhall, and Scheaffer [WMS02, p. 2] point out: “Statistics is a theory of information, with inference making as its objective” and may be viewed as encompassing “the science of basing inferences on observed data and the entire problem of making decisions in the face of uncertainty.”

In this chapter we present an introduction (Section 70.2) to the use of linear algebra in studying properties of random vectors (Section 70.3) and in linear statistical models (Section 70.4); for further uses, see, e.g., [PS05], and for an introduction to the use of linear algebra in multivariate statistical analysis see Chapter 71 or [PSI11].

We begin (in Section 70.2) with a brief introduction to the basic concepts of statistics and random variables [MM04], [WMS02], [WS00], with special emphasis (in Section 70.3) on random vectors — vectors where each entry is a random variable.

All matrices (with at least two rows and two columns) considered in this chapter are nonrandom.

70.2 Introduction to Statistics and Random Variables

Notation:

In this chapter most uppercase, light-face italic letters, in particular X, Y, and Z, denote scalar random variables, but the notation $P(A)$ is reserved for the probability of the set A. Throughout this chapter, the uppercase, light-face roman letter E denotes expectation.

Definitions:

The focus in statistics is on making inferences concerning a large body of data called a **population** based on a subset collected from it called a **sample**. An **experiment** associated with this sample is repeatable and its outcome is not predetermined. A **simple event** is one associated with an experiment, which cannot be decomposed, and a simple event corresponds to one and only one **sample point**. The **sample space** associated with an experiment is the set of all possible sample points.

Suppose that S is a sample space associated with an experiment. To every subset A of S we assign a real number $P(A)$, called the **probability** of A, so that the following axioms hold: (1) $P(A) \geq 0$, (2) $P(S) = 1$, (3) If $A_1, A_2, A_3, \ldots$ form a sequence of pairwise mutually exclusive subsets in S, i.e., $A_i \cap A_j = \emptyset$ if $i \neq j$, then $P(A_1 \cup A_2 \cup A_3 \cup \cdots) = \sum_{i=1}^{\infty} P(A_i)$.

A **random variable** is a real-valued function for which the domain is a sample space.

A random variable that can assume a finite or countably infinite number of values is **discrete**.

The **probability** $P(Y = y)$ that the random variable Y takes on the value y is defined as the sum of the probabilities of all sample points in S that have the value y, and the **probability function** of Y is the set of all the probabilities $P(Y = y)$.

If the random variable Y has the probability function $P(Y = 0) = p$ and $P(Y = 1) = 1 - p$ for some real number p in the interval $[0, 1]$, then Y is a **Bernoulli random variable**.

The **cumulative distribution function** (cdf) is $F(y) = P(Y \leq y)$ of the random variable Y for $-\infty < y < \infty$. A random variable Y is **continuous** when its cdf $F(y)$ is continuous for $-\infty < y < \infty$, and then its **probability density function** (pdf) $f(y) = dF(y)/dy$.

Suppose that the continuous random variable Y has pdf $f(y) = 1$ for $0 \leq y \leq 1$ and $f(y) = 0$ otherwise. Then Y follows a **uniform distribution** on the interval $[0, 1]$.

The **expectation** (or **expected value** or **mean** or **mean value**) $\mathrm{E}(Y)$ of the random variable Y is $\mathrm{E}(Y) = \sum_y yP(Y = y)$ when Y is discrete with probability function $P(Y = y)$ and is $\mathrm{E}(Y) = \int_{-\infty}^{+\infty} yf(y)dy$ when Y is continuous with pdf $f(y)$.

The **variance** σ^2 of the random variable Y is

$$\sigma^2 = \mathrm{var}(Y) = \mathrm{E}\big((Y - \mu)^2\big),$$

where $\mu = \mathrm{E}(Y)$ and the **standard deviation** $\sigma = \sqrt{\sigma^2}$.

Facts:

1. The variance $\sigma^2 = \mathrm{var}(Y) = \mathrm{E}(Y^2) - \mathrm{E}^2(Y)$.
2. For any random variable Y, the expectation of its square $\mathrm{E}(Y^2) \geq \mathrm{E}^2(Y)$ with equality if and only if the random variable $Y = \mathrm{E}(Y)$ with probability 1.
3. If Y is a Bernoulli random variable with probability function $P(Y = 0) = p$ and $P(Y = 1) = 1 - p$, then the expectation $\mathrm{E}(Y) = 1 - p$ and the variance $\mathrm{var}(Y) = p(1 - p)$.
4. If the random variable Z follows a uniform distribution on the interval $[0, 1]$, then the expectation $\mathrm{E}(Z) = 1/2$ and the variance $\mathrm{var}(Z) = 1/12$.

Examples:

1. Every person's blood type is A, B, AB, or O. In addition, each individual either has the Rhesus (Rh) factor (+) or does not (–). A medical technician records a person's blood type and Rh factor. The sample space for this experiment is {A+, B+, AB+, O+, A−, B−, AB−, O−} with eight sample points.
2. Consider the experiment of tossing a single fair coin and define the random variable $Y = 0$ if the outcome is "heads," and $Y = 1$ if the outcome is "tails." Then Y is a Bernoulli random variable, and $P(Y = 0) = \frac{1}{2} = P(Y = 1)$, $\mathrm{E}(Y) = \frac{1}{2}$, $\mathrm{var}(Y) = \frac{1}{4}$.
3. Suppose that a bus always arrives at a particular stop in the interval between 12 noon and 1 p.m. and that the probability that the bus will arrive in any given subinterval of time is proportional only to the length of the subinterval. Let Y denote the length of time that a person arriving at the stop at 12 noon must wait for the bus to arrive, and let us code 12 noon as 0 and measure the time in hours. Then the random variable Y follows a uniform distribution on the interval $[0, 1]$.

70.3 Random Vectors: Basic Definitions and Facts

Linear algebra is extensively used in the study of random vectors, where we consider the simultaneous behavior of two or more random variables assembled as a vector. In this section all vectors and matrices are real.

Notation:

In this section uppercase, light-face italic letters, such as X, Y, and Z, denote scalar random variables and lowercase bold roman letters, such as $\mathbf{x}$, $\mathbf{y}$, and $\mathbf{z}$, denote random vectors. Uppercase, light-face italic letters such as A and B denote nonrandom matrices.

Definitions:

Let $A \in \mathbb{R}^{n\times k}$ and $B \in \mathbb{R}^{n\times q}$. Then the **partitioned matrix** $[A \,|\, B]$ is the $n \times (k + q)$ matrix formed by placing A next to B.

A $k \times 1$ **random vector y** is a vector $\mathbf{y} = [Y_1, \ldots , Y_k]^T$ of k random variables $Y_1, \ldots , Y_k$. The **expectation** (or **expected value** or **mean vector**) of $\mathbf{y}$ is the $k \times 1$ vector $\mathrm{E}(\mathbf{y}) = [\mathrm{E}(Y_1), \ldots , \mathrm{E}(Y_k)]^T$. Sometimes, for clarity, a vector of constants (belonging to $\mathbb{R}^n$) is called a **nonrandom vector** and a matrix of constants a **nonrandom matrix**. (Random matrices are not considered in this chapter.)

The **covariance** $\mathrm{cov}(Y, Z)$ between the two random variables Y and Z is $\mathrm{cov}(Y, Z) = \mathrm{E}\big((Y - \mu)(Z - \nu)\big)$, where $\mu = \mathrm{E}(Y)$ and $\nu = \mathrm{E}(Z)$.

The **correlation** (or **correlation coefficient** or **product-moment correlation**) $\mathrm{cor}(Y, Z)$ between the two random variables Y and Z is $\mathrm{cor}(Y, Z) = \mathrm{cov}(Y, Z)/\sqrt{\mathrm{var}(Y)\mathrm{var}(Z)}$.

The **covariance matrix** (or **variance-covariance matrix** or **dispersion matrix**) of the $k \times 1$ random vector $\mathbf{y} = [Y_1, \ldots , Y_k]^T$ is the $k \times k$ matrix $\mathrm{var}(\mathbf{y}) = \Sigma$ of variances and covariances of all the entries of $\mathbf{y}$:

$$\begin{aligned}\mathrm{var}(\mathbf{y}) = \Sigma = [\sigma_{ij}] &= [\mathrm{cov}(Y_i, Y_j)] = [\mathrm{E}(Y_i - \mu_i)(Y_j - \mu_j)]\\ &= \mathrm{E}\big((\mathbf{y} - \boldsymbol{\mu})(\mathbf{y} - \boldsymbol{\mu})^T\big),\end{aligned}$$

where $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$. The determinant $\det\Sigma$ is the **generalized variance** of the random vector $\mathbf{y}$. The variances σ_{ii} are often denoted as σ_i^2 and, in this, chapter, we will assume that they are all positive. If $\sigma_i = 0$, then the random variable $Y_i = \mathrm{E}(Y_i)$ with probability 1, and then we interpret Y_i as a constant. In statistics it is quite common to denote **standard deviations** as σ_i. (The reader should note that in all the other chapters of this book except in the two statistics chapters, σ_i denotes the ith largest singular value.)

The **cross-covariance matrix** $\operatorname{cov}(\mathbf{y},\mathbf{z})$ between the $k\times 1$ random vector $\mathbf{y}=[Y_1,\dots,Y_k]^T$ and the $q\times 1$ random vector $\mathbf{z}=[Z_1,\dots,Z_q]^T$ is the $k\times q$ matrix of all the covariances $\operatorname{cov}(Y_i,Z_j); i=1,\dots,k$ and $j=1,\dots,q$:

$$\operatorname{cov}(\mathbf{y},\mathbf{z})=[\operatorname{cov}(Y_i,Z_j)]=[\mathrm{E}(Y_i-\mu_i)(Z_j-\nu_j)]=\mathrm{E}\big((\mathbf{y}-\boldsymbol{\mu})(\mathbf{z}-\boldsymbol{\nu})^T\big),$$

where $\boldsymbol{\mu}=[\mu_i]=\mathrm{E}(\mathbf{y})$ and $\boldsymbol{\nu}=[\nu_j]=\mathrm{E}(\mathbf{z})$. The random vectors $\mathbf{y}$ and $\mathbf{z}$ are **uncorrelated** whenever the cross-covariance matrix $\operatorname{cov}(\mathbf{y},\mathbf{z})=\mathbf{0}$.

The **correlation matrix** $\operatorname{cor}(\mathbf{y})=R$, say, of the $k\times 1$ random vector $\mathbf{y}=[Y_1,\dots,Y_k]^T$, is the $k\times k$ matrix of correlations of all the entries in $\mathbf{y}$: $\operatorname{cor}(\mathbf{y})=R=[\rho_{ij}]=[\operatorname{cor}(Y_i,Y_j)]=[\frac{\sigma_{ij}}{\sigma_i\sigma_j}]$, where $\sigma_i=\sqrt{\sigma_{ii}}=$ standard deviation of Y_i ; $\sigma_i,\sigma_j>0$.

Let $\mathbf{1}_k$ denote the $k\times 1$ column vector with every entry equal to 1. Then $J_k=\mathbf{1}_k\mathbf{1}_k^T$ is the $k\times k$ **all-ones matrix** (with all k^2 entries equal to 1) and $C_k=I_k-\frac{1}{k}J_k$ is the $k\times k$ **centering matrix**.

Suppose that the real positive numbers $p_1,p_2,\dots,p_k$ are such that $\sum_{i=1}^k p_i=1$. Then the $k\times 1$ random vector $\mathbf{y}=[Y_1,\dots,Y_k]^T$ follows a **multinomial distribution** with parameters n and $p_1,p_2,\dots,p_k$ if the joint probability function of $Y_1,Y_2,\dots,Y_k$ is given by

$$P(Y_1=y_1,Y_2=y_2,\dots,Y_k=y_k)=\frac{n!}{y_1!y_2!\cdots y_k!}\,p_1^{y_1}p_2^{y_2}\cdots p_k^{y_k},$$

where for each i, $y_i=0,1,2,\dots,n$ and $\sum_{i=1}^k y_i=n$. When $k=2$ the distribution is **binomial**, and when $k=3$ the distribution is **trinomial**.

Let the symmetric matrices $A\in\mathbb{R}^{k\times k}$ and $B\in\mathbb{R}^{k\times k}$. Then $A\succeq B$ means $A-B$ is positive semidefinite and $A\succ B$ means $A-B$ is positive definite. The partial ordering induced by $\succeq$ is called the **partial semidefinite ordering** (or **Loewner partial ordering** or **Löwner partial ordering**). (See Section 9.5 for more information.)

Let the $(k+q)\times 1$ random vector $\mathbf{x}$ have covariance matrix Σ. Consider the following partitioning:

$$\mathbf{x}=\begin{bmatrix}\mathbf{y}\\ \mathbf{z}\end{bmatrix},\qquad \mathrm{E}(\mathbf{x})=\begin{bmatrix}\boldsymbol{\mu}\\ \boldsymbol{\nu}\end{bmatrix},\qquad \operatorname{var}(\mathbf{x})=\Sigma=\begin{bmatrix}\Sigma_{yy} & \Sigma_{yz}\\ \Sigma_{zy} & \Sigma_{zz}\end{bmatrix},$$

where $\mathbf{y}$ and $\mathbf{z}$ have k and q elements, respectively. Then the **partial covariance matrix** $\Sigma_{zz\cdot y}$ of the $q\times 1$ random vector $\mathbf{z}$ after **adjusting for** (or **controlling for** or **removing the effect of** or **allowing for**) the $k\times 1$ random vector $\mathbf{y}$ is the (uniquely defined) **generalized Schur complement**

$$\Sigma/\Sigma_{yy}=[\sigma_{ij\cdot\mathbf{y}}]=\Sigma_{zz}-\Sigma_{zy}\Sigma_{yy}^{-}\Sigma_{yz}$$

of Σ_{yy} in Σ; any **generalized inverse** Σ_{yy}^{-} satisfying $\Sigma_{yy}=\Sigma_{yy}\Sigma_{yy}^{-}\Sigma_{yy}$ may be chosen.

When Σ_{yy} is positive definite, we use the inverse Σ_{yy}^{-1} instead of a generalized inverse Σ_{yy}^{-} and refer to $\Sigma/\Sigma_{yy}=\Sigma_{zz}-\Sigma_{zy}\Sigma_{yy}^{-1}\Sigma_{yz}$ as the **Schur complement** of Σ_{yy} in Σ.

The $q\times 1$ random vector $\mathbf{e}_{\mathbf{z}\cdot\mathbf{y}}=\mathbf{z}-\boldsymbol{\nu}-\Sigma_{zy}\Sigma_{yy}^{-}(\mathbf{y}-\boldsymbol{\mu})$ is the (uniquely defined) vector of **residuals** of the $q\times 1$ random vector $\mathbf{z}$ from its **regression** on the $k\times 1$ random vector $\mathbf{y}$.

The ijth entry of the **partial correlation matrix** of $q\times 1$ random vector $\mathbf{z}=[Z_1,\dots,Z_q]^T$ after adjusting for the $k\times 1$ random vector $\mathbf{y}$ is the **partial correlation coefficient** between z_i and z_j after adjusting for $\mathbf{y}$:

$$\rho_{ij\cdot\mathbf{y}}=\frac{\sigma_{ij\cdot\mathbf{y}}}{\sqrt{\sigma_{ii\cdot\mathbf{y}}\sigma_{jj\cdot\mathbf{y}}}}\ ;\ i,j=1,\dots,q,$$

which is well defined provided the diagonal entries of the associated partial covariance matrix are all positive.

Facts:

1. [WMS02, Th. 5.13, p. 265] Let the $k \times 1$ random vector $\mathbf{y} = [Y_1, \ldots, Y_k]^T$ follow a multinomial distribution with parameters n and $p_1, \ldots, p_k$ and let the $k \times 1$ vector $\mathbf{p} = [p_1, \ldots, p_k]^T$. Then:
   (a) The random variable Y_i can be represented as the sum of n independently and identically distributed Bernoulli random variables with parameter p_i; $i = 1, \ldots, k$.
   (b) The expectation $\mathrm{E}(\mathbf{y}) = n\mathbf{p}$ and the covariance matrix
   $$\mathrm{var}(\mathbf{y}) = n\big(\mathrm{diag}(\mathbf{p}) - \mathbf{p}\mathbf{p}^T\big) = \Psi_k,$$
   say, where $\mathrm{diag}(\mathbf{p})$ is the $k \times k$ diagonal matrix formed from the $k \times 1$ nonrandom vector $\mathbf{p}$.
   (c) The covariance matrix Ψ_k is singular since all its row (and column) totals are 0, and the $\mathrm{rank}(\Psi_k) = k - 1$.
2. When the $k \times 1$ multinomial probability vector $\mathbf{p} = \mathbf{1}_k/k$, then the multinomial covariance matrix $\Psi_k = \frac{n}{k} C_k$, where C_k is the $k \times k$ centering matrix.
3. The $k \times k$ covariance matrix $\mathrm{var}(\mathbf{y}) = \Sigma = \mathrm{E}(\mathbf{y}\mathbf{y}^T) - \boldsymbol{\mu}\boldsymbol{\mu}^T$, where $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$.
4. The $k \times k$ correlation matrix $\mathrm{cor}(\mathbf{y}) = [\mathrm{diag}(\Sigma)]^{-1/2}\Sigma[\mathrm{diag}(\Sigma)]^{-1/2}$, where $\Sigma = \mathrm{var}(\mathbf{y})$.
5. The $k \times q$ cross-covariance matrix
   $$\mathrm{cov}(\mathbf{y}, \mathbf{z}) = \Sigma_{yz} = \Sigma_{zy}^T = \big(\mathrm{cov}(\mathbf{z}, \mathbf{y})\big)^T = \mathrm{E}(\mathbf{y}\mathbf{z}^T) - \boldsymbol{\mu}\boldsymbol{\nu}^T,$$
   where $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$ and $\boldsymbol{\nu} = \mathrm{E}(\mathbf{z})$.
6. [RM71, Lemma 2.2.4, p. 21]: The product AB^-C (for $A \neq \mathbf{0},\ C \neq \mathbf{0}$) is invariant with respect to the choice of $B^- \iff \mathrm{range}(C) \subseteq \mathrm{range}(B)$ and $\mathrm{range}(A^T) \subseteq \mathrm{range}(B^T)$.
7. Consider the $(k+q) \times (k+q)$ covariance matrix
   $$\Sigma = \begin{bmatrix} \Sigma_{yy} & \Sigma_{yz} \\ \Sigma_{zy} & \Sigma_{zz} \end{bmatrix}.$$
   Then the range (or column space) $\mathrm{range}(\Sigma_{yz}) \subseteq \mathrm{range}(\Sigma_{yy})$ and $\mathrm{range}(\Sigma_{zy}) \subseteq \mathrm{range}(\Sigma_{zz})$, and, hence, the matrix $\Sigma_{zy}\Sigma_{yy}^-\Sigma_{yz}$ and the generalized Schur complement $\Sigma/\Sigma_{yy} = \Sigma_{zz} - \Sigma_{zy}\Sigma_{yy}^-\Sigma_{yz}$ are invariant (unique) with respect to the choice of generalized inverse Σ_{yy}^-.
8. Let the $k \times 1$ random vector $\mathbf{x} = [X_1, \ldots, X_k]^T$. Then the $k \times 1$ centered vector $C_k\mathbf{x} = [X_1 - \bar{X}, \ldots, X_k - \bar{X}]^T$, where C_k is the $k \times k$ centering matrix and the arithmetic mean (or average) $\bar{X} = \sum_{i=1}^k X_i/k$.
9. A nonsingular positive semidefinite matrix is positive definite.
10. A covariance matrix is always symmetric and positive semidefinite.
11. A cross-covariance matrix is usually rectangular.
12. A correlation matrix is always symmetric and positive semidefinite.
13. The diagonal entries of a correlation matrix are all equal to 1 and the off-diagonal entries are all at most equal to 1 in absolute value.
14. [PS05, p. 168] The (generalized) Schur complement of the leading principal submatrix of a positive semidefinite matrix is positive semidefinite.
15. Let $\mathbf{y}$ be a $k \times 1$ random vector with covariance matrix Σ. Then the variance $\mathrm{var}(\mathbf{a}^T\mathbf{y}) = \mathbf{a}^T\Sigma\mathbf{a}$ for all nonrandom $\mathbf{a} \in \mathbb{R}^k$. (Since variance must be nonnegative, this fact shows that a covariance matrix must be positive semidefinite.)

16. Let $\mathbf{y}$ be a $k \times 1$ random vector with expectation $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$, covariance matrix $\Sigma = \mathrm{var}(\mathbf{y})$, and let the matrix $A \in \mathbb{R}^{n \times k}$ and the nonrandom vector $\mathbf{b} \in \mathbb{R}^n$. Then the expectation $\mathrm{E}(A\mathbf{y} + \mathbf{b}) = A\mathrm{E}(\mathbf{y}) + \mathbf{b} = A\boldsymbol{\mu} + \mathbf{b}$ and the covariance matrix $\mathrm{var}(A\mathbf{y} + \mathbf{b}) = A\mathrm{var}(\mathbf{y})A^T = A\Sigma A^T$.
17. Let $\mathbf{y}$ be a $k \times 1$ random vector with expectation $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$, covariance matrix $\Sigma = \mathrm{var}(\mathbf{y})$, and let the matrix $A \in \mathbb{R}^{k \times k}$, not necessarily symmetric. Then $\mathrm{E}(\mathbf{y}^T A\mathbf{y}) = \boldsymbol{\mu}^T A\boldsymbol{\mu} + \mathrm{tr}(A\Sigma)$.
18. [Rao73a, p. 522] Let $\mathbf{y}$ be a $k \times 1$ random vector with expectation $\boldsymbol{\mu} = \mathrm{E}(\mathbf{y})$ and covariance matrix $\Sigma = \mathrm{var}(\mathbf{y})$, and let $[\boldsymbol{\mu} \,|\, \Sigma]$ denote the $k \times (k+1)$ partitioned matrix with $\boldsymbol{\mu}$ as its first column. Then $\mathbf{y} - \boldsymbol{\mu} \in \mathrm{range}(\Sigma)$ and $\mathbf{y} \in \mathrm{range}([\boldsymbol{\mu} \,|\, \Sigma])$, both with probability 1.
19. Let the $(k+q) \times 1$ random vector $\mathbf{x}$ have covariance matrix Σ. Consider the following partitioning:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}, \qquad \mathrm{E}(\mathbf{x}) = \begin{bmatrix} \boldsymbol{\mu} \\ \boldsymbol{\nu} \end{bmatrix}, \qquad \Sigma = \begin{bmatrix} \Sigma_{yy} & \Sigma_{yz} \\ \Sigma_{zy} & \Sigma_{zz} \end{bmatrix},$$

where $\mathbf{y}$ and $\mathbf{z}$ have k and q components, respectively. Then

   (a) The variance $\mathrm{var}(\mathbf{a}^T\mathbf{y} + \mathbf{b}^T\mathbf{z}) = \mathbf{a}^T\Sigma_{yy}\mathbf{a} + 2\mathbf{a}^T\Sigma_{yz}\mathbf{b} + \mathbf{b}^T\Sigma_{zz}\mathbf{b}$ for all nonrandom $\mathbf{a} \in \mathbb{R}^k$ and for all nonrandom $\mathbf{b} \in \mathbb{R}^q$.

   (b) The covariance matrix $\mathrm{var}(A\mathbf{y} + B\mathbf{z}) = A\Sigma_{yy}A^T + A\Sigma_{yz}B^T + B\Sigma_{zy}A^T + B\Sigma_{zz}B^T$ for all $A \in \mathbb{R}^{n \times k}$ and all $B \in \mathbb{R}^{n \times q}$.

   (c) [PS05b, pp. 187–188] For any $A \in \mathbb{R}^{q \times k}$ the covariance matrix

$$\mathrm{var}(\mathbf{z} - A\mathbf{y}) \succeq \mathrm{var}(\mathbf{z} - \Sigma_{zy}\Sigma_{yy}^{-}\mathbf{y})$$

   with respect to the partial semidefinite ordering, and the partial covariance matrix

$$\mathrm{var}(\mathbf{z} - \Sigma_{zy}\Sigma_{yy}^{-}\mathbf{y}) = \Sigma_{zz} - \Sigma_{zy}\Sigma_{yy}^{-}\Sigma_{yz} = \Sigma_{zz\cdot y} = \Sigma/\Sigma_{yy}\,,$$

   the generalized Schur complement of Σ_{yy} in Σ.

   (d) Let $q = k$. Then the covariance matrix $\mathrm{var}(\mathbf{y} + \mathbf{z}) = \mathrm{var}(\mathbf{y}) + \mathrm{var}(\mathbf{z})$ if and only if $\mathrm{cov}(\mathbf{y}, \mathbf{z}) = -\mathrm{cov}(\mathbf{z}, \mathbf{y})$, i.e., the cross-covariance matrix $\mathrm{cov}(\mathbf{y}, \mathbf{z})$ is skew-symmetric; the condition that $\mathrm{cov}(\mathbf{y}, \mathbf{z}) = \mathbf{0}$ is sufficient, but not necessary (unless $k = 1$).

   (e) The vector $\Sigma_{zy}\Sigma_{yy}^{-}\mathbf{y}$ is not necessarily invariant with respect to the choice of generalized inverse Σ_{yy}^{-}, but its covariance matrix $\mathrm{var}(\Sigma_{zy}\Sigma_{yy}^{-}\mathbf{y}) = \Sigma_{zy}\Sigma_{yy}^{-}\Sigma_{yz}$ is invariant (and, hence, unique).

Examples:

1. Let the 4×1 random vector $\mathbf{x}$ have covariance matrix Σ. Consider the following partitioning:

$$\mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \mathbf{z} \end{bmatrix}, \qquad \Sigma = \begin{bmatrix} 1 & 0 & a & b \\ 0 & 1 & c & d \\ a & c & 1 & 0 \\ b & d & 0 & 1 \end{bmatrix},$$

where $\mathbf{y}$ and $\mathbf{z}$ each have 2 components. Then $\mathrm{var}(\mathbf{y} + \mathbf{z}) = \mathrm{var}(\mathbf{y}) + \mathrm{var}(\mathbf{z})$ if and only if $a = d = 0$ and $c = -b$, with $b^2 \leq 1$.
2. Let the $k \times 1$ random vector $\mathbf{y} = [Y_1, \ldots, Y_k]^T$ follow a multinomial distribution with parameters n and $\mathbf{p} = [p_1, \ldots, p_k]^T$, with $p_1 + \cdots + p_k = 1$ and $p_1 > 0, \ldots, p_k > 0$, and let the $k \times k$ matrix $A = [a_{ij}]$. Then the expectation $\mathrm{E}(\mathbf{y}^T A\mathbf{y}) = n(n-1)\mathbf{p}^T A\mathbf{p} + n\sum_{i=1}^{k} a_{ii}p_i$.

3. Let the 3×1 random vector $\mathbf{y} = [Y_1, Y_2, Y_3]^T$ follow a trinomial distribution with parameters n and p_1, p_2, p_3, with $p_1 + p_2 + p_3 = 1$ and $p_1 > 0, p_2 > 0, p_3 > 0$, and let the 3×1 vector $\mathbf{p} = [p_1, p_2, p_3]^T$. Then:

   (a) The expectation $\mathrm{E}(\mathbf{y}) = n[p_1, p_2, p_3]^T$ and the covariance matrix

   $$\Psi_3 = \mathrm{var}(\mathbf{y}) = n \begin{bmatrix} p_1(1-p_1) & -p_1p_2 & -p_1p_3 \\ -p_1p_2 & p_2(1-p_2) & -p_2p_3 \\ -p_1p_3 & -p_2p_3 & p_3(1-p_3) \end{bmatrix},$$

   which has rank equal to 2 since Ψ_3 is singular and the determinant of the top left-hand corner of Ψ_3 equals $n^2p_1p_2p_3 > 0$.

   (b) The partial covariance matrix of Y_1 and Y_2 adjusting for Y_3 is the Schur complement $\Psi_3/\big(p_3(1-p_3)\big) = nS$, say, where

   $$S = \begin{bmatrix} p_1(1-p_1) & -p_1p_2 \\ -p_1p_2 & p_2(1-p_2) \end{bmatrix} - \begin{bmatrix} -p_1p_3 \\ -p_2p_3 \end{bmatrix} \frac{1}{p_3(1-p_3)} \begin{bmatrix} -p_1p_3 & -p_2p_3 \end{bmatrix} = \frac{p_1p_2}{p_1+p_2} \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix},$$

   which has rank equal to 1, and so $\mathrm{rank}(\Psi_3) = 2$.

   (c) When $p_1 = p_2 = p_3 = 1/3$, then the covariance matrix $\Psi_3 = (n/3)C_3$ and the partial covariance matrix of Y_1 and Y_2 adjusting for Y_3 is $(n/3)C_2$; here, C_h is the $h \times h$ centering matrix, $h = 2, 3$.

4. [PS05, p. 183] If the 3×3 symmetric matrix

   $$R_3 = \begin{bmatrix} 1 & r_{12} & r_{13} \\ r_{12} & 1 & r_{23} \\ r_{13} & r_{23} & 1 \end{bmatrix} = \begin{bmatrix} R_2 & \boldsymbol{r}_2 \\ \boldsymbol{r}_2^T & 1 \end{bmatrix}$$

   is a correlation matrix, then $r_{ij}^2 \leq 1$ for all $1 \leq i < j \leq 3$. But not all symmetric matrices with diagonal elements equal to 1 and all off-diagonal elements r_{ij} such that $r_{ij}^2 \leq 1$ are correlation matrices. For example, consider R_3 with $r_{13}^2 \leq 1$ and $r_{23}^2 \leq 1$. Then R_3 is a correlation matrix if and only if

   $$r_{13}r_{23} - \sqrt{(1-r_{13}^2)(1-r_{23}^2)} \leq r_{12} \leq r_{13}r_{23} + \sqrt{(1-r_{13}^2)(1-r_{23}^2)}.$$

   When $r_{13} = 0$ and $r_{12} = r_{23} = r$, say, then this condition becomes $r^2 \leq 1/2$ and so the matrix

   $$\begin{bmatrix} 1 & 0.8 & 0 \\ 0.8 & 1 & 0.8 \\ 0 & 0.8 & 1 \end{bmatrix}$$

   is not a correlation matrix.

   When $r_{12}^2 \leq 1$, then the matrix R_3 is a correlation matrix if and only if any one of the following conditions holds:

   (a) $\det(R_3) = 1 - r_{12}^2 - r_{13}^2 - r_{23}^2 + 2r_{12}r_{13}r_{23} \geq 0$.

(b) (i) $\mathbf{r}_2 \in \text{range}(R_2)$ and (ii) $1 \geq \mathbf{r}_2^T R_2^- \mathbf{r}_2$ for some and, hence, for every R_2^-.

5. Let the random vector $\mathbf{x}$ be 2×1 and write

$$\mathbf{x} = \begin{bmatrix} Y \\ Z \end{bmatrix}, \qquad \mathrm{E}(\mathbf{x}) = \begin{bmatrix} \mu \\ \nu \end{bmatrix}, \qquad \mathrm{var}(\mathbf{x}) = \Sigma = \begin{bmatrix} \sigma_y^2 & \sigma_{yz} \\ \sigma_{yz} & \sigma_z^2 \end{bmatrix},$$

with $\sigma_y^2 > 0$. Then the residual vector $\mathbf{e}_{\mathbf{z}\cdot\mathbf{y}} = \mathbf{z} - \boldsymbol{\nu} - \Sigma_{zy}\Sigma_{yy}^-(\mathbf{y} - \boldsymbol{\mu})$ of the random vector $\mathbf{z}$ from its regression on $\mathbf{y}$ becomes the scalar residual

$$e_{Z\cdot Y} = Z - \nu - \frac{\sigma_{yz}}{\sigma_y^2}(Y - \mu)$$

of the random variable Z from its regression on Y. The matrix of partial covariances of the random vector $\mathbf{z}$ after adjusting for $\mathbf{y}$ becomes the single partial variance

$$\sigma_{z\cdot y}^2 = \sigma_z^2 - \frac{\sigma_{yz}^2}{\sigma_y^2} = \sigma_z^2(1 - \rho_{yz}^2)$$

of the random variable Z after adjusting for the random variable Y; here, the correlation coefficient $\rho_{yz} = \sigma_{yz}/(\sigma_y\sigma_z)$.

70.4 Linear Statistical Models: Basic Definitions and Facts

Notation:

In this section, the uppercase, light-face italic letter X is reserved for the nonrandom $n \times p$ model matrix and V is reserved for an $n \times n$ covariance matrix. The uppercase, light-face italic letter H is reserved for the (symmetric idempotent) $n \times n$ hat matrix $X(X^TX)^-X^T$ and $M = I - H$ is reserved for the (symmetric idempotent) $n \times n$ residual matrix. The lowercase, bold-face roman letter $\mathbf{y}$ is reserved for an observable $n \times 1$ random vector and $\mathbf{x}$ is reserved for a column of the $n \times p$ model matrix X.

Definitions:

The **general linear model** (or **Gauss–Markov model** or **Gauß–Markov model**) is the model

$$\mathrm{M} = \{\mathbf{y},\, X\boldsymbol{\beta},\, \sigma^2 V\}$$

defined by the equation $\mathbf{y} = X\boldsymbol{\beta} + \boldsymbol{\varepsilon}$, where $\mathrm{E}(\mathbf{y}) = X\boldsymbol{\beta}$, $\mathrm{E}(\boldsymbol{\varepsilon}) = \mathbf{0}$, $\mathrm{var}(\mathbf{y}) = \mathrm{var}(\boldsymbol{\varepsilon}) = \sigma^2 V$. The vector $\mathbf{y}$ is an $n \times 1$ observable random vector, $\boldsymbol{\varepsilon}$ is an $n \times 1$ unobservable random error vector, X is a known $n \times p$ **model matrix** (or **design matrix**, particularly when its entries are $-1, 0$, or $+1$), $\boldsymbol{\beta}$ is a $p \times 1$ vector of unknown parameters, V is a known $n \times n$ positive semidefinite matrix, and σ^2 is an unknown positive constant. The realization of the $n \times 1$ observable random vector $\mathbf{y}$ will also be denoted by $\mathbf{y}$.

The classical theory of linear statistical models covers the **full-rank model**, where X has full column rank and V is positive definite. In the full-rank model, the **ordinary least squares estimator**

$$\mathrm{OLSE}(\boldsymbol{\beta}) = \hat{\boldsymbol{\beta}} = (X^TX)^{-1}X^T\mathbf{y} = X^\dagger\mathbf{y}$$

and the **generalized least squares estimator** (or **Aitken estimator**)

$$\mathrm{GLSE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}} = (X^TV^{-1}X)^{-1}X^TV^{-1}\mathbf{y},$$

where $X^\dagger$ denotes the Moore–Penrose inverse of X.

When either X or V is (or both X and V are) rank deficient, then it is usually assumed that $\text{rank}(X) < \text{rank}(V)$. The model $\mathrm{M} = \{\mathbf{y},\, X\boldsymbol{\beta},\, \sigma^2 V\}$ is called a **weakly singular model** (or **Zyskind–Martin model**) whenever $\text{range}(X) \subseteq \text{range}(V)$, and then $\text{rank}(X) < \text{rank}(V)$, and is **consistent** if the realization $\mathbf{y}$ satisfies $\mathbf{y} \in \text{range}([X \,|\, V])$.

Let $\hat{\boldsymbol{\beta}}$ be any vector minimizing $\|\mathbf{y}-X\boldsymbol{\beta}\|^2 = (\mathbf{y}-X\boldsymbol{\beta})^T(\mathbf{y}-X\boldsymbol{\beta})$. Then $\hat{\mathbf{y}} = X\hat{\boldsymbol{\beta}} = \text{OLSE}(X\boldsymbol{\beta}) =$ the **ordinary least squares estimator** (OLSE) of $X\boldsymbol{\beta}$. When $\text{rank}(X) < p$, then $\hat{\boldsymbol{\beta}}$ is an **ordinary least squares solution** to $\min_{\boldsymbol{\beta}}(\mathbf{y} - X\boldsymbol{\beta})^T(\mathbf{y} - X\boldsymbol{\beta})$. Moreover, $\hat{\boldsymbol{\beta}}$ is any solution to the **normal equations** $X^T X\hat{\boldsymbol{\beta}} = X^T\mathbf{y}$. The vector of OLS **residuals** is $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - X\hat{\boldsymbol{\beta}}$ and the **residual sum of squares** $SSE = \mathbf{e}^T\mathbf{e} = (\mathbf{y} - \hat{\mathbf{y}})^T(\mathbf{y} - \hat{\mathbf{y}})$.

The **coefficient of determination** (or **coefficient of multiple determination** or **squared multiple correlation**) $R^2 = 1 - (SSE/\mathbf{y}^T C_n \mathbf{y})$ identifies the proportion of variance explained in a **multiple linear regression** where the model matrix $X = [\mathbf{1}_n \,|\, \mathbf{x}_{[1]} \,|\, \cdots \,|\, \mathbf{x}_{[p-1]}]$ with $p - 1$ **regressor vectors** (or **regressors**) $\mathbf{x}_{[1]}, \ldots, \mathbf{x}_{[p-1]}$ each $n \times 1$. In **simple linear regression** $p = 2$ and the model matrix $X = [\mathbf{1}_n \,|\, \mathbf{x}]$ with the single regressor vector $\mathbf{x}$. The **sample correlation coefficient** $r = \mathbf{x}^T C_n \mathbf{y}/\sqrt{\mathbf{x}^T C_n \mathbf{x} \cdot \mathbf{y}^T C_n \mathbf{y}}$, where it is usually assumed that $\mathbf{x}$ is an $n \times 1$ nonrandom vector (such as a regressor vector) and $\mathbf{y}$ is a realization of the $n \times 1$ random vector $\mathbf{y}$.

Let the matrix $A \in \mathbb{R}^{k\times n}$ and let the matrix $K \in \mathbb{R}^{k\times p}$. Then the linear estimator $A\mathbf{y}$ is a **linear unbiased estimator** (LUE) of $K\boldsymbol{\beta}$ if $\mathrm{E}(A\mathbf{y}) = K\boldsymbol{\beta}$ for all $\boldsymbol{\beta} \in \mathbb{R}^p$. Let the matrix $B \in \mathbb{R}^{k\times n}$. Then the LUE $B\mathbf{y}$ of $K\boldsymbol{\beta}$ is the **best linear unbiased estimator** (BLUE) of $K\boldsymbol{\beta}$ if it has the smallest covariance matrix (in the positive semidefinite ordering) in that $\text{var}(A\mathbf{y}) \succeq \text{var}(B\mathbf{y})$ for all LUEs $A\mathbf{y}$ of $K\boldsymbol{\beta}$.

The **hat matrix** $H = X(X^T X)^- X^T$ associated with the model matrix X is so named since $\hat{\mathbf{y}} = H\mathbf{y}$. The **residual matrix** $M = I - H$ and vector of OLS residuals is $\mathbf{e} = \mathbf{y} - \hat{\mathbf{y}} = \mathbf{y} - H\mathbf{y} = M\mathbf{y}$. Let the nonrandom vector $\mathbf{a} \in \mathbb{R}^n$. Then the linear estimator $\mathbf{a}^T\mathbf{y}$, which is unbiased for 0, i.e., $\mathrm{E}(\mathbf{a}^T\mathbf{y}) = 0$, is a **linear zero function**.

The **Watson efficiency** ϕ under the full-rank model $M = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$, with the $n \times p$ model matrix X having full column rank equal to $p < n$ and with the $n \times n$ covariance matrix V positive definite, measures the relative efficiency of the $\text{OLSE}(\boldsymbol{\beta}) = \hat{\boldsymbol{\beta}}$ vs. the $\text{BLUE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}}$ and is defined by the ratio of the corresponding generalized variances:

$$\phi = \frac{\det[\text{var}(\tilde{\boldsymbol{\beta}})]}{\det[\text{var}(\hat{\boldsymbol{\beta}})]} = \frac{\det^2(X^T X)}{\det(X^T V X) \cdot \det(X^T V^{-1} X)}\,.$$

The **Bloomfield–Watson efficiency** ψ under the general linear model $M = \{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ with no rank assumptions measures the relative efficiency of the $\text{OLSE}(X\boldsymbol{\beta}) = X\hat{\boldsymbol{\beta}}$ vs. the $\text{BLUE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}}$ and is defined by: $\psi = \frac{1}{2}\|HV - VH\|^2 = \|HVM\|^2$, where the norm $\|A\| = \text{tr}^{1/2}(A^T A)$ is defined for any $k \times q$ matrix A.

The $n \times n$ covariance matrix $(1 - \rho)I_n + \rho\mathbf{1}_n\mathbf{1}_n^T = (1 - \rho)I_n + \rho J_n$ has **intraclass correlation structure** (or **equicorrelation structure**) and is the **intraclass correlation matrix** (or the **equicorrelation matrix**). The parameter ρ is the **intraclass correlation** (or **intraclass correlation coefficient**).

Facts:

The following facts, except for those with a specific reference, can be found in [Gro04], [PS89], or [SJ03, §4.1–4.3]. Throughout this set of facts, X denotes the $n \times p$ nonrandom model matrix.

1. The hat matrix $H = X(X^T X)^- X^T$ associated with the model matrix X is invariant (unique) with respect to choice of generalized inverse $(X^T X)^-$ and is a symmetric idempotent matrix: $H = H^T = H^2$, and $\text{rank}(H) = \text{tr}(H) = \text{rank}(X)$. Moreover, the hat matrix H is the orthogonal projector onto $\text{range}(X)$.

2. If the $p \times p$ matrix Q is nonsingular, then the hat matrix associated with the model matrix XQ equals the hat matrix associated with the model matrix X.
3. The residual sum of squares $SSE = \mathbf{y}^T M \mathbf{y} = (\mathbf{y} - \hat{\mathbf{y}})^T(\mathbf{y} - \hat{\mathbf{y}}) = \mathbf{y}^T\mathbf{y} - \mathbf{y}^T X \hat{\boldsymbol{\beta}}$, where M is the residual matrix and $\hat{\boldsymbol{\beta}} = \mathrm{OLSE}(\boldsymbol{\beta})$.
4. In simple linear regression the coefficient of determination $R^2 = r^2$, the square of the sample correlation coefficient. In multiple linear regression with model matrix $X = [\mathbf{1}_n \,|\, X_0] = [\mathbf{1}_n \,|\, \mathbf{x}_{[1]} \,|\, \cdots \,|\, \mathbf{x}_{[p-1]}]$ and $(p-1) \times 1$ nonrandom vector $\mathbf{a} \in \mathbb{R}^p$,
$$R^2 = \max_{\mathbf{a}} r_{\mathbf{a}}^2 = \max_{\mathbf{a}} \frac{(\mathbf{a}^T X_0^T C_n \mathbf{y})^2}{\mathbf{a}^T X_0^T C_n X_0 \mathbf{a} \cdot \mathbf{y}^T C_n \mathbf{y}},$$
the square of the sample correlation coefficient $r_{\mathbf{a}}$ between the variables whose observed values are in vectors $\mathbf{y}$ and $X_0\mathbf{a}$.
5. The vector $X\hat{\boldsymbol{\beta}}$ is invariant (unique) with respect to the choice of least squares solution $\hat{\boldsymbol{\beta}}$, but $\hat{\boldsymbol{\beta}}$ is unique if and only if X has full column rank equal to $p \leq n$, and then $\hat{\boldsymbol{\beta}} = \mathrm{OLSE}(\boldsymbol{\beta}) = (X^TX)^{-1}X^T\mathbf{y} = X^\dagger\mathbf{y}$, where $X^\dagger$ is the Moore–Penrose inverse of X. The covariance matrix $\mathrm{var}(\hat{\boldsymbol{\beta}}) = \sigma^2(X^TX)^{-1}X^TVX(X^TX)^{-1}$.
6. The Watson efficiency ϕ is always positive, and $\phi \leq 1$ with equality if and only if $\mathrm{OLSE}(\boldsymbol{\beta}) = \mathrm{BLUE}(\boldsymbol{\beta})$.
7. [DLL02, p. 477], [Gus97, p. 67] *Bloomfield–Watson–Knott Inequality.* The Watson efficiency
$$\phi = \frac{\det^2(X^TX)}{\det(X^TVX) \cdot \det(X^TV^{-1}X)} \geq \prod_{i=1}^{m} \frac{4\lambda_i\lambda_{n-i+1}}{(\lambda_i + \lambda_{n-i+1})^2},$$
for all $n \times p$ model matrices X with full column rank p. Here $m = \min(p, n-p)$ and $\lambda_1 \geq \cdots \geq \lambda_n$ denote the necessarily positive eigenvalues of the $n \times n$ positive definite covariance matrix V. The ratios $4\lambda_i\lambda_{n-i+1}/(\lambda_i + \lambda_{n-i+1})^2$ in the lower bound for the Watson efficiency are the squared *antieigenvalues* of the covariance matrix V.
8. [DLL02, p. 454] Let $p = 1$ and set the $n \times 1$ model matrix $X = \mathbf{x}$. Then the Bloomfield–Watson–Knott Inequality is the *Kantorovich Inequality* (or *Frucht–Kantorovich Inequality*):
$$\frac{(\mathbf{x}^T\mathbf{x})^2}{\mathbf{x}^TV\mathbf{x} \cdot \mathbf{x}^TV^{-1}\mathbf{x}} \geq \frac{4\lambda_1\lambda_n}{(\lambda_1 + \lambda_n)^2},$$
where λ_1 and λ_n are, respectively, the largest and smallest eigenvalues of the $n \times n$ positive definite covariance matrix V.
9. The Bloomfield–Watson efficiency
$$\begin{aligned}\psi &= \frac{1}{2}\|HV - VH\|^2 = \|HVM\|^2 = \mathrm{tr}(HVMVH) = \mathrm{tr}(HVMV) \\ &= \mathrm{tr}(HV^2 - HVHV) = \mathrm{tr}(HV^2) - \mathrm{tr}\big((HV)^2\big) \geq 0,\end{aligned}$$
with equality if and only if $\mathrm{OLSE}(\boldsymbol{\beta}) = \mathrm{BLUE}(\boldsymbol{\beta})$ if and only if the Watson efficiency $\phi = 1$.
10. [DLL02, p. 473] The *Bloomfield–Watson Trace Inequality.* Let A be a nonrandom symmetric $n \times n$ matrix, not necessarily positive semidefinite. Then for all the nonrandom matrices $U \in \mathbb{R}^{n \times p}$ that satisfy $U^TU = I_p$:
$$\mathrm{tr}(U^TA^2U) - \mathrm{tr}\big((U^TAU)^2\big) \leq \frac{1}{4} \sum_{i=1}^{\min(p,n-p)} (\alpha_i - \alpha_{n-i+1})^2,$$
where $\alpha_1 \geq \cdots \geq \alpha_n$ denote the eigenvalues of the $n \times n$ matrix A.

11. The Bloomfield–Watson efficiency

$$\psi = \operatorname{tr}(HV^2) - \operatorname{tr}\big((HV)^2\big) \le \frac{1}{4} \sum_{i=1}^{\min(p,n-p)} (\lambda_i - \lambda_{n-i+1})^2,$$

for all $n \times n$ hat matrices H with rank p (and so for all $n \times p$ model matrices X with full column rank p). Here, $\lambda_1 \ge \cdots \ge \lambda_n$ denote the necessarily positive eigenvalues of the $n \times n$ positive definite covariance matrix V.
12. The $n \times n$ intraclass correlation matrix $R_{\text{ic}} = (1-\rho)I_n - \rho \mathbf{1}_n \mathbf{1}_n^T$ has eigenvalues $1-\rho$ with multiplicity $n-1$ and $1+\rho(n-1)$ with multiplicity 1, and so R_{ic} is singular if and only if $\rho = -1/(n-1)$ or $\rho = 1$.
13. The intraclass correlation coefficient ρ is such that $-1/(n-1) \le \rho \le 1$ and the $n \times n$ intraclass correlation matrix is positive definite if and only if $-1/(n-1) < \rho < 1$.
14. The inverse of the $n \times n$ positive definite intraclass correlation matrix

$$\big((1-\rho)I_n - \rho \mathbf{1}_n \mathbf{1}_n^T\big)^{-1} = \frac{1}{1-\rho}\left(I_n - \frac{\rho}{1+\rho(n-1)} \mathbf{1}_n \mathbf{1}_n^T\right).$$

15. *Gauss–Markov Theorem* (or *Gauß–Markov Theorem*). In the full-rank model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$, the generalized least squares estimator $\tilde{\boldsymbol{\beta}} = \text{GLSE}(\boldsymbol{\beta}) = (X^T V^{-1} X)^{-1} X^T V^{-1} \mathbf{y} = \text{BLUE}(\boldsymbol{\beta})$. In the full-rank model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 I\}$, the ordinary least-squares estimator $\text{OLSE}(\boldsymbol{\beta}) = \hat{\boldsymbol{\beta}} = (X^T X)^{-1} X^T \mathbf{y} = X^\dagger \mathbf{y} = \text{BLUE}(\boldsymbol{\beta})$.
16. In the model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$, where V is positive definite, but with X possibly with less than full column rank, the

$$\text{BLUE}(X\boldsymbol{\beta}) = X(X^T V^{-1} X)^- X^T V^{-1} \mathbf{y}.$$

17. [Sea97, §5.4] Let the matrix $K \in \mathbb{R}^{k \times p}$. Then $K\boldsymbol{\beta}$ is estimable $\iff \exists$ matrix $A \in \mathbb{R}^{n \times k}$: $K^T = X^T A \iff \text{range}(K^T) \subseteq \text{range}(X^T) \iff K\hat{\boldsymbol{\beta}}$ is invariant for any choice of $\hat{\boldsymbol{\beta}} = (X^T X)^- X^T \mathbf{y}$.
18. [Rao73b, p. 282] Consider the general linear model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$, where X and V need not be of full rank. Let the matrix $G \in \mathbb{R}^{n \times n}$. Then $G\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta}) \iff G[X \,|\, VM] = [X \,|\, \mathbf{0}]$, where the residual matrix $M = I - H$. Let the matrix $A \in \mathbb{R}^{k \times n}$ and the matrix $K \in \mathbb{R}^{k \times p}$. Then the corresponding condition for $A\mathbf{y}$ to be the BLUE of an estimable parametric function $K\boldsymbol{\beta}$ is $A[X \,|\, VM] = [K \,|\, \mathbf{0}]$.
19. Let G_1 and G_2 both be $n \times n$. If $G_1\mathbf{y}$ and $G_2\mathbf{y}$ are two BLUEs of $X\boldsymbol{\beta}$ under the model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$, then $G_1\mathbf{y} = G_2\mathbf{y}$ for all $\mathbf{y} \in \text{range}([X \,|\, V])$. The matrix G yielding the BLUE is unique if and only if $\text{range}([X \,|\, V]) = \mathbb{R}^n$.
20. Every linear zero function can be written as $\mathbf{b}^T M \mathbf{y}$ for some nonrandom $\mathbf{b} \in \mathbb{R}^n$. Let the matrix $G \in \mathbb{R}^{n \times n}$. Then an unbiased estimator $G\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta})$ if and only if $G\mathbf{y}$ is uncorrelated with every linear zero function.
21. [Rao71] Let the matrix $A \in \mathbb{R}^{n \times n}$. Then the linear estimator $A\mathbf{y} = \text{BLUE}(X\boldsymbol{\beta})$ under the model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ if and only if there exists a matrix Λ so that A is a solution to *Pandora's box*

$$\begin{bmatrix} V & X \\ X^T & \mathbf{0} \end{bmatrix} \begin{bmatrix} A^T \\ \Lambda \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ X^T \end{bmatrix}.$$

22. [Rao71] Let the $(n+p) \times (n+p)$ matrix B be defined as any generalized inverse:

$$B = \begin{bmatrix} V & X \\ X^T & \mathbf{0} \end{bmatrix}^- = \begin{bmatrix} B_1 & B_2 \\ B_3 & -B_4 \end{bmatrix}.$$

Let $\mathbf{k}^T\boldsymbol{\beta}$ be estimable; then the BLUE$(\mathbf{k}^T\boldsymbol{\beta}) = \mathbf{k}^T\tilde{\boldsymbol{\beta}} = \mathbf{k}^T B_2^T\mathbf{y} = \mathbf{k}^T B_3\mathbf{y}$, the variance $\mathrm{var}(\mathbf{k}^T\tilde{\boldsymbol{\beta}}) = \sigma^2\mathbf{k}^T B_4\mathbf{k}$, and the quadratic form $\mathbf{y}^T B_1\mathbf{y}/f$ is an unbiased estimator of σ^2 with $f = \mathrm{rank}([V \mid X]) - \mathrm{rank}(X)$.

23. [PS89] In the model $\{\mathbf{y}, X\boldsymbol{\beta}, \sigma^2 V\}$ with no rank assumptions, the OLSE$(X\boldsymbol{\beta})$ = BLUE$(X\boldsymbol{\beta})$ if and only if any one of the following equivalent conditions holds:
    (a) $HV = VH$.
    (b) $HV = HVH$.
    (c) $HVM = \mathbf{0}$.
    (d) $X^T VL = \mathbf{0}$, where the $n \times l$ matrix L has range(L) = range(M).
    (e) range$(VX) \subseteq$ range(X).
    (f) range(VX) = range$(X) \cap$ range(V).
    (g) $V \succeq HVH$, i.e., $V - HVH$ is positive semidefinite.
    (h) rank$(V - HVH)$ = rank(V) − rank(HVH).
    (i) rank$(V - HVH)$ = rank(V) − rank(VX).
    (j) range(X) has a basis consisting of r eigenvectors of V, where r = rank(X).
    (k) V can be expressed as $V = \alpha I + XAX^T + LBL^T$, where $\alpha \in \mathbb{R}$, range(L) = range(M), and the $p \times p$ matrices A and B are symmetric, and such that V is positive semidefinite.

    More conditions can be obtained by replacing V with its Moore–Penrose inverse $V^\dagger$ and the hat matrix H with the residual matrix $M = I - H$.
24. Suppose that the positive definite covariance matrix V has h distinct eigenvalues: $\lambda_{\{1\}} > \lambda_{\{2\}} > \cdots > \lambda_{\{h\}} > 0$ with multiplicities $m_1, \ldots, m_h$, $\sum_{i=1}^h m_i = n$, and with associated orthonormalized sets of eigenvectors $U_{\{1\}}, \ldots, U_{\{h\}}$, respectively, $n \times m_1, \ldots, n \times m_h$. Then OLSE$(X\boldsymbol{\beta})$ = BLUE$(X\boldsymbol{\beta})$ if and only if any one of the following equivalent conditions holds:
    (a) rank$(U_{\{1\}}^T X) + \cdots +$ rank$(U_{\{h\}}^T X)$ = rank(X).
    (b) $U_{\{i\}}^T HU_{\{i\}} = (U_{\{i\}}^T HU_{\{i\}})^2$ for all $i = 1, \ldots, h$.
    (c) $U_{\{i\}}^T HU_{\{j\}} = \mathbf{0}$ for all $i \neq j$; $i, j = 1, \ldots, h$.
25. [Rao73b] Let the $p \times p$ matrix U be such that the $n \times n$ matrix $W = V + XUX^T$ has range(W) = range$([X \mid V])$. Then the BLUE$(X\boldsymbol{\beta}) = X(X^T W^- X)^- X^T W^- \mathbf{y}$.
26. When V is nonsingular, the $n \times n$ matrix G such that $G\mathbf{y}$ is the BLUE of $X\boldsymbol{\beta}$ is unique, but when V is singular this may not be so. However, the numerical value of BLUE$(X\boldsymbol{\beta})$ is unique with probability 1.
27. [SJ03, §7.4] The residual vector associated with the BLUE$(X\boldsymbol{\beta})$ is

    $$\tilde{\mathbf{e}} = \mathbf{y} - X\tilde{\boldsymbol{\beta}} = VM(MVM)^- M\mathbf{y} = M\mathbf{y} + HVM(MVM)^- M\mathbf{y},$$

    which is invariant (unique) with respect to choice of generalized inverse $(MVM)^-$. The weighted sum of squares of BLUE residuals, which is needed when estimating σ^2, can be written as $(\mathbf{y} - X\tilde{\boldsymbol{\beta}})^T V^-(\mathbf{y} - X\tilde{\boldsymbol{\beta}}) = \tilde{\mathbf{e}}^T V^- \tilde{\mathbf{e}} = \mathbf{y}^T M(MVM)^- M\mathbf{y}$.

Examples:

1. Let $n = 3$ and $p = 2$ with the model matrix $X = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 1 & -1 \end{bmatrix}$. Then X has full column rank equal to 2, the matrix $X^T X$ is nonsingular, and the hat matrix is

    $$H = X(X^T X)^- X^T = X(X^T X)^{-1} X^T = \frac{1}{6}\begin{bmatrix} 5 & 2 & -1 \\ 2 & 2 & 2 \\ -1 & 2 & 5 \end{bmatrix}$$

with $\text{rank}(H) = \text{tr}(H) = 2$. The OLSE($\boldsymbol{\beta}$) is

$$\hat{\boldsymbol{\beta}} = (X^T X)^{-1} X^T \mathbf{y} = \begin{bmatrix} \frac{1}{3}(y_1 + y_2 + y_3) \\ \frac{1}{2}(y_1 - y_3) \end{bmatrix},$$

where $\mathbf{y} = [y_1, y_2, y_3]^T$. The vector of OLS residuals is

$$M\mathbf{y} = \frac{1}{6} \begin{bmatrix} 1 & -2 & 1 \\ -2 & 4 & -2 \\ 1 & -2 & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = \frac{1}{6}(y_1 - 2y_2 + y_3) \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix}$$

with residual sum of squares $SSE = (y_1 - 2y_2 + y_3)^2/6$.

Now let the variance $\sigma^2 = 1$ and let the covariance matrix

$$V = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \delta & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

with $\delta > 0$. Then V is positive definite and

$$\text{BLUE}(\boldsymbol{\beta}) = \text{GLSE}(\boldsymbol{\beta}) = \tilde{\boldsymbol{\beta}} = \begin{bmatrix} \frac{1}{2\delta+1}(\delta y_1 + y_2 + \delta y_3) \\ \frac{1}{2}(y_1 - y_3) \end{bmatrix},$$

while the covariance matrices are

$$\text{var}(\tilde{\boldsymbol{\beta}}) = \begin{bmatrix} \frac{\delta}{2\delta+1} & 0 \\ 0 & \frac{1}{2} \end{bmatrix}, \quad \text{var}(\hat{\boldsymbol{\beta}}) = \begin{bmatrix} \frac{\delta+2}{9} & 0 \\ 0 & \frac{1}{2} \end{bmatrix}.$$

Hence, the Watson efficiency

$$\phi = \frac{9\delta}{(2\delta + 1)(\delta + 2)} \leq 1$$

with equality if and only if $\delta = 1$. As $\delta \to 0$ or $\delta \to \infty$, the Watson efficiency $\phi \to 0$.

Since the eigenvalues of V here are 1 (multiplicity 2) and δ (multiplicity 1), we find that the lower bound for ϕ in the Bloomfield–Watson–Knott Inequality [here, $m = \min(p, n - p) = \min(2, 1) = 1$] is equal to $4\delta/(1 + \delta)^2$, and it is easy to show that this is less than $9\delta/\big((2\delta + 1)(\delta + 2)\big)$ (unless $\delta = 1$, and then both these ratios are equal to 1).

The Bloomfield–Watson efficiency

$$\psi = \frac{2}{9}(1 - \delta)^2 \geq 0$$

with equality if and only if $\delta = 1$. As $\delta \to 0$ the Bloomfield–Watson efficiency $\psi \to 2/9$, and as $\delta \to \infty$ the Bloomfield–Watson efficiency $\psi \to \infty$. We note that when $\delta = 0$, then Σ is singular, but ψ is well defined and equal to $2/9$. We find that the upper bound for ψ in the Bloomfield–Watson Trace Inequality is $(1 - \delta)^2/4$ and certainly $(1 - \delta)^2/4 \geq 2(1 - \delta)^2/9$ with equality if and only if $\delta = 1$.

2. Let $n = 3$ and $p = 1$ with the model matrix $X = \mathbf{x} = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}$ and with $\boldsymbol{\beta} = \beta$, a scalar. The hat matrix

$$H = X(X^T X)^{-1} X^T = \frac{1}{\mathbf{x}^T \mathbf{x}} \mathbf{x}\mathbf{x}^T = \frac{1}{14} \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 6 \\ 3 & 6 & 9 \end{bmatrix}$$

and so

$$\hat{\beta} = \text{OLSE}(\beta) = \frac{\mathbf{x}^T\mathbf{y}}{\mathbf{x}^T\mathbf{x}} = \frac{y_1 + 2y_2 + 3y_3}{14},$$

where the realization $\mathbf{y} = [y_1, y_2, y_3]^T$.

Let the covariance matrix have intraclass correlation structure:

$$V = \begin{bmatrix} 1 & \rho & \rho \\ \rho & 1 & \rho \\ \rho & \rho & 1 \end{bmatrix}$$

with $-1/2 < \rho < 1$. Then V is positive definite and its inverse

$$V^{-1} = \frac{1}{(1-\rho)(1+2\rho)} \begin{bmatrix} 1+\rho & -\rho & -\rho \\ -\rho & 1+\rho & -\rho \\ -\rho & -\rho & 1+\rho \end{bmatrix}.$$

And so

$$\tilde{\beta} = \text{BLUE}(\beta) = \text{GLSE}(\beta) = \frac{\mathbf{x}^T V^{-1}\mathbf{y}}{\mathbf{x}^T V^{-1}\mathbf{x}} = \frac{(1-4\rho)y_1 + 2(1-\rho)y_2 + 3y_3}{6(1-\rho)}.$$

The variances are (with $\sigma^2 = 1$):

$$\text{var}(\tilde{\beta}) = \frac{1}{\mathbf{x}^T V^{-1}\mathbf{x}} = \frac{(1-\rho)(1+2\rho)}{2(7-4\rho)}; \quad \text{var}(\hat{\beta}) = \frac{\mathbf{x}^T V\mathbf{x}}{(\mathbf{x}^T\mathbf{x})^2} = \frac{7+11\rho}{98},$$

and so the Watson efficiency

$$\phi = \frac{\text{var}(\tilde{\beta})}{\text{var}(\hat{\beta})} = \frac{49(1-\rho)(1+2\rho)}{(7-4\rho)(7+11\rho)} \to 0$$

as $\rho \to -1/2$ or as $\rho \to 1$. As $\rho \to 0$ the Watson efficiency $\phi \to 1$.

Since the eigenvalues of V here are $1-\rho$ (multiplicity 2) and $1+2\rho$ (multiplicity 1), we find that the lower bound for ϕ in the Bloomfield–Watson–Knott Inequality (which is now the Kantorovich Inequality) is $4(1-\rho)(1+2\rho)/(2+\rho)^2$ and it is easy to show that this is less than $\phi = 49(1-\rho)(1+2\rho)/\big((7-4\rho)(7+11\rho)\big)$ (unless $\rho = 0$ and then both these ratios are equal to 1).

The Bloomfield–Watson efficiency $\psi = 54\rho^2/49$, which is well defined for all ρ; when $\rho = -1/2$, then $\psi = 27/98$ and when $\rho = 1$, then $\psi = 54/49$. We find that the upper bound for ψ in the Bloomfield–Watson Trace Inequality is $9\rho^2/4$ and certainly $9\rho^2/4 \geq \psi = 54\rho^2/49$, with equality if and only if $\rho = 0$.

3. [DLL02, p. 475] Let A be a nonrandom symmetric $n \times n$ matrix, not necessarily positive semidefinite, and let the nonrandom vector $\mathbf{u} = [u_1, \ldots, u_n]^T$ be such that $\mathbf{u}^T\mathbf{u} = 1$. Then from the Bloomfield–Watson Trace Inequality with $U = \mathbf{u}$, we obtain the special case

$$\mathbf{u}^T A^2 \mathbf{u} - \big(\mathbf{u}^T A\mathbf{u}\big)^2 \leq \frac{1}{4}(\alpha_1 - \alpha_n)^2,$$

where α_1 and α_n are, respectively, the largest and smallest eigenvalues of A. Now let $a_1, \ldots, a_n$ denote n nonrandom scalars, not necessarily all positive, and let $\bar{a} = \sum_{i=1}^n a_i/n$. Then the Popoviciu–Nair Inequality

$$\frac{1}{n}\sum_{i=1}^{n}(a_i - \bar{a})^2 \leq \frac{1}{4}(a_{\max} - a_{\min})^2$$

follows directly from the special case above of the Bloomfield–Watson Trace Inequality with $\mathbf{u} = \mathbf{1}/\sqrt{n}$ and $A = \text{diag}\{a_i\}$.

4. When the covariance matrix V has intraclass correlation structure, then the OLSE$(X\boldsymbol{\beta})$ $=$ BLUE$(X\boldsymbol{\beta})$ if and only if $X^T\mathbf{1}_n = \mathbf{0}$ or $X\mathbf{f} = \mathbf{1}_n$ for some nonrandom $p \times 1$ vector $\mathbf{f}$, and so OLSE$(X\boldsymbol{\beta})$ $=$ BLUE$(X\boldsymbol{\beta})$ when the columns of X are centered or when $\mathbf{1}_n \in \text{range}(X)$ as in Example 1 above, where $X = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 1 & -1 \end{bmatrix}$ with first column equal to $\mathbf{1}_3$.
5. Let the $n \times p$ model matrix $X = [\mathbf{1} \,|\, X_0]$, where $\mathbf{1}$ is the $n \times 1$ column vector with every entry equal to 1 and X_0 is $n \times (p-1)$. Then the hat matrix associated with X,

$$H = \frac{1}{n}\mathbf{1}_n\mathbf{1}_n^T + C_nX_0(X_0^TC_nX_0)^-X_0^TC_n$$

coincides with the hat matrix associated with $X_c = [\mathbf{1}_n \,|\, C_nX_0]$, since $X_c = XQ$, with the $p \times p$ matrix $Q = \begin{bmatrix} 1 & -\mathbf{q}^T \\ \mathbf{0} & I_{p-1} \end{bmatrix}$ for some $\mathbf{q}$.

When $p = 2$, we may write $X_0 = \mathbf{x}$, an $n \times 1$ vector, and if X now has rank equal to 2, then $\mathbf{x}^TC_n\mathbf{x} > 0$ and the hat matrix

$$H = \frac{1}{n}\mathbf{1}_n\mathbf{1}_n^T + \frac{1}{\mathbf{x}^TC_n\mathbf{x}}C_n\mathbf{x}\mathbf{x}^TC_n.$$

And so the quadratic forms

$$\mathbf{y}^TH\mathbf{y} = n\bar{y}^2 + \frac{(\mathbf{x}^TC_n\mathbf{y})^2}{\mathbf{x}^TC_n\mathbf{x}}, \quad \mathbf{y}^TM\mathbf{y} = \mathbf{y}^TC_n\mathbf{y} + \frac{(\mathbf{x}^TC_n\mathbf{y})^2}{\mathbf{x}^TC_n\mathbf{x}},$$

where $\bar{y} = \sum_{i=1}^n y_i/n = \mathbf{1}_n^T\mathbf{y}/n$.

Vectors and matrices arise naturally in the analysis of statistical data and we have seen this in Chapter 70. For example, suppose we take a random sample of n females and measure their heights x_i $(i = 1, 2, \ldots, n)$, giving us the vector $\mathbf{x} = [x_1, x_2, \ldots, x_n]^T$. We can treat $\mathbf{x}$ simply as a random vector, which can give rise to different values depending on the sample chosen, or as a vector of observed values (the data) taken on by the random vector from which we calculate a statistic like a sample mean (average). We use the former approach when we want to make inferences about the female population. In this case, we find that the value of a given x_i will depend on how it varies across the population, and this is described by its statistical "distribution," which is defined by a univariate function of one variable called a probability density function (pdf). For example, x_i may follow the well-known normal distribution, which seems to apply to many naturally occurring measurements. This distribution has a probability density function totally characterized by two (unknown) parameters, the population mean μ and the population variance σ^2, where σ is the standard deviation; we write $x_i \sim \mathrm{N}_1(\mu, \sigma^2)$, where "$\sim$" means "distributed as." (Throughout this chapter, σ will always refer to a standard deviation and not to a singular value.) When the sample is random, the choice of any female does not affect the choice of any other, so that technically we say that the x_i are statistically independent and they all have the same distribution.

Three important aspects of statistical inference are: (1) estimating μ from the data and deriving the distributional properties of the estimate from the assumed underlying pdf; (2) finding a so-called confidence interval for μ, which is an interval containing the true value of μ with a given probability, e.g., 0.95 or, when typically expressed as a percentage, 95%; and (3) testing a hypothesis (called the null hypothesis H_0) about whether $\boldsymbol{\mu}$ is equal to some predetermined value μ_0, say. Symbolically, we write $H_0 : \mu = \mu_0$. To test H_0, we need to have a test statistic and be able to derive its distribution when H_0 is true and when it is false, called the noncentral distribution in the latter case. Noncentral distributions are usually quite complex, but they have a role in determining how good a test is in detecting departures from the null hypothesis.

In multivariate analysis we are interested in measuring not just a single characteristic or variable on each female, but we may also want to record weight, income, blood pressure, and so on, so that each x_i gets replaced by a d-dimensional vector $\mathbf{x}_i$ of d variables. Then $\mathbf{x}$ from the sample of recorded heights gets replaced by a matrix X with rows $\mathbf{x}_i'$. In this case the probability density function for $\mathbf{x}_i$ is said to be multivariate and the population mean is now a vector $\boldsymbol{\mu}$, say. We can look at X as either a matrix of numbers or a random matrix, which we use for carrying out statistical inferences. In doing this, the univariate normal distribution extends naturally to the multivariate normal distribution, which has a pdf totally characterized by its mean $\boldsymbol{\mu}$ and its covariance matrix $\mathrm{var}(\mathbf{x}) = \Sigma$. One can then derive other distributions based on various functions of X, which can then be used for inference.

The vectors $\mathbf{x}_i$ can be regarded as a cluster of points in $\mathbb{R}^d$. Such a set of points can also come from sampling a mixed population of men and women so that there would be two overlapping clusters. Alternatively, the population of females could be a mixture of races, each with its own characteristics, leading to several overlapping clusters. In order to study such clusters, we need techniques to somehow reduce the dimension of the data (hopefully, to two dimensions) in some optimal fashion, but still retain as much of the original variation as possible. We will introduce just three dimension-reducing techniques below. The first method, called principal component analysis, is used for a single cluster. The second method, called discriminant coordinates, is used for several clusters and the reduction in dimension is carried out to maximize group separation. The third method, called canonical variates, is also used for a single cluster, but utilizes the internal variation within the vectors. Looking at how one variable within a vector depends on the other variables lends itself to a range of other techniques, such as multivariate linear regression where we might compare the internal relationships in one cluster with those in others. For example, comparing how blood pressure depends on other variables for both males and females.

We finally introduce just one other topic called metric multidimensional scaling. Instead of having observations on n people or objects, we simply have measures of similarity or dissimilarity between each pair of objects. The challenge then is to try and represent these objects as a cluster in a low-dimensional space so that the inter-point Euclidean distances will closely reproduce the dissimilarity measures. Once we have the cluster we can then examine it to try to uncover any underlying structure or clustering of the objects.

It is hoped that these few applications will demonstrate the richness of the subject and its interplay between statistics and matrices. In this chapter we assume some of the basic statistical ideas defined in Chapter 70. However, there has to be a change in notation as we now need to continually distinguish between random and nonrandom vectors and matrices.

71.1 Data Matrix

Notation:

The latter part of the alphabet from u to z, upper or lower case, together with Q we reserve for random quantities, and the remainder of the alphabet for nonrandom quantities. All quantities in this section are real, though in practice some of the theory can be extended to complex quantities, as, for example, in the theory of time series.

Definitions:

If $\mathbf{w} = [\mathbf{y}^T, \mathbf{z}^T]^T$ is a random vector, then $\mathbf{y}$ and $\mathbf{z}$ are said to be **uncorrelated** if and only if their cross-covariance $\text{cov}(\mathbf{y}, \mathbf{z}) = \mathbf{0}$. We say that $\mathbf{y}$ and $\mathbf{z}$ are **statistically independent** if and only if the probability density function (pdf) of $\mathbf{w}$ is the product of the pdfs of $\mathbf{y}$ and $\mathbf{z}$.

Let $X = [x_{ij}] = \begin{bmatrix} \mathbf{x}_1^T \\ \mathbf{x}_2^T \\ \cdots \\ \mathbf{x}_n^T \end{bmatrix} = [\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \ldots, \mathbf{x}^{(d)}]$ be an $n \times d$ matrix of random variables with rows $\mathbf{x}_i^T$ such that all $\mathbf{x}_i$ have the same covariance matrix Σ and are uncorrelated, i.e., $\text{cov}(\mathbf{x}_r, \mathbf{x}_s) = \delta_{rs}\Sigma$, where $\delta_{rs} = 1$ for $r = s$ and $\delta_{rs} = 0$ for $r \neq s$. We call a matrix with the above properties a **data matrix**. As mentioned in the introduction, the $\mathbf{x}_i$ often constitute a random sample, which we now formally define. A **random sample** of vectors $\mathbf{x}_i$ $(i = 1, 2, \ldots, n)$ of size n consists of n random vectors that are **independently and identically distributed (i.i.d.)**, that is, they are statistically independent of each other and have the same pdf. When this is the case, we see from the data matrix above that the n elements of $\mathbf{x}^{(j)}$ form a random sample from the jth characteristic or variable, being just the jth elements in each $\mathbf{x}_i$. However, $\mathbf{x}^{(j)}$ and $\mathbf{x}^{(k)}$ $(j \neq k)$ can be correlated.

The **moment generating function** or m.g.f. of any random vector $\mathbf{x}$ is defined to be $M_{\mathbf{x}}(\mathbf{t}) = \text{E}(\text{e}^{\mathbf{t}^T\mathbf{x}})$. It can be used for finding such things as the mean and covariance matrix, or the distribution of related random variables.

Facts:

1. For a random variable x, $M_x(t) = \text{E}(\text{e}^{xt}) = \sum_{r=0}^{\infty} \text{E}(x^r)\frac{t^r}{r!}$. The coefficient of $\frac{t^r}{r!}$ in the power series expansion of $M_x(t)$ gives us $\text{E}(x^r)$ from which we can get $\mu = \text{E}(x)$ and $\text{var}(x) = \text{E}(x^2) - \mu^2$.
2. Statistical independence implies zero covariance but not generally vice versa except for one notable exception, the multivariate normal distribution (see next section).

71.2 Multivariate Normal Distribution

Definitions:

Let $\mathbf{x} = [x_i] = [x_1, x_2, \ldots, x_d]^T$ be a $d \times 1$ random vector with mean $\boldsymbol{\mu}$ and positive definite covariance matrix Σ. Then $\mathbf{x}$ is said to follow a **(nonsingular) multivariate normal distribution** when its pdf is

$$f(\mathbf{x} : \boldsymbol{\mu}, \Sigma) = (2\pi)^{-d/2}(\det \Sigma)^{-1/2} \exp\{-\tfrac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T\Sigma^{-1/2}(\mathbf{x} - \boldsymbol{\mu})\},$$

where $-\infty < x_j < \infty$, $j = 1, 2, \ldots, d$. We write $\mathbf{x} \sim \text{N}_d(\boldsymbol{\mu}, \Sigma)$. When $d = 1$ we have the univariate normal distribution. When Σ is singular, the pdf of $\mathbf{x}$ does not exist but it can be defined via a transformation $\mathbf{x} = A\mathbf{y}$ where $\mathbf{y}$ does have a nonsingular distribution. This is mentioned further below.

The **noncentral χ^2-distribution** with p degrees of freedom and noncentrality parameter δ, denoted by $\chi^2_{p,\delta}$, is the distribution of $\mathbf{x}^T\mathbf{x}$ when $\mathbf{x} \sim \text{N}_p(\boldsymbol{\mu}, I_p)$ and $\delta = \boldsymbol{\mu}^T\boldsymbol{\mu}$. The distribution is said to be **central** whenever $\delta = 0$, and we denote it by χ^2_p.

The **noncentral F-distribution** with m, n degrees of freedom and noncentrality parameter δ, denoted by $F(m, n; \delta)$, is the distribution of the so-called **F-ratio** $F = \frac{u/m}{v/n}$, where $u \sim \chi^2_{m,\delta}$, $v \sim \chi^2_n$, and u and v are independent. The distribution is **central** whenever $\delta = 0$ and we then write $F \sim F(m, n)$.

Facts:

All the following facts except those with a specific reference can be found in [And03, Chap. 2], [Rao73, Sect. 8a], [Seb08, Sect. 20] or [SL03, Chap. 1].

We can extend our definition to include the singular multivariate normal distribution using one of the first two facts below as a definition, each of which includes both the nonsingular and singular cases. When we write $\mathbf{x} \sim \mathrm{N}_d(\boldsymbol{\mu}, \Sigma)$, we include both possibilities unless otherwise stated.

1. Assuming for the trivial case that $y \sim \mathrm{N}_1(b, 0)$ means $y = b$ with probability 1, then the random $d \times 1$ vector $\mathbf{x}$ follows a multivariate normal distribution if and only if $y = \mathbf{a}^T\mathbf{x}$ is univariate normal for all $d \times 1$ vectors $\mathbf{a}$.
2. A random $d \times 1$ vector $\mathbf{x}$ with mean $\boldsymbol{\mu}$ and covariance matrix Σ follows a multivariate normal distribution of rank $m \leq d$ when it has the same distribution as $A\mathbf{z}+\boldsymbol{\mu}$, where A is any $d \times m$ matrix satisfying $\Sigma = AA^T$ and $\mathbf{z} \sim \mathrm{N}_m(\mathbf{0},\, I_m)$.
3. Given $\mathbf{x} \sim \mathrm{N}_d(\boldsymbol{\mu}, \Sigma)$, then the m.g.f. of $\mathbf{x}$ is $M_{\mathbf{x}}(\mathbf{t}) = \mathrm{e}^{\mathbf{t}^T\boldsymbol{\mu}+\frac{1}{2}\mathbf{t}^T\Sigma\mathbf{t}}$. When Σ is positive definite, this m.g.f. uniquely determines the nonsingular multivariate normal distribution.
4. Given $\mathbf{x} \sim \mathrm{N}_d(\boldsymbol{\mu}, \Sigma)$ and A $m \times d$, then $A\mathbf{x} \sim \mathrm{N}_m(A\boldsymbol{\mu},\, A\Sigma A^T)$. The distribution is nonsingular if and only if $A\Sigma$ has full row rank $m\,(m \leq d)$, which is assured when Σ is positive definite and A has rank m.
5. Any subset of the components of a multivariate normal random variable is multivariate normal.
6. If the cross-covariance matrix of any two vectors which contain disjoint subsets of $\mathbf{x}$ is zero, then the two vectors are statistically independent.
7. If the cross-covariance matrix $\mathrm{cov}(A\mathbf{x}, B\mathbf{x}) = \mathbf{0}$, then $A\mathbf{x}$ and $B\mathbf{x}$ are statistically independent.
8. If Σ is positive definite, then $(\mathbf{x}-\boldsymbol{\mu})^T\Sigma^{-1}(\mathbf{x}-\boldsymbol{\mu}) \sim \chi^2_d$, the central χ^2-distribution with d degrees of freedom.
9. Let $\mathbf{x}$ be an $n \times 1$ random vector with $\mathrm{E}(\mathbf{x}) = \boldsymbol{\mu}$ and $\mathrm{var}(\mathbf{x}) = \Sigma$, and having any distribution. If A is any symmetric $n \times n$ matrix, then $\mathrm{E}[(\mathbf{x}-\mathbf{a})^T A(\mathbf{x}-\mathbf{a})] = \mathrm{tr}(A\Sigma) + (\boldsymbol{\mu}-\mathbf{a})^T A(\boldsymbol{\mu}-\mathbf{a})$.
10. Let $\mathbf{x} = [x_i]$ be an $n \times 1$ random vector with $\mathrm{E}(x_i) = \theta_i$ and $\mu_r = \mathrm{E}(x_i-\theta_i)^r$; $r = 2, 3, 4$. If A is any $n \times n$ symmetric matrix and $\mathbf{a}$ is the column vector of the diagonal elements of A, then

$$\mathrm{var}(\mathbf{x}^T A\mathbf{x}) = (\mu_4 - 3\mu_2^2)\mathbf{a}^T\mathbf{a} + 2\mu_2^2\mathrm{tr}A^2 + 4\mu_2\boldsymbol{\theta}^T A^2\boldsymbol{\theta} + 4\mu_3\boldsymbol{\theta}^T A\mathbf{a}.$$

Examples:

1. If $x \sim \mathrm{N}_1(0, \sigma^2)$, then $M_x(t) = \mathrm{e}^{\frac{1}{2}\sigma^2t^2}$ from Fact 3 above. Since $\mu = 0$, $\mu_r = \mathrm{E}(x^r)$ can be found by expanding $M_x(t)$ and finding the coefficient of $t^r/r!$. For example, $\mu_2 = \sigma^2, \mu_3 = 0$, and $\mu_4 = 3\mu_2^2$.
2. If the x_i $(i = 1, 2, \ldots, n)$ are i.i.d. as $\mathrm{N}_1(0,\, \sigma^2)$, then by either multiplying pdfs together for independent random variables or using m.g.f.s we find that $\mathbf{x} \sim \mathrm{N}_n(\mathbf{0},\, \sigma^2 I_n)$. Substituting the results from the previous example into Fact 10 we get $\mathrm{var}(\mathbf{x}^T A\mathbf{x}) = 2\sigma^4\mathrm{tr}A^2$.

71.3 Inference for the Multivariate Normal

Definitions:

Given a random sample $\{\mathbf{x}_i\}$ that are i.i.d., from the nonsingular multivariate normal distribution, the **likelihood function** is defined to be the joint pdf of the sample expressed as a function of the unknown parameters, namely,

$$L(\mathbf{u},\Sigma)=\prod_{i=1}^{n} f(\mathbf{x}_i;\boldsymbol{\mu},\Sigma).$$

The parameter estimates that maximize this function are called the **maximum likelihood estimates**. The **sample mean** of the sample is defined to be $\bar{\mathbf{x}}=\sum_{i=1}^{n}\mathbf{x}_i/n$, and is not to be confused with the complex conjugate.

Facts:

1. The maximum likelihood estimates of $\boldsymbol{\mu}$ and Σ are, respectively, $\widehat{\boldsymbol{\mu}}=\bar{\mathbf{x}}$ and $\widehat{\Sigma}=Q/n=\sum_{i=1}^{n}(\mathbf{x}_i-\bar{\mathbf{x}})(\mathbf{x}_i-\bar{\mathbf{x}})^T/n$. Here, "$\widehat{\ }$" denotes "estimate of" in statistics.
2. $Q=X^TCX$, where X is the data matrix previously defined and the centering matrix $C=I_n-\frac{1}{n}\mathbf{1}\mathbf{1}^T$ is symmetric and idempotent. Also, $CX=[\mathbf{x}_1-\bar{\mathbf{x}},\ldots,\mathbf{x}_n-\bar{\mathbf{x}}]^T=\tilde{X}$, say, and $Q=\tilde{X}^T\tilde{X}$.

71.4 Principal Component Analysis

Definitions:

Let $\mathbf{x}$ be a random d-dimensional vector with mean $\boldsymbol{\mu}$ and positive definite covariance matrix Σ. Let $T=[\mathbf{t}_1,\mathbf{t}_2,\ldots,\mathbf{t}_d]$ be an orthogonal matrix such that $T^T\Sigma T=\Lambda=\text{diag}(\lambda_1,\lambda_2,\ldots,\lambda_d)$, where $\lambda_1\geq\lambda_2\geq\cdots\geq\lambda_d>0$ are the ordered eigenvalues of Σ. The sum $\text{tr}\Sigma$ is sometimes called the **total variance**. If $\mathbf{y}=[y_j]=T^T(\mathbf{x}-\boldsymbol{\mu})$, then $y_j=\mathbf{t}_j^T(\mathbf{x}-\boldsymbol{\mu})$ $(j=1,2,\ldots,d)$ is called the jth **population principal component** of $\mathbf{x}$, and $z_j=\lambda_j^{-1/2}y_j$ is called the jth **standardized population principal component**.

In practice, $\boldsymbol{\mu}$ and Σ are unknown and have to be estimated from a sample $\mathbf{x}_1,\mathbf{x}_2,\ldots,\mathbf{x}_n$. Assuming that the underlying distribution is multivariate normal we can use the estimates of the previous section, $\bar{\mathbf{x}}$ and $\widehat{\Sigma}=\tilde{X}^T\tilde{X}/n$. Carrying out a similar factorization on $\widehat{\Sigma}$ as we did for Σ, we obtain the eigenvalues $\hat{\lambda}_1\geq\hat{\lambda}_2\geq\cdots\geq\hat{\lambda}_d>0$ and an orthogonal matrix $\widehat{T}=[\hat{\mathbf{t}}_1,\hat{\mathbf{t}}_2,\ldots,\hat{\mathbf{t}}_d]$ of corresponding eigenvectors. For each observation $\mathbf{x}_i$, we can define a vector $\widehat{\mathbf{y}}_i=\widehat{T}^T(\mathbf{x}_i-\bar{\mathbf{x}})$ of **sample principal components** or **estimated principal components** yielding $\widehat{Y}^T=[\widehat{\mathbf{y}}_1,\widehat{\mathbf{y}}_2,\ldots,\widehat{\mathbf{y}}_n]=\widehat{T}^T\tilde{X}^T$.

Although the above method is mainly used descriptively, asymptotic inference for large n can be carried out on the assumption that the underlying distribution is normal.

Facts:

The following facts can be found in [Chr01, Sects. 3.1–3.3], [PSI11, Sect. 19.4], [Rao73, Sect. 8g2], or [Seb04, Sect. 5.2].

1. As $\text{var}(\mathbf{y})=\Lambda$, which is diagonal, the y_j are uncorrelated and $\text{var}(y_j)=\lambda_j$.
2. $\sum_{j=1}^{d}\text{var}(y_j)=\sum_{j=1}^{d}\text{var}(x_j)=\text{tr}\Sigma$. We can use $\lambda_j/\text{tr}\Sigma$ to measure the relative magnitude of λ_j. If the λ_i $(i=k+1,\ldots,d)$ are relatively small so that the corresponding y_i are "small" (with zero means and small variances), then $\mathbf{y}_{(k)}=[y_1,y_2,\ldots,y_k]^T$ can be regarded as a k-dimensional approximation for $\mathbf{y}$. Thus, $\mathbf{y}_{(k)}$ can be used as a "proxy" for $\mathbf{x}$ in terms of explaining a major part of the total variance.
3. Let $T_{(k)}=[\mathbf{t}_1,\ldots,\mathbf{t}_k]$. Then:

   (a) $\max\limits_{\mathbf{a}^T\mathbf{a}=1}\text{var}(\mathbf{a}^T\mathbf{x})=\text{var}(\mathbf{t}_1^T\mathbf{x})=\text{var}\big(\mathbf{t}_1^T(\mathbf{x}-\boldsymbol{\mu})\big)=\text{var}(y_1)=\lambda_1,$
   so that y_1 is the normalized linear combination of the elements of $\mathbf{x}-\boldsymbol{\mu}$ with maximum variance λ_1.

(b) $\max\limits_{\mathbf{a}^T\mathbf{a}=1,T_{(k-1)}^T\mathbf{a}=\mathbf{0}} \operatorname{var}(\mathbf{a}^T\mathbf{x}) = \operatorname{var}(\mathbf{t}_k^T\mathbf{x}) = \operatorname{var}(y_k) = \lambda_k,$

so that $\mathbf{t}_k^T(\mathbf{x}-\boldsymbol{\mu})$ is the normalized linear combination of the elements $\mathbf{x}-\boldsymbol{\mu}$ uncorrelated with $y_1, y_2, \ldots, y_{k-1}$, with maximum variance λ_k.

4. $\hat{y}_{ij} = \hat{\mathbf{t}}_j^T(\mathbf{x}_i - \bar{\mathbf{x}})$, the score of the ith individual on the jth sample principal component, is related to the orthogonal projection of $\mathbf{x}_i - \bar{\mathbf{x}}$ onto range$(\hat{\mathbf{t}}_j)$, namely $P_{\hat{\mathbf{t}}_j}(\mathbf{x}_i - \bar{\mathbf{x}}) = \hat{\mathbf{t}}_j\hat{\mathbf{t}}_j^T(\mathbf{x}_i - \bar{\mathbf{x}}) = \hat{y}_{ij}\hat{\mathbf{t}}_j$.

Examples:

1. Suppose we assume that each $\mathbf{x}_i$ is just an observed vector, i.e., a constant. Let $\mathbf{v}$ be a discrete random vector taking the values $\mathbf{x}_i$ $(i = 1, 2, \ldots, n)$ with probability $\frac{1}{n}$. Then $\mathrm{E}(\mathbf{v}) = \sum_{i=1}^n \mathbf{x}_i\, P(\mathbf{v} = \mathbf{x}_i) = \sum_{i=1}^n \mathbf{x}_i/n = \bar{\mathbf{x}}$ and, similarly, $\operatorname{var}(\mathbf{v}) = \widehat{\Sigma}$. This means that the sample principal components for $\mathbf{x}$ are the population components for $\mathbf{v}$ so that all the optimal properties of population principal components hold correspondingly for the sample principal components.
2. Entomologists are interested in the number of distinct taxa present in a population of winged aphids as they are difficult to identify. Forty aphids were trapped and 19 variables on each aphid were measured. A principal component analysis was carried out and the first two components accounted for 85% of the estimate of the total variance giving an effective reduction from 19 to 2 dimensions. The 2-dimensional $\widehat{\mathbf{y}}_i$ were plotted showing the presence of four groups. Also, the $\widehat{\mathbf{t}}_r$ $(r = 1, 2)$ suggested which two linear combinations of the 19 measurements gave the best discrimination. As the aphids came from slightly different populations, the original assumption that the sample is from a homogeneous population is not quite true, but it does provide a starting place for further study, e.g., use discriminant coordinates described in the next section with four groups.

71.5 Discriminant Coordinates

Definitions:

Suppose we have n d-dimensional observations of which n_i belong to group i from the ith underlying population $(i = 1, 2, \ldots, g;\ n = \sum_{i=1}^g n_i)$. Let $\mathbf{x}_{ij}$ be the jth observation in group i, and define

$$\bar{\mathbf{x}}_{i\cdot} = \frac{1}{n_i}\sum_{j=1}^{n_i} \mathbf{x}_{ij} \quad \text{and} \quad \bar{\mathbf{x}}_{\cdot\cdot} = \frac{1}{n}\sum_{i=1}^{g}\sum_{j=1}^{n_i} \mathbf{x}_{ij}\,.$$

Let $W_g = \sum_{i=1}^g \sum_{j=1}^{n_i}(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})(\mathbf{x}_{ij} - \bar{\mathbf{x}}_{i\cdot})^T$, the **within-groups matrix**, and let $W_b = \sum_{i=1}^g n_i(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})(\bar{\mathbf{x}}_{i\cdot} - \bar{\mathbf{x}}_{\cdot\cdot})^T$, the **between-groups matrix**. Since W_g and W_b are positive definite with probability 1, the eigenvalues of $W_g^{-1}W_b$, which are the same as those of $W_g^{-1/2}W_bW_g^{-1/2}$, are positive and distinct with probability 1, say $\lambda_1 > \lambda_2 > \cdots > \lambda_d > 0$.

Let $W_g^{-1}W_b\mathbf{c}_r = \lambda_r\mathbf{c}_r$ be suitably scaled eigenvectors and define $C^T = [\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_k]$ $(k \leq d)$. If we define $\mathbf{y}_{ij} = C\mathbf{x}_{ij}$, then the k elements of $\mathbf{z}_{ij}$ are called the first k **discriminant coordinates** (or **canonical variates**). These coordinates are determined so as to emphasize group separation, but with decreasing effectiveness so that k has to be determined. The coordinates can be computed using an appropriate transformation combined with a principal component analysis. Typically the $\mathbf{c}_i$ are scaled so that $CSC^T = I_r$, where $S = W_g/(n-g)$.

Examples:

1. Trivariate measurements $\mathbf{x}_{ij}$ were taken on the skulls of six collections (four subspecies with three collections apparently from the same species) of anteaters. Using six groups of data from six underlying populations in the above theory, we found that $[\lambda_1, \lambda_2, \lambda_3] = [2.400, 0.905, 0.052]$. Since λ_3 was small, we chose $k = 2$. We could, therefore, transform the 3-dimensional observations $\mathbf{x}_{ij}$ into the 2-dimensional $\mathbf{y}_{ij} = C\mathbf{x}_{ij}$ and still account for most of the variation in the data. The 2-dimensional reductions were then plotted to help us look for any patterns. As an aid to our search, it was possible to draw a circle with center the reduced mean of each group so that the circle contained any reduced random observation from its population with probability 0.95. The center of the circle locates the center of gravity of the group and the boundary of the circle shows where the bulk of the observations are expected to lie. The closeness of these circles indicated how "close" the groups and subspecies were. We found that three of the circles overlapped almost completely, confirming a common underlying species, and the remaining circles had little overlap, suggesting the presence of four species.

71.6 Canonical Correlations and Variates

Definitions:

Let $\mathbf{z} = \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix}$ denote a d-dimensional random vector with mean $\boldsymbol{\mu}$ and positive definite covariance matrix Σ. Let $\mathbf{x}$ and $\mathbf{y}$ have dimensions d_1 and $d_2 = d - d_1$, respectively, and consider the partition

$$\Sigma = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix},$$

where Σ_{ii} is $d_i \times d_i$ and $\Sigma_{21} = \Sigma_{12}^T$ has rank r. Let ρ_1^2 be the maximum value of the squared correlation between arbitrary linear combinations $\boldsymbol{\alpha}^T\mathbf{x}$ and $\boldsymbol{\beta}^T\mathbf{y}$, and let $\boldsymbol{\alpha} = \mathbf{a}_1$ and $\boldsymbol{\beta} = \mathbf{b}_1$ be the corresponding maximizing values of $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$. Then the positive square root $\sqrt{\rho_1^2}$ is called the **first (population) canonical correlation** between $\mathbf{x}$ and $\mathbf{y}$, and $u_1 = \mathbf{a}_1^T\mathbf{x}$ and $v_1 = \mathbf{b}_1^T\mathbf{y}$ are called the **first (population) canonical variables**.

Let ρ_2^2 be the maximum value of the squared correlation between $\boldsymbol{\alpha}^T\mathbf{x}$ and $\boldsymbol{\beta}^T\mathbf{y}$, where $\boldsymbol{\alpha}^T\mathbf{x}$ is uncorrelated with $\mathbf{a}_1^T\mathbf{x}$ and $\boldsymbol{\beta}^T\mathbf{y}$ is uncorrelated with $\mathbf{b}_1^T\mathbf{y}$, and let $u_2 = \mathbf{a}_2^T\mathbf{x}$ and $v_2 = \mathbf{b}_2^T\mathbf{y}$ be the maximizing values. Then the positive square root $\sqrt{\rho_2^2}$ is called the **second canonical correlation**, and u_2 and v_2 are called the **second canonical variables**. Continuing in this manner, we obtain r pairs of canonical variables $\mathbf{u} = [u_1, u_2, \ldots, u_r]^T$ and $\mathbf{v} = [v_1, v_2, \ldots, v_r]^T$. We can then regard $\mathbf{u}$ and $\mathbf{v}$ as lower-dimensional "representations" of $\mathbf{x}$ and $\mathbf{y}$.

Facts:

1. [Seb04, Sect. 5.7] If $m = \text{rank}\Sigma_{12} \geq 1$ and Σ is positive definite, then $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ has m positive eigenvalues $\rho_1^2 \geq \rho_2^2 \geq \cdots \geq \rho_m^2$, say, and $\rho_1^2 < 1$. Moreover, $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ and $\Sigma_{22}^{-1}\Sigma_{21}\Sigma_{11}^{-1}\Sigma_{12}$ have the same (nonzero) eigenvalues. Let $\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_m$ and $\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_m$ be the corresponding eigenvectors of $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ and $\Sigma_{22}^{-1}\Sigma_{21}\Sigma_{11}^{-1}\Sigma_{12}$, respectively. Suppose that $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ are arbitrary vectors such that for $r \leq m$, $\boldsymbol{\alpha}^T\mathbf{x}$ is uncorrelated with each $\mathbf{a}_j^T\mathbf{x}$ $(j = 1, 2, \ldots, r-1)$, and $\boldsymbol{\beta}^T\mathbf{y}$ is uncorrelated with each $\mathbf{b}_j^T\mathbf{y}$ $(j = 1, 2, \ldots, r-1)$. Let $u_j = \mathbf{a}_j^T\mathbf{x}$ and $v_j = \mathbf{b}_j^T\mathbf{y}$, for $j = 1, 2, \ldots, r$. Then:

(a) The maximum squared correlation between $\boldsymbol{\alpha}^T\mathbf{x}$ and $\boldsymbol{\beta}^T\mathbf{y}$ is given by ρ_r^2 and it occurs when $\boldsymbol{\alpha} = \mathbf{a}_r$ and $\boldsymbol{\beta} = \mathbf{b}_r$.

(b) $\mathrm{cov}(u_j, u_k) = 0$ for $j \neq k$, and $\mathrm{cov}(v_j, v_k) = 0$ for $j \neq k$.

(c) The squared correlation between u_j and v_j is ρ_j^2.

(d) Since ρ_j^2 is independent of scale, we can scale $\mathbf{a}_j$ and $\mathbf{b}_j$ such that $\mathbf{a}_j^T\Sigma_{11}\mathbf{a}_j = 1$ and $\mathbf{b}_j^T\Sigma_{22}\mathbf{b}_j = 1$. The u_j and v_j then have unit variances.

(e) If the $d_1 \times d_2$ matrix Σ_{12} has row full rank, and $d_1 < d_2$, then $m = d_1$. All the eigenvalues of $\Sigma_{11}^{-1}\Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}$ are then positive, while $\Sigma_{22}^{-1}\Sigma_{21}\Sigma_{11}^{-1}\Sigma_{12}$ has d_1 positive eigenvalues and $d_2 - d_1$ zero eigenvalues. The rank of Σ_{12} can vary as there may be constraints on Σ_{12}, such as $\Sigma_{12} = \mathbf{0}$ (rank 0) or $\Sigma_{12} = a\mathbf{1}_{d_1}\mathbf{1}_{d_1}^T$ (rank 1).

2. [Bri01, p. 370]. Suppose $\mathbf{x}$ and $\mathbf{y}$ have means $\boldsymbol{\mu}_\mathbf{x}$ and $\boldsymbol{\mu}_\mathbf{y}$, respectively. Let $\mathbf{u} = A(\mathbf{x} - \boldsymbol{\mu}_\mathbf{x})$ and $\mathbf{v} = B(\mathbf{y} - \boldsymbol{\mu}_\mathbf{y})$, where A and B are any matrices, each with r rows that are linearly independent, satisfying $A\Sigma_{11}A^T = I_r$ and $B\Sigma_{22}B^T = I_r$. Then $\mathrm{E}[(\mathbf{u}-\mathbf{v})^T(\mathbf{u}-\mathbf{v})]$ is minimized when $\mathbf{u}$ and $\mathbf{v}$ are vectors of the canonical variables.
3. [BS93], [SS80] When Σ is singular, then the (population) canonical correlations are the positive square roots of the eigenvalues of $\Sigma_{11}^-\Sigma_{12}\Sigma_{22}^-\Sigma_{21}$; any generalized inverses Σ_{11}^- and Σ_{22}^- may be chosen. There will be u canonical correlations equal to 1, where $u = \mathrm{rank}(\Sigma_{11}) + \mathrm{rank}(\Sigma_{22}) - \mathrm{rank}(\Sigma)$.

71.7 Estimation of Canonical Correlations and Variates

Definitions:

Let $\mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_n$ be a random sample and let $\bar{\mathbf{z}} = \frac{1}{n}\sum_{i=1}^n \mathbf{z}_i = \begin{bmatrix}\bar{\mathbf{x}}\\ \bar{\mathbf{y}}\end{bmatrix}$ be the sample mean and $\widehat{\Sigma} = \frac{1}{n}\sum_{i=1}^n (\mathbf{z}_i - \bar{\mathbf{z}})(\mathbf{z}_i - \bar{\mathbf{z}})^T$, where $\widehat{\Sigma}$ is partitioned in the same way as Σ, namely

$$n\widehat{\Sigma} = \begin{bmatrix}\tilde{X}^T\tilde{X}, & \tilde{X}^T\tilde{Y}\\ \tilde{Y}^T\tilde{X}, & \tilde{Y}^T\tilde{Y}\end{bmatrix} = \begin{bmatrix}Q_{11} & Q_{12}\\ Q_{21} & Q_{22}\end{bmatrix},$$

say. Assuming that $d_1 \leq d_2$, let $r_1^2 > r_2^2 > \cdots > r_{d_1}^2 > 0$ be the eigenvalues of $Q_{11}^{-1}Q_{12}Q_{22}^{-1}Q_{21}$, with corresponding eigenvectors $\hat{\mathbf{a}}_1, \hat{\mathbf{a}}_2, \ldots, \hat{\mathbf{a}}_{d_1}$. We define $u_{ij} = \hat{\mathbf{a}}_j^T(\mathbf{x}_i - \bar{\mathbf{x}})$, the ith element of $\mathbf{u}_j = \tilde{X}\hat{\mathbf{a}}_j$, where $\hat{\mathbf{a}}_j$ is scaled so that $1 = n^{-1}\hat{\mathbf{a}}_j^T\tilde{X}^T\tilde{X}\hat{\mathbf{a}}_j = \sum_{i=1}^n u_{ij}^2/n = \mathbf{u}_j^T\mathbf{u}_j/n$. Then $\sqrt{r_j^2}$ is the jth **sample canonical correlation**. Moreover, u_{ij} is the jth **sample canonical variable** of $\mathbf{x}_i$. In a similar fashion, we define $v_{ij} = \hat{\mathbf{b}}_j^T(\mathbf{y}_i - \bar{\mathbf{y}})$, the ith element of $\mathbf{v}_j = \tilde{Y}\hat{\mathbf{b}}_j$, to be the jth sample canonical variable of $\mathbf{y}_i$. Here, $\hat{\mathbf{b}}_1, \hat{\mathbf{b}}_2, \ldots, \hat{\mathbf{b}}_{d_1}$ are the corresponding eigenvectors of $Q_{22}^{-1}Q_{21}Q_{11}^{-1}Q_{12}$, scaled so that $\mathbf{v}_j^T\mathbf{v}_j/n = 1$. The u_{ij} and v_{ij} are the **scores** of the ith observation on the jth canonical variables.

Facts:

1. When Σ is positive definite and $n - 1 \geq d$, then, with probability 1, $n\widehat{\Sigma}$ is positive definite and $\mathrm{rank}(Q_{12}) = d_1$.
2. The canonical correlations $\sqrt{r_j^2}$ are all distinct with probability 1.
3. r_j^2 is the square of the sample correlation between the canonical variables whose values are in the vectors $\mathbf{u}_j$ and $\mathbf{v}_j$.

Examples:

1. Length and breadth head measurements were carried out on the first and second sons of 25 families to see what relationships existed. Here, $\mathbf{x}$ refers to the two measurements on the first son and $\mathbf{y}$ to the second. It was found that $r_1 = 0.7885$ and $r_2 = 0.0537$, indicating that just one pair of sample canonical variables (u_1, v_1) would give a reasonable reduction in dimension from 2 to 1. Plotting u_1 against v_1 using the 21 pairs (u_{i1}, v_{i1}) gave a reasonably linear plot. The first linear combinations (u_1, v_1) of the two measurements suggested that they could be interpreted as a measure of "girth" while the second (u_2, v_2) could be interpreted as "shape" measurements. We can conclude that there is a strong correlation between the head sizes of first and second brothers, but not between the head shapes.

71.8 Matrix Quadratic Forms

To carry out inference for multivariate normal distributions we now require further theory.

Definitions:

If X is an $n \times d$ data matrix and $A = [a_{ij}]$ is a symmetric $n \times n$ matrix, then the expression $X^T AX = \sum_{i=1}^n \sum_{j=1}^n a_{ij}\mathbf{x}_i\mathbf{x}_j^T$ is said to be a **matrix quadratic form**. We have already had one example, namely, $Q = X^T CX$ in Section 71.3. When the $\{\mathbf{x}_i\}$ are a random sample from a distribution with mean $\boldsymbol{\mu}$ and covariance matrix Σ we define $S = Q/(n-1)$ to be the **sample covariance matrix**. (Some authors define it as $\widehat{\Sigma}$ in Section 71.3)

If the $\mathbf{x}_i$ are i.i.d. as $\mathrm{N}_d(\mathbf{0}, \Sigma)$, with $d \leq n$ and $\Sigma = [\sigma_{ij}]$ positive semidefinite, then $W = X^T X$ is said to have a **Wishart distribution** with n degrees of freedom and scale matrix Σ, and we write $W \sim \mathrm{W}_d(n, \Sigma)$. If Σ is positive definite, then the distribution is said to be **nonsingular**.

Suppose $\mathbf{y} \sim \mathrm{N}_d(\mathbf{0}, \Sigma)$ independently of $W \sim \mathrm{W}_d(m, \Sigma)$ and that both distributions are nonsingular. Then **Hotelling's T^2 distribution** is defined to be the distribution of $T^2 = m\mathbf{y}^T W^{-1}\mathbf{y}$ and we denote this distribution by $T^2 \sim T^2_{d,m}$.

Finally, in inference we are usually interested in **contrasts $\mathbf{a}^T\boldsymbol{\mu}$**, in the μ_i, where $\mathbf{a}$ is a vector whose entries sum to 0, i.e., $\mathbf{a}^T\mathbf{1}_d = 0$. Examples are $\mu_1 - \mu_2 = [1, -1, 0, \ldots, 0]\boldsymbol{\mu}$ and $\mu_1 - \frac{1}{2}(\mu_2 + \mu_3)$.

Facts:

All facts, unless otherwise indicated, appear in [Seb04, Sects. 2.3–2.4, 3.3–3.4, 3.6.2].

1. $\mathrm{E}(S) = \Sigma$, irrespective of the distribution of the $\mathbf{x}_i$.
2. [HS79] Let X be an $n \times d$ data matrix and let A and B be matrices of appropriate sizes. If vec is the usual "stacking" operator, then:
   (a) $\mathrm{cov}[\mathrm{vec}\,(AXB), \mathrm{vec}\,(CXD)] = (B^T\Sigma D) \otimes (AC^T)$.
   (b) If $U = AXB$ and $V = CXD$, then U and V are pairwise uncorrelated, that is, $\mathrm{cov}(u_{ij}, v_{rs}) = 0$ for all i, j, r, and s, if $AC^T = 0$ and/or $B^T\Sigma D = \mathbf{0}$.
3. Suppose $W = [w_{ij}]$ has a Wishart distribution $\mathrm{W}_d(m, \Sigma)$, with Σ possibly singular. Then the following hold:
   (a) $\mathrm{E}(W) = m\Sigma$.
   (b) Let A be a $q \times d$ matrix with rank $q \leq d$. Then $AWA^T \sim \mathrm{W}_q(m, A\Sigma A^T)$. When Σ is positive definite, then this distribution is nonsingular.
   (c) When $\sigma_{jj} > 0$, then $w_{jj}/\sigma_{jj} \sim \chi^2_m$, $(j = 1, 2, \ldots, d)$. However, the w_{jj} $(j = 1, \ldots, d)$ are not statistically independent.

   (d) When Σ is positive definite, then $\det \Sigma > 0$ and $\det W/ \det \Sigma$ is distributed as the product of d independent chi-square variables with respective degrees of freedom $m, m-1, \ldots, m-d+1$.

4. (See [SK79, p. 97], [Sty89].) Let $W \sim \mathrm{W}_d(m, \Sigma)$ with Σ possibly singular, and let A be an $n \times n$ symmetric matrix. Then:
   (a) $\mathrm{E}(WAW) = m[\Sigma A^T \Sigma + \mathrm{tr}(A\Sigma)\Sigma] + m^2 \Sigma A \Sigma$.
   (b) If $m > d+1$ and Σ is nonsingular, then
$$\mathrm{E}(WAW^{-1}) = \frac{1}{m-d-1}[m\Sigma A \Sigma^{-1} - A^T - (\mathrm{tr}A)I],$$
$$\mathrm{E}(W^{-1}AW) = \frac{1}{m-d-1}[m\Sigma^{-1} A \Sigma - A^T - (\mathrm{tr}A)I].$$
   (c) If $m > d+3$ and Σ is nonsingular, then
$$\mathrm{E}(W^{-1}AW^{-1}) = \frac{(m-d-2)\Sigma^{-1}A\Sigma^{-1} + \Sigma^{-1}A^T\Sigma^{-1} - (\mathrm{tr}A\Sigma^{-1})\Sigma^{-1}}{(m-d)(m-d-1)(m-d-3)}.$$

5. Suppose that the rows $\mathbf{x}_i^T$ of X are uncorrelated with $\mathrm{var}(\mathbf{x}_i) = \Sigma_i$ for $i = 1, 2, \ldots, n$, and A is an $n \times n$ symmetric matrix. Then:
   (a) $\mathrm{E}(X^T AX) = \sum_{i=1}^{n} a_{ii}\Sigma_i + \mathrm{E}(X^T)A\mathrm{E}(X)$.
   (b) If $\Sigma_i = \Sigma$ for all i, then $\mathrm{E}(X^T AX) = (\mathrm{tr}A)\Sigma + \mathrm{E}(X^T)A\mathrm{E}(X)$.

6. [Gup71, Th. 5], [EP73, Th. 2.3] Suppose that the rows of X are independent and A is an $n \times n$ positive semidefinite matrix of rank $r \geq d$. If for each $\mathbf{x}_i$ and all $\mathbf{b}$ and c with $\mathbf{b} \neq \mathbf{0}$ the probability $\Pr(\mathbf{b}^T\mathbf{x}_i = c) = 0$, then $X^T AX$ is positive definite with probability 1.

7. Suppose that rows of X are i.i.d. as $\mathrm{N}_d(\mathbf{0}, \Sigma)$, with Σ possibly singular, and let A and B be $n \times n$ symmetric matrices.
   (a) If A has rank $r \leq d$, then $X^T AX \sim \mathrm{W}_d(r, \Sigma)$ if and only if $A = A^2$.
   (b) Suppose $X^T AX$ and $X^T BX$ have Wishart distributions. They are statistically independent if and only if $AB = \mathbf{0}$.

8. Referring to the definition of Hotelling's T^2, $\frac{m-d+1}{md}T^2_{d,m} \sim F(d, m-d+1)$, the F-distribution with d and $m-d+1$ degrees of freedom. When $\mathbf{y} \sim \mathrm{N}_d(\boldsymbol{\theta}, \Sigma)$, then $F \sim F(d, m-d+1; \delta)$, the corresponding noncentral F-distribution with noncentrality parameter $\delta = \boldsymbol{\theta}^T \Sigma \boldsymbol{\theta}$.

9. Suppose that the rows of X are i.i.d. as nonsingular $\mathrm{N}_d(\boldsymbol{\mu}, \Sigma)$. Then:
   (a) $\bar{\mathbf{x}} \sim \mathrm{N}_d(\boldsymbol{\mu}, \Sigma/n)$.
   (b) $Q = (n-1)S \sim \mathrm{W}_d(n-1, \Sigma)$.
   (c) $\bar{\mathbf{x}}$ and S are statistically independent.
   (d) $T^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu})^T S^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}) \sim T^2_{d,n-1}$. This statistic can be used for testing the null hypothesis $H_0 : \boldsymbol{\mu} = \boldsymbol{\mu}_0$.

10. Given $H_0 : \boldsymbol{\mu} \in \mathcal{V}$, where $\mathcal{V}$ is a p-dimensional vector subspace of $\mathbb{R}^d$, then:
   (a) $T^2_{\min} = \min_{\boldsymbol{\mu} \in \mathcal{V}} T^2 \sim T^2_{d-p,n-1}$.
   (b) If $H_0 : \boldsymbol{\mu} = K\boldsymbol{\beta}$, where K is a known $d \times p$ matrix of rank p and $\boldsymbol{\beta}$ is a vector of p unknown parameters, then $\mathcal{V} = \mathrm{range}(K)$, and $T^2_{\min} = n(\bar{\mathbf{x}}^T S^{-1}\bar{\mathbf{x}} - \bar{\mathbf{x}}^T S^{-1} K\boldsymbol{\beta}^*)$, where $\boldsymbol{\beta}^* = (K^T S^{-1} K)^{-1} K^T S^{-1} \bar{\mathbf{x}}$.

11. If $H_0 : A\boldsymbol{\mu} = \mathbf{0}$, where A is $(d-p) \times d$ of rank $d-p$, then $\mathcal{V} = \ker(A)$ (also called the null space) and $T^2_{\min} = n(A\bar{\mathbf{x}})^T(ASA^T)^{-1}A\bar{\mathbf{x}}$.
    (a) Let A be a $q \times d$ matrix of rank $q \leq d$. Then the quadratic $n(A\bar{\mathbf{x}} - A\boldsymbol{\mu})^T(ASA^T)^{-1}(A\bar{\mathbf{x}} - A\boldsymbol{\mu}) \sim T^2_{q,n-1}$. This can be used for testing $H_0 : A\boldsymbol{\mu} = \mathbf{c}$.
    (b) If A is a matrix with rows that are contrasts so that $A\mathbf{1}_d = \mathbf{0}$, then
    $$n\bar{\mathbf{x}}^T A^T(ASA^T)^{-1}A\bar{\mathbf{x}} = n\bar{\mathbf{x}}^T S^{-1}\bar{\mathbf{x}} - \frac{n(\bar{\mathbf{x}}^T S^{-1}\mathbf{1}_d)^2}{\mathbf{1}_d^T S^{-1}\mathbf{1}_d}.$$
12. Let $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_{n_1}$ be a random sample from $\mathrm{N}_d(\boldsymbol{\mu}_1, \Sigma)$ and let $\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_{n_2}$ be an independent random sample from $\mathrm{N}_d(\boldsymbol{\mu}_2, \Sigma)$, both distributions being nonsingular. Let $Q_1 = \sum_{i=1}^{n_1}(\mathbf{v}_i - \bar{\mathbf{v}})(\mathbf{v}_i - \bar{\mathbf{v}})^T$ and $Q_2 = \sum_{i=1}^{n_2}(\mathbf{w}_i - \bar{\mathbf{w}})(\mathbf{w}_i - \bar{\mathbf{w}})^T$. If $\boldsymbol{\theta} = \boldsymbol{\mu}_1 - \boldsymbol{\mu}_2$ and A is a $q \times d$ matrix of rank $q \leq d$, then:
    (a) $\bar{\mathbf{z}} = \bar{\mathbf{v}} - \bar{\mathbf{w}} \sim \mathrm{N}_d\big(\boldsymbol{\theta}, (\frac{1}{n_1} + \frac{1}{n_2})\Sigma\big)$.
    (b) $Q = Q_1 + Q_2 \sim \mathrm{W}_d(n_1 + n_2 - 2, \Sigma)$.
    (c) The statistic
    $$\frac{n_1 n_2}{n_1 + n_2}(A\bar{\mathbf{z}} - A\boldsymbol{\theta})^T(AS_pA^T)^{-1}(A\bar{\mathbf{z}} - A\boldsymbol{\theta}) \sim T^2_{q,n_1+n_2-2},$$
    where $S_p = Q/(n_1 + n_2 - 2)$. This can be used to test $H_0 : A\boldsymbol{\theta} = \mathbf{0}$. When A is a certain $(d-1) \times d$ contrast matrix, then the methodology relating to H_0 is called *profile analysis.*

Examples:

1. Suppose the rows of X are i.i.d. nonsingular $\mathrm{N}_d(\mathbf{0}, \Sigma)$. Then $\bar{\mathbf{x}} = X^T\mathbf{1}_n/n$ and $W_1 = n\bar{\mathbf{x}}\bar{\mathbf{x}}^T = X^TAX$, where $A = \mathbf{1}_n\mathbf{1}_n^T/n$ is symmetric and idempotent of rank 1. Also, from Section 71.3, $W_2 = (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})^T = X^TCX$, where $C = I_n - A$ is symmetric and idempotent of rank $n-1$. Since $AC = \mathbf{0}$, we have from Fact 7 above that $W_1 \sim \mathrm{W}_d(1, \Sigma)$, $W_2 \sim \mathrm{W}_d(n-1, \Sigma)$, and W_1 and W_2 are statistically independent.
2. (cf. Fact 10) Suppose we have a group of 30 animals all subject to the same conditions, and the length of each animal is observed at d points in time $t_1, t_2, \ldots, t_d$. The d lengths for the ith animal will give us a d-dimensional vector, $\mathbf{x}_i$ say, and we assume that the $\mathbf{x}_i$ are all i.i.d. as nonsingular $\mathrm{N}_d(\boldsymbol{\mu}, \Sigma)$. We are interested in testing the hypothesis H_0 that the "growth curve" is a third-degree polynomial so that $H_0 : \mu_j = \beta_0 + \beta_1 t_j + \beta_2 t_j^2 + \beta_3 t_j^3$ $(j = 1, 2, \ldots, d)$ or $H_0 : \boldsymbol{\mu} = K\boldsymbol{\beta}$, where the jth row of K is $[1, t_j, t_j^2, t_j^3]$ and $\boldsymbol{\beta} = [\beta_0, \beta_1, \beta_2, \beta_3]^T$ is a vector of unknown parameters. We then test H_0 by calculating $T^2_{\min}$ given in Fact 10, and this statistic, which has a Hotelling's T^2 distribution when H_0 is true, can then be converted to an F-statistic using Fact 8. If this F-value is significantly large, we reject H_0.
3. (cf. Fact 11) The lengths of the femur and humerus on the left- and right-hand sides are measured for $n = 100$ males aged over 40 years to see if men are symmetrical with respect to the lengths of these bones. For the ith male, we therefore have a four-dimensional observation vector $\mathbf{x}_i$. Assuming that the population of measurements is multivariate normal with mean $\boldsymbol{\mu} = [\mu_1, \mu_2, \mu_3, \mu_4]^T$, where μ_1 and μ_2 refer to the left side, then we are interested in testing the contrasts $\mu_1 - \mu_3 = 0$ and $\mu_2 - \mu_4 = 0$. Thus, A has rows $[1, 0, -1, 0]$ and $[0, 1, 0, -1]$, giving us $H_0 : A\mathbf{1}_4 = \mathbf{0}$. We can then test H_0 using $T^2_{\min}$ defined in Fact 11, and this T^2 statistic is then converted to an F-statistic, as in the previous example.

71.9 Multivariate Linear Model: Least Squares Estimation

Definitions:

Let Y be an $n \times d$ data matrix which comes from an experimental design giving rise to n observations, the rows of Y. Then we can use observations on the jth characteristic (variable) $\mathbf{y}^{(j)}$, the jth column of Y, to construct a linear regression model $\mathbf{y}^{(j)} = \boldsymbol{\theta}^{(j)} + \mathbf{u}^{(j)} = K\boldsymbol{\beta}^{(j)} + \mathbf{u}^{(j)}$ as in Section 70.2 (with K replaced by X there). Because the design is the same for each variable, the design matrix K will be independent of j ($j = 1, 2, \ldots, d$), though the models will not be independent as the $\mathbf{y}^{(j)}$ are not independent. Putting all d regression models together, we get $Y = \Theta + U$, where $\Theta = KB$, B is $p \times d$ matrix of unknown parameters, K is $n \times p$ of rank r ($r \leq p$), and $U = [\mathbf{u}^{(1)}, \ldots, \mathbf{u}^{(d)}] = [\mathbf{u}_1, \ldots, \mathbf{u}_n]^T$. We shall assume that the $\mathbf{u}_i$ are a random sample from a distribution with mean $\mathbf{0}$ and covariance matrix $\Sigma = [\sigma_{ij}]$. Then $Y = KB + U$ is called a **multivariate linear model**. When $d = 1$, this reduces to the **univariate linear model** or **Gauss–Markov model**; see Chapter 70 and [Seb04, Chap. 8].

Now, for the jth model, $\widehat{\boldsymbol{\theta}}^{(j)} = P\mathbf{y}^{(j)}$ is the (ordinary) least squares estimate of $\boldsymbol{\theta}^{(j)}$, where $P = K(K^TK)^-K^T$, and $\widehat{\Theta} = PY$ is defined to be the **least squares estimate of** Θ. When $r = p$, then setting $\widehat{\Theta} = K\widehat{B}$ we have $\widehat{B} = (K^TK)^{-1}K^T\widehat{\Theta} = (K^TK)^{-1}K^TY$, called the **least squares estimate of** B. If $r < p$, then $\widehat{B}$ is not unique and is given by $\widehat{B} = (K^TK)^-K^TY$, where $(K^TK)^-$ is any generalized inverse of K^TK.

If K has less than full rank, then each of the d associated univariate models also has less than full rank. Moreover, $\mathbf{a}_i^T\boldsymbol{\beta}^{(j)}$ is estimable for each $i = 1, 2, \ldots, q$ and each model $j = 1, 2, \ldots, d$ if $\mathbf{a}_i \in \text{range}(K^T)$. Let $A = [\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_q]^T$. Combining these linear combinations we say that AB is **estimable** when $A = LK$ for some $q \times n$ matrix L.

Facts:

All the following facts can be found in [Seb04, Chap. 8].

1. If $K^T = [\mathbf{k}_1, \ldots, \mathbf{k}_n]$ then, transposing the model, $\mathbf{y}_i = B^T\mathbf{k}_i + \mathbf{u}_i$.
2. The cross-covariance $\text{cov}(\mathbf{y}_r, \mathbf{y}_s) = \text{cov}(\mathbf{u}_r, \mathbf{u}_s) = \delta_{rs}\Sigma$, where $\delta_{rs} = 1$ when $r = s$ and 0, otherwise.
3. The cross-covariance $\text{cov}(\mathbf{y}^{(j)}, \mathbf{y}^{(k)}) = \text{cov}(\mathbf{u}^{(j)}, \mathbf{u}^{(k)}) = \sigma_{jk}I_d$ for all $j, k = 1, \ldots, d$.
4. If K has full rank p, then $\hat{\boldsymbol{\beta}}^{(j)} = (K^TK)^{-1}K^T\mathbf{y}^{(j)}$ and $\text{cov}(\hat{\boldsymbol{\beta}}^{(j)}, \hat{\boldsymbol{\beta}}^{(k)}) = \sigma_{jk}(K^TK)^{-1}$ (all $j, k = 1, \ldots, d$).
5. Let $F(\Theta) = (Y - \Theta)^T(Y - \Theta)$. Then:
   (a) $F(\widehat{\Theta}) = Y^T(I_n - P)Y = U^T(I_n - P)U$.
   (b) $\text{E}[U^T(I_n - P)U] = (n - r)\Sigma$.
6. $F(\Theta) - F(\hat{\Theta})$ is positive semidefinite for all $\Theta = XB$, and equal to $\mathbf{0}$ if and only if $\Theta = \widehat{\Theta}$. We say that $\widehat{\Theta}$ is the minimum of $F(\Theta)$. Then:
   (a) $\text{tr}F(\Theta) \geq \text{tr}F(\widehat{\Theta})$.
   (b) $\det F(\Theta) \geq \det F(\widehat{\Theta})$.
   (c) $||F(\Theta)|| \geq ||F(\widehat{\Theta})||$, where $||A|| = \{\text{tr}(AA^T)\}^{1/2}$.

   Any of these three results could be used as a definition of $\widehat{\Theta}$.
7. *Multivariate Gauss–Markov Theorem.* If $\phi = \sum_{j=1}^d \mathbf{h}_j^T\boldsymbol{\theta}^{(j)}$, a linear combination of all the elements of Θ, then $\hat{\phi} = \sum_{j=1}^d \mathbf{h}_j^T\hat{\boldsymbol{\theta}}^{(j)}$ is the linear unbiased estimate with minimum variance or BLUE (best linear unbiased estimate) of ϕ. (See also Chapter 70.)

Examples:

1. [Seb04, Sect. 8.6.4] By setting $V^T = [\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_{n_1}]$, $W^T = [\mathbf{w}_1, \mathbf{w}_2, \dots, \mathbf{w}_{n_2}]$, and $Y = \begin{bmatrix} V \\ W \end{bmatrix}$, we see that the *two-sample problem* mentioned in Fact 71.8.12 is a special case of the multivariate model with
$$XB = \begin{bmatrix} \mathbf{1}_{n_1} & \mathbf{0} \\ \mathbf{0} & \mathbf{1}_{n_2} \end{bmatrix} \begin{bmatrix} \boldsymbol{\mu}_1^T \\ \boldsymbol{\mu}_2^T \end{bmatrix}.$$

71.10 Multivariate Linear Model: Statistical Inference

Definitions:

Let $Y = \Theta + U$, where $\Theta = KB$, be a multivariate linear model. We now assume that the underlying distribution (of the $\mathbf{u}_i$) is a nonsingular multivariate normal distribution $\mathrm{N}_d(\mathbf{0}, \Sigma)$.

Facts:

The following facts appear in [Seb04, Sect. 8.6].

1. The likelihood function for Y, i.e., the pdf of $\operatorname{vec} Y$, can be expressed in the form
$$(2\pi)^{-nd/2}(\det \Sigma)^{-n/2} \exp\{\operatorname{tr}[-\frac{1}{2}(Y - \Theta)^T \Sigma^{-1}(Y - \Theta)]\}.$$
2. The maximum likelihood estimates of Σ and Θ that maximize the likelihood function are $\widehat{\Theta}$ (the least squares estimate) and $\widehat{\Sigma} = E/n$, where $E = (Y - \widehat{\Theta})^T(Y - \widehat{\Theta})$; E is usually called the residual matrix or error matrix. If the $n \times p$ matrix K has full rank (i.e., rank p), then the maximum likelihood estimate of B is $\widehat{B}$.
3. Let E be the residual matrix and assume $n - r \geq d$. Then
   (a) E is positive definite with probability 1.
   (b) $E \sim \mathrm{W}_d(n - r, \Sigma)$.
   (c) E is statistically independent of $\widehat{\Theta}$, and of $\widehat{B}$ if K has full rank.
   (d) The maximum value of the likelihood function is $(2\pi)^{-nd/2}(\det \widehat{\Sigma})^{-n/2} e^{-nd/2}$.
   (e) If K has full rank, then $\widehat{\boldsymbol{\beta}}^{(j)} \sim \mathrm{N}_n(\boldsymbol{\beta}^{(j)}, \sigma_{jj}(K^T K)^{-1})$.
4. Suppose that K has rank $r < p$. Let A be a known $q \times p$ matrix of rank q and let AB be estimable. We are interested in testing $H_0 : AB = C$, where C is known.
   (a) The minimum, E_H say, of $(Y - KB)^T(Y - KB)$ subject to $AB = C$ occurs when B equals
   $$\widehat{B}_H = \widehat{B} - (K^T K)^- A^T [A(K^T K)^- A^T]^{-1}(A\widehat{B} - C).$$
   Although $\widehat{B}_H$ is not unique, $\widehat{\Theta}_H = K\widehat{B}_H$ is unique. Moreover, $E_H = (Y - \widehat{\Theta}_H)^T(Y - \widehat{\Theta}_H)$ is positive definite with probability 1.
   (b) $H = E_H - E = (A\widehat{B} - C)^T[A(K^T K)^- A^T]^{-1}(A\widehat{B} - C)$ is positive definite with probability 1, and H and E are statistically independent (both irrespective of whether H_0 is true or not).
   (c) $\mathrm{E}(H) = q\Sigma + (AB - C)^T[A(X^T X)^- A^T]^{-1}(AB - C) = q\Sigma + D$, where D is positive definite; D is zero when H_0 is true. This means that $\mathrm{E}(H)$, and, therefore, H itself, tends to be "inflated" when H_0 is false so that a test statistic for H_0 can be based on a suitable function of H.
   (d) When H_0 is true, $H \sim \mathrm{W}_d(q, \Sigma)$.

   (e) Let $E_H^{1/2}$ be the positive definite square root of E_H. Then when H_0 is true, $V = E_H^{-1/2} H E_H^{-1/2}$, a scaled function of H, has a d-dimensional multivariate Beta distribution with parameters q and $n - r$.

5. [Seb04, Sect. 8.6.2] Four different criteria are usually computed for testing H_0, and these are essentially based on the eigenvalues of V given above, which measure the scaled magnitude of H in some sense. They detect different kinds of departures from H_0 and are all significantly large when H_0 is false.
   (a) *Roy's maximum root statistic* ϕ_{max}, the maximum eigenvalue of HE^{-1}.
   (b) *Wilks' Lambda* or *likelihood ratio statistic* $\Lambda = (\det E / \det E_H)^{n/2}$.
   (c) *Lawley–Hotelling trace statistic* $(n - r)\mathrm{tr}(HE^{-1})$.
   (d) *Pillai's trace statistic* $\mathrm{tr}(HE_H^{-1})$.

Examples:

1. [Seb04, Sect. 8.7.2] To test the general linear hypothesis $H_0 : ABD = \mathbf{0}$, where A is $q \times p$ of rank $q \leq p$ and D is $d \times v$ of rank $v \leq d$, we let $Y_D = YD$ so that the linear model $Y = KB + U$ is transformed to

$$Y_D = KBD + UD = K\Lambda + U_0,$$

   say, where the rows of U_0 are i.i.d. $\mathrm{N}_v(\mathbf{0}, D^T \Sigma D)$. Then H_0 becomes $A\Lambda = \mathbf{0}$ and
   (a) H becomes $H_D = D^T H D = (A\widehat{B}D)^T [A(K^T K)^{-1} A^T]^{-1} A\widehat{B}D$ and E becomes $E_D = D^T E D \sim \mathrm{W}_v(n - r, D^T \Sigma D)$.
   (b) When $ABD = \mathbf{0}$ is true, then $H_D \sim \mathrm{W}_v(q, D^T \Sigma D)$.

   We can now use Facts 4 and 5 above to test H_0 using H_D and E_D instead of H and E. This hypothesis arises in carrying out a so-called profile analysis of more than two populations.

71.11 Metric Multidimensional Scaling

Definitions:

Given a set of n objects, a **proximity measure** d_{rs} is a measure of the "closeness" of objects r and s; here, "closeness" does not necessarily refer to physical distance. We shall consider only one such measure as there are several. A proximity d_{rs} is called a **(symmetric) dissimilarity** if $d_{rr} = 0$, $d_{rs} \geq 0$, and $d_{rs} = d_{sr}$, for all $r, s = 1, 2, \ldots, n$; the matrix $D = [d_{rs}]$ is called a **dissimilarity matrix**. We say that D is **Euclidean** if there exists a p-dimensional configuration of points $\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_n$ for some p such that all interpoint Euclidean distances satisfy $||\mathbf{y}_r - \mathbf{y}_s|| = d_{rs}$.

Facts:

1. Let $A = [a_{ij}]$ be a symmetric $n \times n$ matrix, where $a_{rs} = -\frac{1}{2} d_{rs}^2$. Define $b_{rs} = a_{rs} - \bar{a}_{r\cdot} - \bar{a}_{\cdot s} + \bar{a}_{\cdot\cdot}$, where $\bar{a}_{r\cdot}$ is the average of the elements of A in the rth row, $\bar{a}_{\cdot s}$ is the average for the sth column, and $\bar{a}_{\cdot\cdot}$ is the average of all the elements. Hence, $B = [b_{rs}] = CAC$, where $C = I - \frac{1}{n}\mathbf{1}\mathbf{1}^T$ is the usual centering matrix. Then $D = [d_{rs}]$ is Euclidean if and only if B is positive semidefinite; see [Seb04, p. 236].
2. If D is not Euclidean, then some eigenvalues of B will be negative. However, if the first k eigenvalues are comparatively large and positive, and the remaining positive or negative eigenvalues are near zero, then the rows of $Y_k = [\mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \ldots, \mathbf{y}^{(k)}]$ will give a reasonable configuration. If the original objects are d-dimensional points $\mathbf{x}_i$ $(i = 1, 2, \ldots, n)$ to begin with so that $||\mathbf{x}_r - \mathbf{x}_s||^2 = d_{rs}^2$, then D is Euclidean and the n rows of Y_k will give a k-dimensional reduction of a d-dimensional system of points.

Example:

1. The migration pattern that occurred with the colonization of islands in the Pacific Ocean can be investigated linguistically and values of d_{rs} can be constructed based on linguistic information. For example, the proportion p_{rs} of the words for, say, 50 items that islands r and s have in common can be used as a measure of similarity (with $p_{rr} = 1$), which we can convert into a dissimilarity $d_{rs} = (2 - 2p_{rs})^{1/2}$. Then $a_{rs} = -\frac{1}{2}d_{rs}^2 = p_{rs} - 1$ and, when computing b_{rs}, the -1 drops out so that we can leave it out and set $a_{rs} = p_{rs}$. If A is positive semidefinite, then so is B, which implies that D is Euclidean. Using B, we can then find a Y_k from which we can construct a lower dimensional map to see which islands are closest together linguistically. The same method can also be applied to blood groups using a different d_{rs}.

Markov chains are encountered in several applications arising in different contexts, and model many real problems which evolve in time. Throughout, we denote by $\mathrm{P}[X = j]$ the probability that the random variable X takes the value j, and by $\mathrm{P}[X = j|Y = i]$ the conditional probability that X takes the value j, given that the random variable Y takes the value i. Moreover, we denote by $\mathrm{E}[X]$ the expected value of the random variable X and by $\mathrm{E}[X|A]$ the conditional expectation of X, given the event A.

72.1 Basic Concepts

Definitions:

Given a denumerable set E, a **discrete stochastic process** on E is a family $\{X_t : t \in T\}$ of random variables X_t indexed by some denumerable set T and with values in E, i.e., $X_t \in E$ for all $t \in T$. Here, E is the **state space**, and T is the **time space**.

The discrete stochastic process $\{X_n : n \in \mathbb{N}\}$ is a **Markov chain** if

$$\mathrm{P}[X_{n+1} = j_{n+1}|X_0 = j_0, X_1 = j_1, \ldots, X_n = j_n] = \mathrm{P}[X_{n+1} = j_{n+1}|X_n = j_n], \qquad (72.1)$$

for any $(n + 2)$-tuple of states $\{j_0, \ldots, j_{n+1}\} \in E$, and for all time $n \in \mathbb{N}$.

A Markov chain $\{X_n : n \in \mathbb{N}\}$ is **homogeneous** if

$$\mathrm{P}[X_{n+1} = j|X_n = i] = \mathrm{P}[X_1 = j|X_0 = i], \qquad (72.2)$$

for all states i, $j \in E$ and for all time $n \in \mathbb{N}$.

Given a homogeneous Markov chain $\{X_n : n \in \mathbb{N}\}$ we define the **transition matrix** of the Markov chain to be the matrix $P = [p_{i,j}]_{i,j\in E}$ such that

$$p_{i,j} = \mathrm{P}[X_1 = j|X_0 = i], \qquad \text{for all } i,\ j \text{ in } E.$$

Throughout, unless differently specified, for the sake of notational simplicity we will indicate with the term **Markov chain** a homogeneous Markov chain.

A **finite Markov chain** is a Markov chain with finite space state E; an **infinite Markov chain** is a Markov chain with infinite space state E.

A row vector $\boldsymbol{\pi} = (\pi_i)_{i\in E}$ such that

$$\boldsymbol{\pi} P = \boldsymbol{\pi} \tag{72.3}$$

is an **invariant vector**.

If the invariant vector $\boldsymbol{\pi}$ is such that

$$\pi_i \geq 0 \text{ for all } i, \quad \text{and} \quad \sum_{i\in E} \pi_i = 1, \tag{72.4}$$

then $\boldsymbol{\pi}$ is an **invariant probability vector**, or **stationary distribution**. The definition of stationary distribution extends the definition given in Section 10.4 to the case of an infinite matrix P.

Facts:

1. The Markov property in Eq. (72.1) means that the state X_n of the system at time n is sufficient to determine which state might be occupied at time $n+1$, and the past history X_0, X_1, ..., X_{n-1} does not influence the future state at time $n+1$.
2. In a homogeneous Markov chain, the property in Eq. (72.2) means that the laws which govern the evolution of the system are independent of the time n; therefore, the evolution of the Markov chain is ruled by the transition matrix P, whose (i, j)th entry represents the probability to change from state i to state j in one time unit.
3. The number of rows and columns of the transition matrix P is equal to the cardinality of E. In particular, if the set E is finite, P is a finite matrix (see Examples 1 and 5); if the set E is infinite, P is an infinite matrix, i.e., a matrix with an infinite number of rows and columns (see Examples 2–4).
4. The matrix P is row stochastic, i.e., it is a matrix with nonnegative entries such that $\sum_{j\in E} p_{i,j} = 1$ for any $i \in E$, i.e., the sum of the entries on each row is equal to 1 (see Section 10.4).
5. If $|E| < \infty$, the matrix P has spectral radius 1. Moreover, the vector $\mathbf{1}_{|E|}$ is a right eigenvector of P corresponding to the eigenvalue 1; any nonzero invariant vector is a left eigenvector of P corresponding to the eigenvalue 1; the invariant probability vector $\boldsymbol{\pi}$ is a nonnegative left eigenvector of P corresponding to the eigenvalue 1, normalized so that $\boldsymbol{\pi}\mathbf{1}_{|E|} = 1$ (Fact 10.4.1).
6. In the analysis of Markov chains, we may encounter matrix products $A = BC$, where $B = [b_{i,j}]_{i,j\in E}$ and $C = [c_{i,j}]_{i,j\in E}$ are nonnegative matrices such that $\sum_{j\in E} b_{i,j} \leq 1$ and $\sum_{j\in E} c_{i,j} \leq 1$ for any $i \in E$ (see, for instance, Fact 7 below). The (i, j)th entry of A, given by $a_{i,j} = \sum_{h\in E} b_{i,h}c_{h,j}$, is well defined also if the set E is infinite, since $0 \leq \sum_{h\in E} b_{i,h}c_{h,j} \leq \sum_{h\in E} b_{i,h} \leq 1$. Moreover, A is a nonnegative matrix such that $\sum_{j\in E} a_{i,j} \leq 1$ for any $i \in E$. Indeed, $\sum_{j\in E} a_{i,j} = \sum_{j\in E} \sum_{h\in E} b_{i,h}c_{h,j} = \sum_{h\in E} b_{i,h} \sum_{j\in E} c_{h,j} \leq \sum_{h\in E} b_{i,h} \leq 1$. Similarly, the product $\boldsymbol{v} = \boldsymbol{u}B$, where $\boldsymbol{u} = (u_i)_{i\in E}$ is a nonnegative row vector such that $\sum_{i\in E} u_i \leq 1$, is well defined also in the case where E is infinite; moreover, $\boldsymbol{v} = (v_i)_{i\in E}$ is a nonnegative vector such that $\sum_{i\in E} v_i \leq 1$.
7. [Nor99, Theorem 1.1.3] The dynamic behavior of a homogeneous Markov chain is completely characterized by the transition matrix P:

   $$\mathrm{P}[X_{n+k} = j | X_n = i] = (P^k)_{i,j},$$

   for all times $n \geq 0$, all intervals of time $k \geq 0$, and all pairs of states i and j in E.
8. In addition to the system dynamics, one must choose the starting point X_0. Let $\boldsymbol{\pi}^{(0)} = (\pi_i^{(0)})_{i\in E}$ be a probability distribution on E, i.e., a nonnegative row vector

such that the sum of its components is equal to one. Assume that $\pi_i^{(0)} = \mathrm{P}[X_0 = i]$, and define the row vector $\boldsymbol{\pi}^{(n)} = (\pi_i^{(n)})_{i \in E}$ to be the probability vector of the Markov chain at time $n \geq 1$, that is, $\pi_i^{(n)} = \mathrm{P}[X_n = i | X_0]$. Then

$$\boldsymbol{\pi}^{(n+1)} = \boldsymbol{\pi}^{(n)} P, \qquad n \geq 0, \tag{72.5}$$

$$\boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}^{(0)} P^n, \qquad n \geq 0. \tag{72.6}$$

9. If the initial distribution $\boldsymbol{\pi}^{(0)}$ coincides with the invariant probability vector $\boldsymbol{\pi}$, then $\boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}$ for any $n \geq 0$.
10. In certain applications (see, for instance, Example 5) we are interested in the asymptotic behavior of the Markov chain. In particular, we would like to compute, if it exists, the vector $\lim_{n\to\infty} \boldsymbol{\pi}^{(n)}$. From Eq. (72.5) of Fact 8 one deduces that, if such a limit exists, it coincides with the invariant probability vector, i.e., $\lim_{n\to\infty} \boldsymbol{\pi}^{(n)} = \boldsymbol{\pi}$.

Examples:

1. *Random walk on* $\{0, 1, \ldots, k\}$: Consider a particle which moves on the interval $[0, k]$ in unit steps at integer instants of time; let $X_n \in \{0, 1, \ldots, k\}$, $n \geq 0$, be the position of the particle at time n and let $0 < p < 1$. Assume that, if the particle is in the open interval $(0, k)$, at the next unit time it will move to the right with probability p and to the left with probability $q = 1 - p$; if the particle is in position 0, it will move to the right with probability 1; if the particle is in position k, it will move to the left with probability 1. Clearly, the discrete stochastic process $\{X_n : n \in \mathbb{N}\}$ is a homogeneous Markov chain with space state the set $E = \{0, 1, \ldots, k\}$. The transition matrix is the $(k+1) \times (k+1)$ matrix $P = [p_{i,j}]_{i,j=0,\ldots,k}$, given by

$$P = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ q & 0 & p & \ddots & \vdots \\ 0 & \ddots & \ddots & \ddots & 0 \\ \vdots & \ddots & q & 0 & p \\ 0 & \ldots & 0 & 1 & 0 \end{bmatrix}.$$

From Eq. (72.6) of Fact 8 one has that, if the particle is in position 0 at time 0, the probability vector at time $n = 10$ is the vector

$$[\pi_0^{(10)}, \pi_1^{(10)}, \ldots, \pi_k^{(10)}] = [1, 0, \ldots, 0] P^{10}.$$

2. *Random walk on* $\mathbb{N}$: If we allow the particle to move on $\mathbb{N}$, we have a homogeneous Markov chain with state space the set $E = \mathbb{N}$. The transition matrix is semi-infinite and is given by

$$P = \begin{bmatrix} 0 & 1 & 0 & 0 & \ldots \\ q & 0 & p & 0 & \ddots \\ 0 & q & 0 & p & \ddots \\ 0 & 0 & q & 0 & \ddots \\ \vdots & \ddots & \ddots & \ddots & \ddots \end{bmatrix}.$$

3. *Random walk on* $\mathbb{Z}$: If we allow the particle to move on $\mathbb{Z}$, we still have a homogeneous Markov chain, with state space the set $E = \mathbb{Z}$. The transition matrix is bi-infinite and is given by

$$P = \begin{bmatrix} \ddots & \ddots & \ddots & \ddots & \ddots \\ \ddots & 0 & p & 0 & \ddots \\ \ddots & q & 0 & p & \ddots \\ \ddots & 0 & q & 0 & \ddots \\ \ddots & \ddots & \ddots & \ddots & \ddots \end{bmatrix}.$$

4. *A simple queueing system* [BLM05, Example 1.3]: Simple queues consist of one server which attends to one customer at a time, in order of their arrivals. We assume that time is discretized into intervals of length one, that a random number of customers join the system during each interval, that customers do not leave the queue, and that the server removes one customer from the queue at the end of each interval, if there is any. Defining α_n as the number of new arrivals during the interval $[n-1, n)$ and X_n as the number of customers in the system at time n, we have

$$X_{n+1} = \begin{cases} X_n + \alpha_{n+1} - 1 & \text{if } X_n + \alpha_{n+1} \geq 1 \\ 0 & \text{if } X_n + \alpha_{n+1} = 0. \end{cases}$$

If $\{\alpha_n\}$ is a collection of independent random variables, then X_{n+1} is conditionally independent of $X_0, \ldots, X_{n-1}$ if X_n is known. If, in addition, the α_n's are identically distributed, then $\{X_n\}$ is homogeneous. The state space is $\mathbb{N}$ and the transition matrix is

$$P = \begin{bmatrix} q_0 + q_1 & q_2 & q_3 & q_4 & \cdots \\ q_0 & q_1 & q_2 & q_3 & \ddots \\ & q_0 & q_1 & q_2 & \ddots \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix},$$

where q_i is the probability $\mathrm{P}[\alpha = i]$ that i new customers join the queue during a unit time interval, α denoting any of the identically distributed random variables α_n. Markov chains having transition matrix of the form

$$P = \begin{bmatrix} B_1 & B_2 & B_3 & B_4 & \cdots \\ A_0 & A_1 & A_2 & A_3 & \ddots \\ & A_0 & A_1 & A_2 & \ddots \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix},$$

where A_i, B_{i+1}, $i \geq 0$, are nonnegative $k \times k$ matrices, are called M/G/1-type Markov chains, and model a large variety of queuing problems. (See [Neu89], [LR99], and [BLM05].)

5. *Search engines* (see Section 76.5, [PBM99], [ANT02] and [Mol04, Sect. 2.11]): PageRank is used by Google to sort, in order of relevance, the pages on the Web that match the query of the user. From the Web page *Google Technology* at `http://www.google.com/technology/`: "The heart of our software is PageRank^{TM}, a system for ranking Web pages developed by our founders Larry Page and Sergey Brin at Stanford University. And while we have dozens

of engineers working to improve every aspect of Google on a daily basis, PageRank continues to provide the basis for all of our Web search tools." Surfing on the Web is seen as a random walk, where either one starts from a Web page and goes from one page to the next page by randomly following a link (if any), or one simply chooses a random page from the Web. Let E be the set of Web pages that can be reached by following a sequence of hyperlinks starting from a given Web page. If k is the number of Web pages, i.e., $k = |E|$, the connectivity matrix is defined as the $k \times k$ matrix $G = [g_{i,j}]$ such that $g_{i,j} = 1$ if there is a hyperlink from page i to page j, and zero otherwise. Let $r_i = \sum_j g_{i,j}$ and $c_i = \sum_j g_{j,i}$ be the row and column sums of G; the quantities r_i and c_i are called the out-degree and the in-degree, respectively, of the page i. Let $0 < q < 1$ and let $P = [p_{i,j}]$ be the $k \times k$ stochastic matrix such that $p_{i,j} = qg_{i,j}/r_i + (1-q)/k$, $i, j = 1, \ldots, k$. The value q is the probability that the random walk on E follows a link and, therefore, $1 - q$ is the probability that an arbitrary page is chosen. The matrix P is the transition matrix of the Markov chain that models the random walk on E. The importance of a Web page is related to the probability of reaching such page during this randow walk as the time tends to infinity. Therefore, Google's PageRank is determined by the invariant probability vector $\boldsymbol{\pi}$ of P: The larger the value of an entry π_i of $\boldsymbol{\pi}$, the higher the relevance of the ith Web page in the set E.

72.2 Irreducible Classes

Some of the Definitions and Facts given in this section extend the corresponding Definitions and Facts of Chapter 10 and Chapter 40. Indeed, in these chapters, it is assumed that the matrices have a finite size, while in the framework of Markov chains we may encounter infinite matrices.

Definitions:

The **transition graph** of a Markov chain with transition matrix P is the digraph of P, $\Gamma(P)$. That is, the digraph is defined as follows: To each state in E there corresponds a vertex of the digraph and one defines a directed arc from vertex i to vertex j for each pair of states such that $p_{i,j} > 0$. More information about digraphs can be found in Chapter 10 and Chapter 40.

A **closed walk** in a digraph is a walk in which the first vertex equals the last vertex.

State i **leads** to j (or i **has access** to j) if there is a walk from i to j in the transition graph. States i and j **communicate** if i leads to j and j leads to i.

A Markov chain is called **irreducible** if the transition graph is strongly connected, i.e., if all the states communicate. A Markov chain is called **reducible** if it is not irreducible.

The strongly connected components of the transition graph are the **communicating classes of states**, or of the Markov chain. Communicating classes are also called **access equivalence classes** or **irreducible classes**.

A communicating class C is a **final class** if for every state i in C, there is no state j outside of C such that i leads to j. If, on the contrary, there is a state in C that leads to some state outside of C, the class is a **passage class**. A single state that forms a final class by itself is **absorbing**. In Section 10.4, passage classes are called transient classes, and final classes are called ergodic classes; in fact, transient and ergodic states of Markov chains will be introduced in Section 72.3, and for finite Markov chains the states in a passage class are transient, and the states in a final class are ergodic, cf. Section 72.4.

A state i is **periodic** with period $\delta \geq 2$ if all closed walks through i in the transition graph have a length that is a multiple of δ. A state i is **aperiodic** if it is not periodic.

A Markov chain is **periodic** with period δ if all states are periodic and have the same period δ.

Facts:

1. A Markov chain is irreducible if and only if the transition matrix P is irreducible, i.e., if P is not permutation similar to a block triangular matrix, cf. Section 10.2, Section 38.1.
2. If we adopt the convention that each state communicates with itself, then the relation *communicates* is an equivalence relation and the communicating classes are the equivalence classes of this relation, cf. Section 10.1.
3. A Markov chain is irreducible if and only if the states form one single communicating class, cf. Section 10.1, Section 10.2.
4. If a Markov chain with transition matrix P has $K \geq 2$ communicating classes, denoted by $C_1, C_2, \ldots, C_K$, then the states may be permuted so that the transition matrix $P' = \Pi P \Pi^T$ associated with the permuted states is block triangular:

$$P' = \begin{bmatrix} P_{1,1} & P_{1,2} & \cdots & P_{1,K} \\ & P_{2,2} & \ddots & \vdots \\ & & \ddots & P_{K-1,K} \\ 0 & & & P_{K,K} \end{bmatrix}$$

   where $P_{i,j}$ is the submatrix of transition probabilities from the states of C_i to C_j, the diagonal blocks are irreducible square matrices, and Π is the permutation matrix associated with the rearrangement, cf. Section 10.2.
5. [Çin75, Theorem (3.16), Chap. 5] Periodicity is a class property and all states in a communicating class have the same period. Thus, for irreducible Markov chains, either all states are aperiodic or all have the same period δ, which we may call the period of the Markov chain itself.

Examples:

1. Figure 72.1 is the transition graph associated with the Markov chain on $E = \{1, 2, 3\}$ with transition matrix

$$P = \begin{bmatrix} 1 & 0 & 0 \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \end{bmatrix}.$$

   The two sets $C_1 = \{1\}$ and $C_2 = \{2, 3\}$ are two communicating classes. C_2 is a passage class, while C_1 is a final class; therefore, state 1 is absorbing.

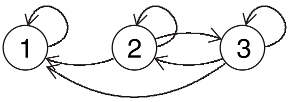

FIGURE 72.1 Transition graph of the Markov chain of Example 1.

2. Figure 72.2 is the transition graph associated with the Markov chain on $E = \{k \in \mathbb{N} : k \geq 1\}$

with transition matrix having the following structure:

$$P = \begin{bmatrix} 0 & * & & & & & 0 \\ 0 & 0 & * & & & & \\ * & 0 & 0 & * & & & \\ 0 & 0 & 0 & 0 & * & & \\ 0 & 0 & * & 0 & 0 & * & \\ 0 & 0 & 0 & 0 & 0 & 0 & \ddots \\ 0 & 0 & 0 & 0 & * & 0 & \ddots \\ \vdots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots \end{bmatrix},$$

where "$*$" denotes a nonzero element. This is an example of a periodic irreducible Markov chain of period 3.

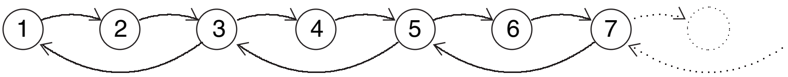

FIGURE 72.2 Graph of an infinite irreducible periodic Markov chain of period 3.

72.3 Classification of the States

Definitions:

Let T_j be the time of the first visit to j, without taking into account the state at time 0, i.e.,

$$T_j = \min\{n \geq 1 : X_n = j\}.$$

Define

$$f_j = \mathrm{P}[T_j < \infty | X_0 = j],$$

that is, f_j is the probability that, starting from j, the Markov chain returns to j in a finite time.

A state $j \in E$ is **transient** if $f_j < 1$.

A state $j \in E$ is **recurrent** if $f_j = 1$. A recurrent state $j \in E$ is **positive recurrent** if the expected return time $\mathrm{E}[T_j | X_0 = j]$ is finite; it is **null recurrent** if the expected return time $\mathrm{E}[T_j | X_0 = j]$ is infinite. Positive recurrent states are also called **ergodic**.

A Markov chain is **positive/null recurrent** or **transient** if all its states are positive/null recurrent or transient, respectively.

A **regular Markov chain** is a positive recurrent Markov chain that is aperiodic.

The matrix $R = \sum_{n=0}^{\infty} P^n$ is the **potential matrix** of the Markov chain.

Facts:

1. Transient states may be visited only a finite number of times by the Markov chain. On the contrary, once the Markov chain has visited one recurrent state, it will return to it over and over again; if j is null recurrent, the expected time between two successive visits to j is infinite.

2. [Çin75, Cor. (2.13), Chap. 5] For the potential matrix $R = [r_{i,j}]$ one has $r_{j,j} = 1/(1 - f_j)$, where we set $1/0 = \infty$.
3. [Çin75, Sect. 3, Chap. 5] The (j, j)th entry of R is the expected number of returns of the Markov chain to state j. A state j is recurrent if and only if $r_{j,j} = \infty$. A state j is transient if and only if $r_{j,j} < \infty$.
4. [Nor99, Theorems 1.5.4, 1.5.5, 1.7.7] The nature of a state is a class property. More specifically, the states in a passage class are transient; in a final class, the states are either all positive recurrent, or all null recurrent, or all transient.
5. [Nor99, Theorem 1.5.6] If a final class contains a finite number of states only, then all its states are positive recurrent.
6. From Facts 4 and 5 one has that, for a communicating class with a finite number of states, either all the states are transient or all the states are positive recurrent.
7. From Fact 4 above, if a Markov chain is irreducible, the states are either all positive recurrent, or all null recurrent, or all transient. Therefore, an irreducible Markov chain is either positive recurrent or null recurrent or transient.
8. [Nor99, Sects. 1.7 and 1.8] Assume that the Markov chain is irreducible. The Markov chain is positive recurrent if and only if there exists a strictly positive invariant probability vector, that is, a row vector $\boldsymbol{\pi} = (\pi_i)_{i\in E}$ such that $\pi_i > 0$ that satisfies Eqs. (72.3) and (72.4). The invariant vector $\boldsymbol{\pi}$ is unique among nonnegative vectors, up to a multiplicative constant.
9. [Nor99, Sects. 1.7 and 1.8], [BLM05, Sect. 1.5] If the Markov chain is irreducible and null recurrent, there exists a strictly positive invariant vector, unique up to a multiplicative constant, such that the sum of its elements is not finite. Thus, there always exists an invariant vector for the transition matrix of a recurrent Markov chain. Some transient Markov chains also have an invariant vector (with infinite sum of the entries, like in the null recurrent case) but some do not.
10. [Çin75, Theorem (3.2), Chap. 5], [Nor99, Sects. 1.7 and 1.8] If j is a transient or null recurrent state, then for any $i \in E$, $\lim_{n\to\infty}(P^n)_{i,j} = 0$. If j is a positive recurrent and aperiodic state, then $\lim_{n\to\infty}(P^n)_{j,j} > 0$. If j is periodic with period δ, then $\lim_{n\to\infty}(P^{n\delta})_{j,j} > 0$.
11. [Nor99, Sects. 1.7 and 1.8] Assume that the Markov chain is irreducible, aperiodic, and positive recurrent. Then $\lim_{n\to\infty}(P^n)_{i,j} = \pi_j > 0$ for all j, independently of i, where $\boldsymbol{\pi} = (\pi_i)_{i\in E}$ is the stationary distribution.
12. Facts 3, 4, 6, and 10 provide a criterium to classify the states. First, identify the communicating classes. If a communicating class contains a finite number of states, the states are all positive recurrent if the communicating class is final; the states are all transient if the communicating class is a passage class. If a communicating class has infinitely many states, we apply Fact 3 to determine if they are recurrent or transient; for recurrent states we use Fact 10 to determine if they are null or positive recurrent.

Examples:

1. Let P be the transition matrix of Example 72.2.1. Observe that with positive probability the Markov chain moves from state 2 or 3 to state 1, and when the Markov chain will be in state 1, it will remain there forever. Indeed, according to Facts 4 and 5, states 2 and 3 are transient since they belong to a passage class, and state 1 is positive recurrent since it is absorbing. Moreover, if we partition the matrix P into the 2×2 block matrix

$$P = \begin{bmatrix} 1 & 0 \\ A & B \end{bmatrix},$$

where

$$A = \begin{bmatrix} \frac{1}{3} \\ \frac{1}{4} \end{bmatrix}, \quad B = \begin{bmatrix} \frac{1}{3} & \frac{1}{3} \\ \frac{1}{2} & \frac{1}{4} \end{bmatrix},$$

we may easily observe that

$$P^n = \begin{bmatrix} 1 & 0 \\ \sum_{i=0}^{n-1} B^i A & B^n \end{bmatrix}.$$

Since $\|B\|_1 = \frac{5}{6}$, then $\rho(B) < 1$, and therefore $\lim_{n\to\infty} B^n = 0$ and $\sum_{n=0}^{\infty} B^n = (I - B)^{-1}$. A simple computation leads to

$$\lim_{n\to\infty} P^n = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad R = \sum_{n=0}^{\infty} P^n = \begin{bmatrix} \infty & 0 & 0 \\ \infty & \frac{9}{4} & 1 \\ \infty & \frac{3}{2} & 2 \end{bmatrix},$$

in accordance with Facts 3 and 10.

2. [BLM05, Ex. 1.19] The transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{1}{2} & 0 & \frac{1}{2} & & \\ & \frac{1}{2} & 0 & \frac{1}{2} & \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix}$$

is irreducible, and $\boldsymbol{\pi} = [\frac{1}{2}, 1, 1, \ldots]$ is an invariant vector. The vector $\boldsymbol{\pi}$ has "infinite" mass; that is, the sum of its components is infinite. In fact, the Markov chain is actually null recurrent (see [BLM05, Sect. 1.5]).

3. [BLM05, Ex. 1.20] For the transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{1}{4} & 0 & \frac{3}{4} & & \\ & \frac{1}{4} & 0 & \frac{3}{4} & \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix}$$

one has $\boldsymbol{\pi} P = \boldsymbol{\pi}$ with $\boldsymbol{\pi} = [1, 4, 12, 36, 108, \ldots]$. The vector $\boldsymbol{\pi}$ has unbounded elements. In this case, the Markov chain is transient.

4. [BLM05, Ex. 1.21] For the transition matrix

$$P = \begin{bmatrix} 0 & 1 & & & 0 \\ \frac{3}{4} & 0 & \frac{1}{4} & & \\ & \frac{3}{4} & 0 & \frac{1}{4} & \\ 0 & & \ddots & \ddots & \ddots \end{bmatrix}$$

one has $\boldsymbol{\pi} P = \boldsymbol{\pi}$ with $\boldsymbol{\pi} = \frac{4}{3}[\frac{1}{4}, \frac{1}{3}, \frac{1}{9}, \frac{1}{27}, \ldots]$ and $\sum_i \pi_i = 1$. In this case, the Markov chain is positive recurrent by Fact 8.

72.4 Finite Markov Chains

The transition matrix of a finite Markov chain is a finite dimensional stochastic matrix; the reader is advised to consult Section 10.4 for properties of finite stochastic matrices.

Definitions:

A $k \times k$ matrix A is **weakly cyclic of index** δ if there exists a permutation matrix Π such that $A' = \Pi A \Pi^T$ has the block form

$$A' = \begin{bmatrix} 0 & 0 & \dots & 0 & A_{1,\delta} \\ A_{2,1} & 0 & \ddots & & 0 \\ 0 & A_{3,2} & \ddots & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 & 0 \\ 0 & \dots & 0 & A_{\delta,\delta-1} & 0 \end{bmatrix},$$

where the zero diagonal blocks are square.

Facts:

1. If P is the transition matrix of a finite Markov chain, there exists an invariant probability vector $\boldsymbol{\pi}$. If P is irreducible, the vector $\boldsymbol{\pi}$ is strictly positive and unique, cf. Section 10.4.
2. For a finite Markov chain no state is null recurrent, and not all states are transient. The states belonging to a final class are positive recurrent, and the states belonging to a passage class are transient, cf. Section 10.4.
3. [BP94, Theorem (3.9), Chap. 8] Let P be the transition matrix of a finite Markov chain. The Markov chain is
   (a) Positive recurrent if and only if P is irreducible.
   (b) Regular if and only if P is primitive.
   (c) Periodic if and only if P is irreducible and periodic.
4. [BP94, Theorem (3.16), Chap. 8] Let P be the transition matrix of a finite irreducible Markov chain. Then the Markov chain is periodic if and only if P is a weakly cyclic matrix.
5. If P is the transition matrix of a regular Markov chain, then there exists $\lim_{n\to\infty} P^n = \mathbf{1}\boldsymbol{\pi}$, where $\boldsymbol{\pi}$ is the probability invariant vector. If the Markov chain is periodic, the sequence $\{P^n\}_{n\geq 0}$ is bounded, but not convergent.
6. [Mey89] Assume that $E = \{1, 2, \dots, k\}$ and that P is irreducible. Let $1 \leq m \leq k-1$ and $\alpha = \{1, \dots, m\}$, $\beta = \{m+1, \dots, k\}$. Then
   (a) The matrix $I - P[\alpha]$ is an M-matrix.
   (b) The matrix $P' = P[\alpha] + P[\alpha, \beta](I - P[\beta])^{-1} P[\beta, \alpha]$, such that $I - P'$ is the Schur complement of $I - P[\beta]$ in the matrix

   $$\begin{bmatrix} I - P[\alpha] & -P[\alpha, \beta] \\ -P[\beta, \alpha] & I - P[\beta] \end{bmatrix},$$

   is a stochastic irreducible matrix.
   (c) If we partition the invariant probability vector $\boldsymbol{\pi}$ as $\boldsymbol{\pi} = [\boldsymbol{\pi}_\alpha, \boldsymbol{\pi}_\beta]$, with $\boldsymbol{\pi}_\alpha = (\pi_i)_{i\in\alpha}$ and $\boldsymbol{\pi}_\beta = (\pi_i)_{i\in\beta}$, we have $\boldsymbol{\pi}_\alpha P' = \boldsymbol{\pi}_\alpha$, $\boldsymbol{\pi}_\beta = \boldsymbol{\pi}_\alpha P[\alpha, \beta](I - P[\beta])^{-1}$.

Examples:

1. The matrix

$$P = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

is the transition matrix of a periodic Markov chain of period 2. In fact, P is an irreducible matrix of period 2.

2. The Markov chain with transition matrix

$$P = \begin{bmatrix} \frac{1}{5} & \frac{1}{5} \\ 1 & 0 \end{bmatrix}$$

is regular. In fact, $P^2 > 0$, i.e., P is primitive.

3. Let

$$P = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0 & 0 \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} & 0 \\ \frac{1}{3} & 0 & \frac{1}{3} & \frac{1}{3} \\ 0 & 0 & \frac{1}{2} & \frac{1}{2} \end{bmatrix}$$

be the transition matrix of a Markov chain. The matrix P is irreducible and aperiodic, therefore the Markov chain is regular. The vector $\boldsymbol{\pi} = \frac{1}{13}[4, 4, 3, 2]$ is the stationary distribution. According to Fact 5, one has

$$\lim_{n\to\infty} P^n = \frac{1}{13} \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \begin{bmatrix} 4 & 4 & 3 & 2 \end{bmatrix}.$$

72.5 Censoring

Definitions:

Partition the state space E into two disjoint subsets, α and β, and denote by $\{t_0, t_1, t_2, \ldots\}$ the time when the Markov chain visits the set α:

$$t_0 = \min\{n \geq 0 : X_n \in \alpha\}, \qquad t_{k+1} = \min\{n \geq t_k + 1 : X_n \in \alpha\},$$

for $k \geq 0$. The **censored process** restricted to the subset α is the sequence $\{Y_n\}_{n\geq 0}$, where $Y_n = X_{t_n}$, of successive states visited by the Markov chain in α.

Facts:

1. [BLM05, Sect. 1.6] The censored process $\{Y_n\}$ is a Markov chain.
2. [BLM05, Sect. 1.6] Arrange the states so that the transition matrix can be partitioned as

$$P = \begin{bmatrix} P[\alpha] & P[\alpha, \beta] \\ P[\beta, \alpha] & P[\beta] \end{bmatrix}.$$

Then the transition matrix of $\{Y_n\}$ is

$$P' = P[\alpha] + \sum_{n=0}^{+\infty}(P[\alpha,\beta]P[\beta]^n P[\beta,\alpha])$$

provided that $\sum_{n=0}^{+\infty}(P[\alpha,\beta]P[\beta]^n P[\beta,\alpha])$ is convergent. If the series $S' = \sum_{n=0}^{+\infty} P[\beta]^n$ is convergent, then we may rewrite P' as $P' = P[\alpha] + P[\alpha,\beta]S'P[\beta,\alpha]$.

3. [BLM05, Theorem 1.23] Assume that the Markov chain is irreducible and positive recurrent. Partition the stationary distribution $\boldsymbol{\pi}$ as $\boldsymbol{\pi} = [\boldsymbol{\pi}_\alpha, \boldsymbol{\pi}_\beta]$, with $\boldsymbol{\pi}_\alpha = (\pi_i)_{i\in\alpha}$ and $\boldsymbol{\pi}_\beta = (\pi_i)_{i\in\beta}$. Then one has $\boldsymbol{\pi}_\alpha P' = \boldsymbol{\pi}_\alpha$, $\boldsymbol{\pi}_\beta = \boldsymbol{\pi}_\alpha P[\alpha,\beta]S'$, where P' and S' are defined in Fact 2.
4. [BLM05, Sects. 1.6, 3.5, 4.5] In the case of finite Markov chains, censoring is equivalent to Schur complementation (see Fact 72.4.6). Censoring is at the basis of several numerical methods for computing the invariant probability vector $\boldsymbol{\pi}$; indeed, from Fact 3, if the invariant probability vector $\boldsymbol{\pi}_\alpha$ associated with the censored process is available, the vector $\boldsymbol{\pi}_\beta$ can be easily computed from $\boldsymbol{\pi}_\alpha$. A smart choice of the sets α and β can lead to an efficient computation of the stationary distribution. As an example of this fact, Ramaswami's recursive formula for computing the vector $\boldsymbol{\pi}$ associated with an M/G/1-type Markov chain is based on successive censorings, where the set α is finite, and $\beta = \mathbb{N} - \alpha$.

72.6 Numerical Methods

Definitions:

Let A be a $k \times k$ matrix. A splitting $A = M - N$, where $\det M \neq 0$, is a **regular splitting** if $M^{-1} \geq 0$ and $N \geq 0$. A regular splitting is said to be **semiconvergent** if the matrix $M^{-1}N$ is semiconvergent.

Facts:

1. The main computational problem in Markov chains is the computation of the invariant probability vector $\boldsymbol{\pi}$. If the space state E is finite and the Markov chain is irreducible, classical techniques for solving linear systems can be adapted and specialized to this purpose. We refer the reader to the book [Ste94] for a comprehensive treatment on these numerical methods; in facts below we analyze the methods based on LU factorization and on regular splittings of M_0-matrices. If the space state E is infinite, general numerical methods for computing $\boldsymbol{\pi}$ can be hardly designed. Usually, when the state space is infinite, the matrix P has some structures which are specific of the real problem modeled by the Markov chain, and numerical methods for computing $\boldsymbol{\pi}$ which exploit the structure of P can be designed. Quite common structures arising in queueing problems are the (block) tridiagonal structure, the (block) Hessenberg structure, and the (block) Toeplitz structure (see, for instance, Example 72.1.4). We refer the reader to the book [BLM05] for a treatment on the numerical solution of Markov chains, where the matrix P is infinite and structured.
2. [BP94, Cor. (4.17), Chap. 6], [Ste94, Sect. 2.3] If P is a $k \times k$ irreducible stochastic matrix, then the matrix $I - P$ has a unique LU factorization $I - P = LU$, where L is a lower triangular matrix with unit diagonal entries and U is upper triangular. Moreover, L is an M-matrix, U is a singular M_0-matrix, $U\mathbf{1}_k = 0$, and $(U)_{k,k} = 0$.

3. [Ste94, Sect. 2.5] The computation of the LU factorization of an M_0-matrix by means of Gaussian elimination involves additions of nonnegative numbers in the computation of the off-diagonal entries of L and U, and subtractions of nonnegative numbers in the computation of the diagonal entries of U. Therefore, numerical cancellation cannot occur in the computation of the off-diagonal entries of L and U. In order to avoid possible cancellation errors in computing the diagonal entries of U, Grassmann, Taksar, and Heyman have introduced in [GTH85] a simple trick, which fully exploits the property that U is an M_0-matrix such that $U\mathbf{1}_k = 0$. At the general step of the elimination procedure, the diagonal entries are not updated by means of the classical elimination formulas, but are computed as minus the sum of the off-diagonal entries on its row. Details are given in Algorithm 1.
4. If $I - P = LU$ is the LU factorization of $I - P$, the invariant probability vector $\boldsymbol{\pi}$ is computed by solving the two triangular systems $\boldsymbol{y}L = \boldsymbol{x}$ and $\boldsymbol{x}U = 0$, where $\boldsymbol{x}$ and $\boldsymbol{y}$ are row vectors, and then by normalizing the solution $\boldsymbol{y}$. From Fact 2, the nontrivial solution of the latter system is $\boldsymbol{x} = \alpha \boldsymbol{e}_k^T$, for any $\alpha \neq 0$. Therefore, if we choose $\alpha = 1$, the vector $\boldsymbol{\pi}$ can be simply computed by solving the system $\boldsymbol{y}L = \boldsymbol{e}_k^T$ by means of back substitution, and then by setting $\boldsymbol{\pi} = (1/\boldsymbol{y}\mathbf{1})\boldsymbol{y}$, as described in Algorithm 2.
5. [BP94, Cor. (4.17), Chap. 6] If P is a $k \times k$ irreducible stochastic matrix, the matrix $I - P^T$ has a unique LU factorization $I - P^T = LU$, where L is a lower triangular matrix with unit diagonal entries, and U is upper triangular. Moreover, L is an M-matrix, U is a singular M_0-matrix, and $(U)_{k,k} = 0$. Since L is nonsingular, the invariant probability vector can be computed by calculating a nonnegative solution of the system $U\boldsymbol{y} = 0$ by means of back substitution, and by setting $\boldsymbol{\pi} = (1/\boldsymbol{y}^T\mathbf{1})\boldsymbol{y}^T$.
6. If P is a $k \times k$ irreducible stochastic matrix, and if $\hat{P}$ is the $(k-1) \times (k-1)$ matrix obtained by removing the ith row and the ith column of P, where $i \in \{1, \ldots, k\}$, then the matrices $I - \hat{P}^T$ and $I - \hat{P}$ have a unique LU factorization, where both the factors L and U are M-matrices. Therefore, if $i = k$ and if the matrix $I - P^T$ is partitioned as

$$I - P^T = \begin{bmatrix} I - \hat{P}^T & \boldsymbol{a} \\ \boldsymbol{b}^T & c \end{bmatrix},$$

   one finds that the vector $\hat{\boldsymbol{\pi}} = [\pi_1, \ldots, \pi_{k-1}]^T$ solves the nonsingular system $(I - \hat{P}^T)\hat{\boldsymbol{\pi}} = -\pi_k \boldsymbol{a}$. Therefore, the vector $\boldsymbol{\pi}$ can be computed by solving the system $(I - \hat{P}^T)\boldsymbol{y} = -\boldsymbol{a}$, say by means of LU factorization, and then by setting $\boldsymbol{\pi} = [\boldsymbol{y}^T, 1]/(1 + \boldsymbol{y}^T\mathbf{1})$.
7. [Ste94, Sect. 3.6] Let P be a finite irreducible stochastic matrix, and let $I - P^T = M - N$ be a regular splitting of $I - P^T$. Then the matrix $H = M^{-1}N$ has spectral radius 1 and 1 is a simple eigenvalue of H.
8. [Ste94, Theorem 3.3], [BP94], [Var00] Fact 7 above is not sufficient to guarantee that any regular splitting of $I - P^T$, where P is a finite stochastic irreducible matrix, is semiconvergent (see the following example). In order to be semiconvergent, the matrix H must not have eigenvalues of modulus 1 different from 1, and the Jordan blocks associated with 1 must have dimension 1.
9. An iterative method for computing $\boldsymbol{\pi}$ based on a regular splitting $I - P^T = M - N$ consists in generating the sequence $\boldsymbol{x}_{n+1} = M^{-1}N\boldsymbol{x}_n$, for $n \geq 0$, starting from an initial column vector $\boldsymbol{x}_0$. If the regular splitting is semiconvergent, by choosing $\boldsymbol{x}_0 \geq 0$ such that $\|\boldsymbol{x}_0\|_1 = 1$, the sequence $\{\boldsymbol{x}_n\}_n$ converges to $\boldsymbol{\pi}^T$. The convergence is linear and the asymptotic rate of convergence is the second largest modulus eigenvalue of $M^{-1}N$.
10. [Ste94, Theorem 3.6] If P is a finite stochastic matrix, the methods of Gauss–Seidel, Jacobi, and SOR, for $0 < \omega \leq 1$, applied to $I - P^T$, are based on regular splittings.
11. If E is finite, the invariant probability vector is, up to a multiplicative constant, the nonnegative left eigenvector associated with the dominating eigenvalue of P. The

power method applied to the matrix P^T is the iterative method defined by the trivial regular splitting $I - P^T = M - N$, where $M = I$, $N = P^T$. If P is primitive, the power method is convergent.

12. [Ste94, Theorems 3.6 and 3.7] If P is a $k \times k$ irreducible stochastic matrix, and if $\hat{P}$ is the $(k-1)\times(k-1)$ matrix obtained by removing the ith row and the ith column of P, where $i \in \{1, \ldots, k\}$, then any regular splitting of the matrix $I - \hat{P}^T = M - N$ is convergent. In particular, the methods of Gauss–Seidel, Jacobi, and SOR, for $0 < \omega \leq 1$, applied to $I - \hat{P}^T$, being based on regular splittings, are convergent.
13. [Ste94, Theorem 3.17] Let P be a $k \times k$ irreducible stochastic matrix and let $\epsilon > 0$. Then the splitting $I - P^T = M_\epsilon - N_\epsilon$, where $M_\epsilon = D - L + \epsilon I$ and $N_\epsilon = U + \epsilon I$, is a semiconvergent regular splitting for every $\epsilon > 0$.
14. [Ste94, Theorem 3.18] Let P be a $k \times k$ irreducible stochastic matrix, let $I - P^T = M - N$ be a regular splitting of $I - P^T$, and let $H = M^{-1}N$. Then the matrix $H_\alpha = (1-\alpha)I + \alpha H$ is semiconvergent for any $0 < \alpha < 1$.

Algorithms:

1. The following algorithm computes the LU factorization of $I - P$ by using the Grassmann, Taksar, Heyman (GTH) trick of Fact 3:

```
Computation of the LU factorization of $I - P$ with GTH trick
Input: the $k \times k$ irreducible stochastic matrix $P = [p_{i,j}]$.
Output: the matrix $A = [a_{i,j}]$ such that $a_{i,j} = l_{i,j}$ for $i > j$,
and $a_{i,j} = u_{i,j}$ for $i \leq j$, where $L = [l_{i,j}]$, $U = [u_{i,j}]$ are the factors
of the LU factorization of $I - P$.
Computation:
    1– set $a_{i,j} = -p_{i,j}$ if $i \neq j$, and $a_{i,i} = \sum_{l=1, l\neq i}^{k} p_{i,l}$, for $i, j = 1, \ldots, k$;
    2– for $m = 1, \ldots, k-1$:
        (a) for $i = m+1, \ldots, k$, set $a_{i,m} = a_{i,m}/a_{m,m}$;
        (b) for $i, j = m+1, \ldots, k$, set $a_{i,j} = a_{i,j} - a_{i,m}a_{m,j}$ if $i \neq j$;
        (c) for $i = m+1, \ldots, k$ set $a_{i,i} = -\sum_{l=m+1, l\neq i}^{k} a_{i,l}$.
```

2. The algorithm derived by Fact 4 is the following:

```
Computation of $\boldsymbol{\pi}$ through LU factorization
Input: the factor $L = [l_{i,j}]$ of the LU factorization of the matrix $I - P$,
where $P$ is a $k \times k$ irreducible stochastic matrix.
Output: the invariant probability vector $\boldsymbol{\pi} = (\pi_i)_{i=1,k}$.
Computation:
    1– set $\pi_k = 1$;
    2– for $j = k-1, \ldots, 1$ set $\pi_j = -\sum_{i=j+1}^{k} \pi_i l_{i,j}$;
    3– set $\boldsymbol{\pi} = (\sum_{i=1}^{k} \pi_i)^{-1} \boldsymbol{\pi}$.
```

Examples:

1. The matrix
$$P = \begin{bmatrix} 0.5 & 0 & 0 & 0.5 \\ 0.2 & 0.8 & 0 & 0 \\ 0 & 0.6 & 0.4 & 0 \\ 0 & 0 & 0.1 & 0.9 \end{bmatrix}$$
is the transition matrix of an irreducible and aperiodic Markov chain. The splitting $I - P^T = M - N$ associated with the Jacobi method is a regular splitting. One may easily verify that the iteration matrix is
$$M^{-1}N = D \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix} D^{-1},$$
where $D = \operatorname{diag}(1, \frac{5}{2}, \frac{5}{6}, 5)$. Therefore, the regular splitting is not semiconvergent since the iteration matrix has period 4 (see Fact 8). Also the splitting $I - P^T = M - N$ associated with the Gauss-Seidel method is a regular splitting; however, in this case the iteration matrix is
$$M^{-1}N = \begin{bmatrix} 0 & \frac{2}{5} & 0 & 0 \\ 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & \frac{2}{3} \\ 0 & 2 & 0 & 0 \end{bmatrix},$$
which is semiconvergent.

Sometimes errors occur when data is transmitted over a channel. A binary 0 may be corrupted to a 1, or vice versa. Error control coding adds redundancy to a transmitted message allowing for detection and correction of errors. For example, if 0 stands for "no" and 1 stands for "yes", a single bit error will completely change a message. If we repeat the message seven times, so 0000000 stands for "no" and 1111111 stands for "yes", then it would require at least 4 bit errors to change a message, assuming that a message is decoded to either 0000000 or 1111111 according to which bit is in the majority in the received string. Thus, this simple code can be used to correct up to 3 errors. This code also detects up to 6 errors, in the sense that if between 1 and 6 errors occur in transmission, the received string will not be a codeword, and the receiver will recognize that one or more errors have occurred. The extra bits provide *error protection.*

Let $\mathbb{F} = \mathbb{F}_q$ be the finite field with q elements. It is customary in the coding literature to write message blocks and vectors of the vector spaces $\mathbb{F}^k$ and $\mathbb{F}^n$ as row vectors, and we shall follow that practice in this chapter.

73.1 Basic Concepts

Definitions:

A **block code of length** n **over** $\mathbb{F}$ is a subset $\mathcal{C}$ of the vector space $\mathbb{F}^n$. Elements of $\mathcal{C}$ are **codewords**. Elements of the finite field $\mathbb{F}$ form the **alphabet**.

Message blocks of length k are strings of k symbols from the alphabet. Message blocks may also be identified with vectors in the vector space $\mathbb{F}^k$.

An **encoder** is a one-to-one mapping

$$\varphi : \mathbb{F}^k \longrightarrow \mathbb{F}^n$$

whose image is contained in the code $\mathcal{C}$.

The process of applying φ to a k-digit message block to obtain a codeword is **encoding**.

A **noisy channel** is a channel in which transmission errors may occur. For example, the

symmetric channel is characterized through the property that symbols are interchanged during transmission in a symmetric way with a fixed probabilty for all symbols.

A codeword $\mathbf{v} \in \mathcal{C} \subseteq \mathbb{F}^n$ that has been transmitted may be received as $\mathbf{y} = \mathbf{v} + \mathbf{e}$, where $\mathbf{e} \in \mathbb{F}^n$ is an **error vector**.

Given a received word $\mathbf{y} = \mathbf{v} + \mathbf{e} \in \mathbb{F}^n$, the receiver estimates the corresponding codeword, thus obtaining $\tilde{\mathbf{v}} \in \mathcal{C}$. This estimation process is called **decoding**. If $\tilde{\mathbf{v}} = \mathbf{v}$, then correct decoding has occurred.

Decoding may be thought of as a mapping $\psi : \mathbb{F}^n \longrightarrow \mathcal{C}$. The mapping ψ is a **decoder**. Generally a decoder ψ should have the property that if the received word is in fact a codeword, it is decoded to itself.

The **word error rate** for a particular decoder is the probability P_{err} that the decoder outputs a wrong codeword.

The process of encoding, transmission, and decoding is summarized by

$$\begin{tikzcd}
\mathbb{F}^k \arrow[r, "\varphi"] & \mathbb{F}^n \arrow[r, "\text{n.t.}"] & \mathbb{F}^n \arrow[r, "\psi"] & \mathcal{C} \\
\mathbf{u} \arrow[r, mapsto] & \mathbf{v} \arrow[r, mapsto] & \mathbf{y} \arrow[r, mapsto] & \tilde{\mathbf{v}},
\end{tikzcd}$$

where "n.t." stands for "noisy transmission."

For $\mathbf{v}, \mathbf{w} \in \mathbb{F}^n$ the **Hamming distance**, or simply the **distance**, between $\mathbf{v}$ and $\mathbf{w}$ is $\mathrm{d}(\mathbf{v}, \mathbf{w}) = |\{i \mid v_i \neq w_i\}|$.

The **distance of a code** $\mathcal{C} \subseteq \mathbb{F}^n$ is defined by $\mathrm{d}(\mathcal{C}) = \min\{\mathrm{d}(\mathbf{v}, \mathbf{w}) \mid \mathbf{v}, \mathbf{w} \in \mathcal{C} \text{ and } \mathbf{v} \neq \mathbf{w}\}$.

The **Hamming weight** or **weight** of $\mathbf{v}$ is defined to be $\mathrm{wt}(\mathbf{v}) = \mathrm{d}(\mathbf{v}, \mathbf{0})$.

The **closed ball of radius t about the vector $\mathbf{v} \in \mathbb{F}^n$** is the set

$$B(\mathbf{v}, t) = \{\mathbf{y} \in \mathbb{F}^n \mid \mathrm{d}(\mathbf{v}, \mathbf{y}) \leq t\}.$$

Nearest-neighbor decoding refers to decoding a received word $\mathbf{y}$ to a nearest codeword (with respect to Hamming distance).

A code $\mathcal{C} \subseteq \mathbb{F}^n$ is called a **perfect code** if there exists a nonnegative integer t such that

1. $\mathbb{F}^n = \bigcup_{\mathbf{v} \in \mathcal{C}} B(\mathbf{v}, t)$, and
2. For distinct $\mathbf{v}, \mathbf{w} \in \mathcal{C}, B(\mathbf{v}, t) \cap B(\mathbf{w}, t) = \phi$.

That is, $\mathbb{F}^n$ is the disjoint union of closed t-balls about the codewords.

Facts:

1. The minimum number of symbol errors it would take for $\mathbf{v}$ to be changed to $\mathbf{w}$ is $\mathrm{d}(\mathbf{v}, \mathbf{w})$.
2. A nearest-neighbor decoder need not be unique as it is possible that some received words $\mathbf{y}$ might have two or more codewords at an equal minimum distance. The decoder may decode $\mathbf{y}$ to any of these nearest codewords.
3. [Hil86, p. 5] The Hamming distance is a metric on $\mathbb{F}^n$.
4. [Hil86, p. 7] If the distance of a code $\mathcal{C}$ is d, then $\mathcal{C}$ can detect up to $d - 1$ errors. It can correct up to $\left[\frac{d-1}{2}\right]$ errors.
5. When the noisy channel is the symmetric channel, nearest-neighbor decoding with respect to the Hamming distance gives a maximum likelihood estimate of the sent message vector.

Examples:

1. The binary message block 1011 can be identified with the vector $(1, 0, 1, 1) \in \mathbb{F}_2^4$.
2. The distance between the binary strings 0011 and 1110 is 3 since these two bit strings differ in three places.
3. We may picture nearest-neighbor decoding by taking a closed ball of expanding radius about the received word $\mathbf{y}$. As soon as the ball includes a codeword, that codeword is a nearest-neighbor to which we may decode $\mathbf{y}$.

73.2 Linear Block Codes

Definitions:

A **linear block code of length** n **and dimension** k over $\mathbb{F} = \mathbb{F}_q$ is a k-dimensional *linear* subspace, $\mathcal{C}$, of the vector space $\mathbb{F}^n$. One says $\mathcal{C}$ is an $[n, k]$-code over $\mathbb{F}$. If one wants to include the distance as a parameter, one says that $\mathcal{C}$ is an $[n, k, d]$-code over $\mathbb{F}$. A **binary linear block code (BLBC)** is a linear block code over the binary field $\mathbb{F}_2 = \{0, 1\}$.

Two linear codes over $\mathbb{F}_q$ are **equivalent** if one can be obtained from the other by steps of the following types: (i) permutation of the coordinates of the codewords, and (ii) multiplication of the field elements in one coordinate of the code by a nonzero scalar in $\mathbb{F}_q$.

The **rate** of a linear $[n, k]$-code is $\frac{k}{n}$.

Let $\mathcal{C}$ be a linear $[n, k]$-code over $\mathbb{F}$. A **generator matrix for** $\mathcal{C}$ is a matrix $G \in \mathbb{F}^{k\times n}$ whose k rows form a basis for $\mathcal{C}$. A generator matrix for $\mathcal{C}$ is also called an **encoder for** $\mathcal{C}$.

A generator matrix G for an $[n, k]$-code is a **systematic encoder** if G can be partitioned, perhaps after a column permutation, as $G = [I_k \mid A]$, where $A \in \mathbb{F}^{k\times(n-k)}$. Then $\mathbf{u} \in \mathbb{F}^k$ is encoded as $\mathbf{u}G = [\mathbf{u} \mid \mathbf{u}A]$ so that the first k symbols of the codeword $\mathbf{u}G$ are the message word $\mathbf{u}$, and the last $n - k$ symbols form the **parity check** symbols.

Let $\mathcal{C}$ be a linear $[n, k]$-code over $\mathbb{F}$. A **parity check matrix for** $\mathcal{C}$ is a matrix $H \in \mathbb{F}^{(n-k)\times n}$ such that $\mathcal{C} = \{\mathbf{v} \in \mathbb{F}^n \mid \mathbf{v}H^T = 0 \in \mathbb{F}^{(n-k)}\}$.

Let $\mathcal{C}$ be a linear $[n, k]$-code over $\mathbb{F}$ with generator matrix $G \in \mathbb{F}^{k\times n}$ and parity check matrix $H \in \mathbb{F}^{(n-k)\times n}$. Then H itself is the generator matrix of another code, denoted $\mathcal{C}^{\perp}$. $\mathcal{C}^{\perp}$ is the **dual code** of $\mathcal{C}$.

A linear block code, $\mathcal{C}$, is **self-dual** if $\mathcal{C} = \mathcal{C}^{\perp}$. Extensive material on self-dual codes is provided in [NRS06].

Let $\mathcal{C}$ be an $[n, k]$-code with parity check matrix H. For any vector $\mathbf{y} \in \mathbb{F}^n$, the **syndrome of** $\mathbf{y}$ is the vector $\mathbf{y}H^T \in \mathbb{F}^{(n-k)}$.

Facts:

1. [Hil86, p. 47] There are q^k codewords in an $[n, k]$-code over $\mathbb{F} = \mathbb{F}_q$.
2. The rate, $\frac{k}{n}$, of an $[n, k]$-code tells what fraction of transmitted symbols carry information. The complementary fraction, $\frac{n-k}{n}$, tells how much of the transmission is redundant (for error protection).
3. If G is a generator matrix for the linear $[n, k]$-code, $\mathcal{C}$, then $\mathcal{C} = \{\mathbf{u}G \mid \mathbf{u} \in \mathbb{F}^k\}$. Thus, the mapping $\varphi : \mathbb{F}^k \longrightarrow \mathbb{F}^n$ given by $\varphi(\mathbf{u}) = \mathbf{u}G$ is an encoder for $\mathcal{C}$.
4. [Hil86, p. 48] The distance of a linear code is equal to the minimum weight of all nonzero codewords.
5. Every $[n, k]$ linear block code has an $(n - k) \times n$ parity check matrix.
6. For a given $[n, k]$ linear code $\mathcal{C}$ with generator matrix G, an $(n - k) \times n$ matrix H is a parity check matrix for $\mathcal{C}$ if and only if the rows of H are a basis for the left kernel of G^T.
7. If H is a parity check matrix for the linear code $\mathcal{C}$, then $\mathcal{C}$ is the left kernel of H^T.
8. A generator matrix of $\mathcal{C}$ is a parity check matrix of $\mathcal{C}^{\perp}$.
9. [MS77, p. 33] Suppose $H \in \mathbb{F}^{(n-k)\times n}$ is a parity check matrix for an $[n, k]$-code $\mathcal{C}$ over $\mathbb{F}$. Then the distance of $\mathcal{C}$ is equal to the smallest number of columns of H for which a linear dependency may be found.
10. [Hil86, p. 70] If $G = [I_k \mid A]$ is a systematic encoder for the $[n, k]$-code $\mathcal{C}$, then $H = [-A^T \mid I_{n-k}]$ is a parity check matrix for $\mathcal{C}$.
11. [MS77, p. 22]*Shannon's Coding Theorem for the Binary Symmetric Channel.* Assume

that the transmission channel has a fixed symbol error probability p that the symbol 1 is corrupted to a 0 or vice versa. Let

$$C := 1 + p\log_2 p + (1-p)\log_2(1-p).$$

Then for every $\epsilon > 0$ and every $R < C$ there exists, for any sufficiently large n, a binary linear $[n,k]$ code having transmission rate $k/n \geq R$ and word error probability $P_{\text{err}} \leq \epsilon$.

12. Nearest-neighbor decoding (with respect to the Hamming distance) is an NP-hard problem [BMT78].

Examples:

1. The binary repetition code of length 7 is a $[7,1]$ BLBC. A generator matrix is

$$G = \begin{bmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{bmatrix}.$$

This code consists of two codewords, namely 0000000 and 1111111. The rate of this code is $\frac{1}{7}$. For every 7 bits transmitted, there is only 1 bit of information, with the remaining 6 redundant bits providing error protection. The distance of this code is 7. A parity check matrix for this code is the 6×7 matrix

$$H = \left[J_{6,1} \;\middle|\; I_6 \right].$$

2. *Binary even weight codes.* The binary even weight code of length n is a $[n, n-1]$-code that consists of all even weight words in $\mathbb{F}_2^n$. A generator matrix is given by

$$G = \left[I_{n-1} \;\middle|\; J_{(n-1),1} \right].$$

This code detects any single error, but cannot correct any errors. A binary even weight code may also be constructed by taking all binary strings of length $n-1$ and to each adding an nth parity check bit chosen so that the weight of the resulting string is even. The 8-bit ASCII code (American Standard Code for Information Interchange) is constructed in this manner.

Note that the binary even weight code of length n and the binary repetition code of length n are dual codes.

3. The ISBN (International Standard Book Number) code is a $[10,9]$-code over $\mathbb{F}_{11}$ (the finite field $\{0,1,2,3,4,5,6,7,8,9,X\}$ where field operations are performed modulo 11. X is the symbol for 10 in this field). This code may be defined by the parity check matrix

$$H = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & X \end{bmatrix}.$$

Thus, a string of 10 digits, $v_1v_2v_3v_4v_5v_6v_7v_8v_9v_{10}$, from $\mathbb{F}_{11}$ is a valid ISBN if and only if $\sum_{i=1}^{10} iv_i \equiv 0 \pmod{11}$. The ISBN code will detect any single error or any error where two digits are interchanged (transposition error). The first nine digits of an ISBN carry information about the book (such as publisher). The tenth digit is a check digit. Given the first 9 digits of an ISBN, the check digit may be computed by forming the sum $\sum_{i=1}^{9} iv_i$ and reducing modulo 11. The value thus obtained is v_{10} (if the value is 10, then $v_{10} = X$).

Note: Currently the ISBN system does not use X as any of the first 9 digits. However, mathematically there is no reason not to use X anywhere in an ISBN.

4. The binary linear $[8,4]$ code with generator matrix

$$G = \begin{bmatrix} 1 & 0 & 1 & 1 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 1 & 1 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}$$

is a self-dual code (note that over the binary field, $GG^T = 0$). This code is called the extended binary $[8, 4, 4]$ code. All pairs of different codewords are at distance 4 or 8.

73.3 Main Linear Coding Problem and Distance Bounds

Definitions:

Let $A_q(n, d)$ be the largest possible number so that there exists a block code $\mathcal{C} \subseteq \mathbb{F}_q^n$ of distance $d = \mathrm{d}(\mathcal{C})$ and cardinality $|\mathcal{C}| = A_q(n, d)$. The **Main Coding Theory Problem** asks for the determination of $A_q(n, d)$ for different values of n, d, q.

Similarly, let $B_q(n, d)$ be the largest possible number so that there exists a linear $[n, k]$ block code $\mathcal{C}$ of distance $d = \mathrm{d}(\mathcal{C})$ and cardinality $|\mathcal{C}| = B_q(n, d)$. The **Main Linear Coding Problem** asks for the determination of $B_q(n, d)$ for different values of n, d, q.

An $[n, k, d]$ linear code is **maximum distance separable (MDS)** if $d = n - k + 1$.

Facts:

1. Finding a value of $B_q(n, d)$ is equivalent to finding the largest dimension, k, for which there is an $[n, k, d]$-code over $\mathbb{F}_q$. For such maximal k, we have $B_q(n, d) = q^k$.
2. $B_q(n, d) \leq A_q(n, d)$ for all n, q, d.
3. [Rom92, p. 170] $A_q(n, 1) = B_q(n, 1) = q^n$.
4. $B_q(n, 2) = q^{n-1}$. Such a code is achieved by taking $\mathcal{C}$ to be a code with parity check matrix $J_{1,n}$.
5. [Rom92, p. 170] $A_q(n, n) = B_q(n, n) = q$.
6. [Rom92, p. 170] For $n \geq 2$, $A_q(n, d) \leq qA_q(n - 1, d)$.
7. [Hil86, Theorem 14.5] $B_q(n, 3) = q^{n-r}$, where r is the unique integer such that
$$(q^{r-1} - 1)/(q - 1) < n \leq (q^r - 1)/(q - 1).$$
8. [Rom92, Theorem 4.5.7] *The sphere-packing bound.* Suppose $\mathcal{C}$ is a block code of length n over $\mathbb{F}_q$ with distance d. Let $t = \left\lfloor \frac{d-1}{2} \right\rfloor$. Then
$$A_q(n, d)\left(1 + \binom{n}{1}(q - 1) + \binom{n}{2}(q - 1)^2 + \cdots \binom{n}{t}(q - 1)^t\right) \leq q^n.$$
9. [Hil86, pp. 20–21] The code $\mathcal{C}$ is perfect if and only if equality holds in the sphere-packing bound.
10. [Rom92, Theorem 4.5.7] Suppose $\mathcal{C}$ is a block code of length n over $\mathbb{F}_q$ with distance d. Then
$$A_q(n, d) \leq q^{n-d+1}.$$
11. *The Singleton bound for linear block codes.* For any $[n, k, d]$ linear code over $\mathbb{F}_q$, we have
$$d \leq n - k + 1.$$
12. An $(n - k) \times n$ matrix H with entries in $\mathbb{F}$ is the parity check matrix of an MDS code if and only if any $n - k$ columns of H are linearly independent. Equivalently, H has the property that any full size minor of H is invertible.
13. [MS77, pp. 546–547] *The Griesmer bound.* Let $N(k, d)$ be the length of the shortest binary linear code of dimension k and distance d. Then one has
$$N(k, d) \geq \sum_{i=0}^{k-1} \left\lceil \frac{d}{2^i} \right\rceil.$$

The right-hand side in the above inequality is, of course, always at least $d + k - 1$.

14. [Rom92, Theorem 4.5.16] *The Plotkin bound.* If $d \geq \frac{qn-n}{q}$, then

$$A_q(n, d) \leq \frac{dq}{d - qn - n}.$$

15. [Hil86, pp. 91–92] *The Gilbert Varshamov bound.* Assume q is a prime power. For any n and d, if k is the largest integer satisfying

$$q^k < \frac{q^n}{\displaystyle\sum_{i=0}^{d-2} \binom{n-1}{i} (q-1)^i},$$

then $A_q(n, d) \geq q^k$.

Examples:

1. Consider the binary [7,4] code $\mathcal{C}$ defined by the parity check matrix

$$H = \begin{bmatrix} 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 1 & 0 & 1 & 0 & 1 & 0 & 1 \end{bmatrix}.$$

This code has $2^4 = 16$ elements. Since any two columns of H are linearly independent, but the first three columns are dependent, it follows that $\mathrm{d}(\mathcal{C}) = 3$. So this code meets the sphere packing bound with $t = 1$. Observe that reading downward, the 7 columns of H form the numbers 1 through 7 in binary. This leads to a very nice nearest-neighbor decoding scheme that corrects any single error. If the received word is $\mathbf{y}$, the syndrome $\mathbf{s} = \mathbf{y}H^T$ consists of 3 bits. Interpret these 3 bits as a binary number, x. If x is 0, the received word is a codeword and we assume that no errors have occurred. If x is not 0, it is one of the numbers from 1 to 7. In $\mathbf{y}$ we change the bit in position x. This will give us a codeword (the unique codeword) at a distance of 1 from $\mathbf{y}$. We presume that this codeword is the intended transmission. For instance, if we receive the vector $\mathbf{y} = 1100100$, we compute the syndrome $\mathbf{s} = \mathbf{y}H^T = 110$. Interpreting 110 as a binary number, we obtain $x = 6$. We change the sixth bit of $\mathbf{y}$ and obtain the codeword 1100110. This codeword is at a Hamming distance 1 from $\mathbf{y}$, and we assume it was the intended transmission.

2. Assume $\alpha_1, \ldots, \alpha_n$ are pairwise different nonzero elements of a finite field $\mathbb{F}$. Let

$$H := \begin{bmatrix} \alpha_1 & \alpha_2 & \ldots & \alpha_n \\ \alpha_1^2 & \alpha_2^2 & \ldots & \alpha_n^2 \\ \vdots & & & \vdots \\ \alpha_1^{n-k} & \alpha_2^{n-k} & \ldots & \alpha_n^{n-k} \end{bmatrix}.$$

Then any full-size minor is the determinant of a Vandermonde matrix and, hence, nonzero. So H represents the parity check matrix of an MDS code.

73.4 Important Classes of Linear Codes 1

Definitions:

Let $\mathbb{F} = \mathbb{F}_q$.

Let r be a positive integer. Let $\mathbb{P}(\mathbb{F}^r)$ be the set of all 1-dimensional subspaces of $\mathbb{F}^r$. Choose a basis vector for each element of $\mathbb{P}(\mathbb{F}^r)$. Let H be a matrix whose columns are these basis vectors. The matrix H is the parity check matrix of a **Hamming code**, $\mathcal{C}$.

A **cyclic code** is a linear code $\mathcal{C}$ for which every cyclic shift of a codeword is again a codeword.

Let $\mathbb{F}[x]$ be the polynomial ring in one indeterminate over $\mathbb{F}$. Let $\langle x^n - 1\rangle$ be the ideal generated by $x^n - 1$. The quotient ring $\mathbb{F}[x]/\langle x^n - 1\rangle$ is denoted R_n. The polynomials of R_n are identified with vectors in $\mathbb{F}^n$ via

$$a_0 + a_1x + a_2x^2 + \cdots a_{n-1}x^{n-1} \longmapsto [a_0 \quad a_1 \quad a_2 \quad \cdots \quad a_{n-1}].$$

Suppose $k < n$ are positive integers and $r = n-k$. A polynomial $g(x) = a_0+a_1x+a_2x^2+\cdots+a_rx^r$ dividing $x^n - 1 \in \mathbb{F}[x]$ is a **generator polynomial** of a cyclic $[n, k]$-code, $\mathcal{C}$. The polynomial $h(x) = b_0 + b_1x + b_2x^2 + \cdots + b_kx^k$ chosen so that $g(x)h(x) = x^n - 1$ is the **parity check polynomial** of $\mathcal{C}$.

Facts:

1. The ring R_n forms an n-dimensional vector space over $\mathbb{F}$. The monomials $\{1, x, x^2, \ldots, x^{n-1}\}$ form a basis. It further has an algebra structure over $\mathbb{F}$ (i.e., there is a well-defined multiplication). In fact, polynomials in R_n are multiplied as usual, but $x^n = 1$ in R_n, so exponents are reduced modulo n.
2. The cardinality of $\mathbb{P}(\mathbb{F}^r)$ is $n = (q^r - 1)/(q - 1)$. Thus, the parity check matrix, H, of a Hamming code is of size $r \times n$. The corresponding Hamming code $\mathcal{C}$ has q^k elements where $k = n - r$. Furthermore, the distance $d(\mathcal{C}) = 3$. The Hamming code reaches the sphere packing bound and hence is a perfect code in all cases.
3. [Hil86, pp. 147–148] For cyclic codes, R_n has the structure of a principal ideal ring (any ideal is generated by a single polynomial). Thus, any cyclic code has a generator polynomial $g(x)$ where $g(x)$ is a divisor of $x^n - 1$. Moreover, every cyclic code has a parity check polynomial, namely $h(x) = (x^n - 1)/g(x)$.
4. [Hil86, Chap. 12] If $\mathcal{C}$ is a cyclic code with generator polynomial $g(x) = a_0 + a_1x + a_2x^2 + \cdots + a_rx^r$ and parity check polynomial $h(x) = b_0 + b_1x + b_2x^2 + \cdots + b_kx^k$, then the corresponding generator matrix, G, and parity check matrix, H, of $\mathcal{C}$ are given by

$$G = \begin{bmatrix} a_0 & a_1 & a_2 & \cdots & a_r & 0 & 0 & \cdots & 0 \\ 0 & a_0 & a_1 & a_2 & \cdots & a_r & 0 & \cdots & 0 \\ 0 & 0 & a_0 & a_1 & a_2 & \cdots & a_r & \cdots & 0 \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \\ 0 & 0 & 0 & \cdots & a_0 & a_1 & a_2 & \cdots & a_r \end{bmatrix}$$

and

$$H = \begin{bmatrix} b_k & \cdots & b_2 & b_1 & b_0 & 0 & 0 & \cdots & 0 \\ 0 & b_k & \cdots & b_2 & b_1 & b_0 & 0 & \cdots & 0 \\ 0 & 0 & b_k & \cdots & b_2 & b_1 & b_0 & \cdots & 0 \\ & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \ddots & \\ 0 & 0 & 0 & \cdots & b_k & \cdots & b_2 & b_1 & b_0 \end{bmatrix}.$$

Examples:

1. For $q = 5$ and $r = 2$, we get the $[6, 4, 3]$-Hamming code over $\mathbb{F}_5$ with parity check matrix

$$H = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 2 & 3 & 4 \end{bmatrix}$$

and generator matrix

$$G = \begin{bmatrix} 4 & 4 & 1 & 0 & 0 & 0 \\ 4 & 3 & 0 & 1 & 0 & 0 \\ 4 & 2 & 0 & 0 & 1 & 0 \\ 4 & 1 & 0 & 0 & 0 & 1 \end{bmatrix}.$$

2. The binary repetition code of length n is a cyclic code with generator polynomial $1 + x + \cdots + x^{n-1}$. The binary even weight code is a cyclic code with generator polynomial $1 + x$.
3. Over $\mathbb{F}_2$, the polynomial $x^7 - 1 = x^7 + 1 = (1 + x)(1 + x + x^3)(1 + x^2 + x^3)$. Hence, $g(x) = 1+x+x^3$ is the generator polynomial of a binary $[7, 4]$-cyclic code. The corresponding parity check polynomial is $h(x) = (1 + x)(1 + x^2 + x^3) = 1 + x + x^2 + x^4$. So, the generator matrix G and parity check matrix H for this code are given by

$$G = \begin{bmatrix} 1 & 1 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 1 \end{bmatrix} \quad \text{and} \quad H = \begin{bmatrix} 1 & 0 & 1 & 1 & 1 & 0 & 0 \\ 0 & 1 & 0 & 1 & 1 & 1 & 0 \\ 0 & 0 & 1 & 0 & 1 & 1 & 1 \end{bmatrix}.$$

Noting that the columns of H represent all the nonzero elements of $\mathbb{F}_2^3$, we see that this code is an equivalent version of the Hamming $[7, 4]$-perfect code.

73.5 Important Classes of Linear Codes 2

Definitions:

The **Golay codes** [Gol49] are two cyclic codes defined as follows.

The **binary Golay code**, G_{23}, is a $[23, 12, 7]$ binary cyclic code with generator polynomial $g(x) = \left(x^{11} + x^{10} + x^6 + x^5 + x^4 + x^2 + 1\right)$.

The **ternary Golay code**, G_{11}, is an $[11, 6, 5]$ cyclic code over the ternary field $\mathbb{F}_3$ with generator polynomial $g(x) = \left(x^5 + 2\,x^3 + x^2 + 2\,x + 2\right)$.

Denote by $\mathbb{F}[x; k - 1]$ the set of all polynomials of degree at most $k - 1$ over $\mathbb{F}$. Assume $\mathbb{F}$ has size $|\mathbb{F}| > n$ and let α be a primitive of $\mathbb{F}$ (i.e., α is a generator of the cyclic group $\mathbb{F}^*$). Define the linear map (called the evaluation map) by

$$\begin{array}{rccc} ev: & \mathbb{F}[x; k-1] & \longrightarrow & \mathbb{F}^n \\ & f & \longmapsto & (f(\alpha), \ldots, f(\alpha^n)) \,. \end{array}$$

The image of this map is a **Reed–Solomon code**.

Let $\mathbb{F} = \mathbb{F}_q$ be a fixed finite field and consider the polynomial $p(x) = x^n - 1 \in \mathbb{F}[x]$ and let the root w of $p(x)$ be a primitive nth root of unity. Let b, d be positive integers.

$$\mathcal{B}_q(n, d, b, w) := \{c(x) \in \mathbb{F}[x; k - 1] \mid c(w^{b+i}) = 0 \text{ for } i = 0, \ldots, d - 2\}$$

is called a **Bose–Chadhuri–Hocquenghem (BCH) code** having designed distance d. In the special case when $n = q^m - 1$, $\mathcal{B}_q(n, d, b, w)$ is a **primitive BCH code**; and if $b = 1$, $\mathcal{B}_q(n, d, b, w)$ is a **narrow sense BCH code**.

Facts:

1. Over the binary field $\mathbb{F}_2$,

$$x^{23}+1=(x^{11}+x^{10}+x^6+x^5+x^4+x^2+1)(x^{11}+x^9+x^7+x^6+x^5+x+1)(x+1).$$

Therefore, the binary Golay code, G_{23}, has parity check polynomial $h(x)=(x^{11}+x^9+x^7+x^6+x^5+x+1)(x+1)$.

2. [Hil86, pp. 153–157] The binary Golay code G_{23} is a $[23,12,7]$ code having 4096 elements. G_{23} is a perfect code.
3. Over the ternary field $\mathbb{F}_3$,

$$x^{11}-1=(x^5+2x^3+x^2+2x+2)(x^5+x^4+2x^3+x^2+2)(x+2).$$

Therefore, the ternary Golay code, G_{11}, has parity check polynomial $h(x)=(x^5+x^4+2x^3+x^2+2)(x+2)$.

4. [Hil86, pp. 157–159] The Golay code G_{11} is a ternary $[11,6,5]$ code having 729 elements. G_{11} is a perfect code.
5. [Hil86, Theorem 9.5] Here is a complete catalog of perfect linear codes up to equivalence:
   (a) The trivial perfect codes: All of $\mathbb{F}^n$, and the binary repetition codes of odd length.
   (b) The Hamming codes.
   (c) The Golay codes G_{23} and G_{11}.
6. Regarding Reed–Solomon codes, the linear map *ev* is one-to-one. Hence, the defined Reed–Solomon code is an $[n,k]$ code. By the fundamental theorem of algebra the minimum weight of a nonzero code word is $n-k+1$. It follows that a Reed–Solomon code is MDS. With regard to the natural basis $1,x,\dots,x^{k-1}$ of $\mathbb{F}[x;k-1]$, this code has a generator matrix:

$$G:=\begin{bmatrix} 1 & 1 & \dots & 1 \\ \alpha & \alpha^2 & \dots & \alpha^n \\ \vdots & & & \vdots \\ \alpha^{k-1} & \alpha^{2(k-1)} & \dots & \alpha^{n(k-1)} \end{bmatrix}.$$

7. Regarding BCH codes, it is immediate from the definition that $\mathcal{B}_q(n,d,b,w)$ has a parity check matrix of the form

$$H:=\begin{bmatrix} 1 & w^b & \dots & w^{(n-1)b} \\ 1 & w^{b+1} & \dots & w^{(n-1)(b+1)} \\ \vdots & & & \vdots \\ 1 & w^{b+d-2} & \dots & w^{(n-1)(b+d-2)} \end{bmatrix}.$$

It should be noted that $\mathcal{B}_q(n,d,b,w)$ is the $\mathbb{F}_q$ kernel of H and that the entries of H are in general not in the base field $\mathbb{F}_q$. Assume $w\in\mathbb{F}_{q^s}$, where $\mathbb{F}_{q^s}$ is an extension field of $\mathbb{F}_q$. The $\mathbb{F}_{q^s}$ kernel of H is a Reed–Solomon code of distance d. As a consequence, we have that $\mathcal{B}_q(n,d,b,w)$ has distance at least d.

8. [Rom92, Chap. 8] The BCH code $\mathcal{B}_q(n,d,b,w)$ is a cyclic code. For $i=0,\dots,d-2$, let $m_i(x)\in\mathbb{F}_q[x]$ be the minimal polynomial of w^{b+i} and let

$$g(x):=\operatorname{lcm}\{m_i(x)\mid i=0,\dots,d-2\}\in\mathbb{F}_q[x].$$

Then $g(x)$ is a generator of the cyclic code $\mathcal{B}_q(n,d,b,w)$ and its dimension is

$$\dim\mathcal{B}_q(n,d,b,w)=n-\deg g(x).$$

9. [Mas69], [FWR$^+$94], [Sud97], [KV03] Reed–Solomon codes and BCH codes can be efficiently decoded up to half the designed distance using the Berlekamp–Massey algorithm [Mas69]. Extensions for this algorithm exist for algebraic geometric codes [FWR$^+$94]. Using improved algorithms for evaluating polynomials over finite fields, the decoding complexity of BCH codes and more general algebraic geometric codes has recently been improved [ERS12].
10. The above algorithms have the major drawback that no *soft information* can be processed. This means that the decoder needs a vector in $\mathbb{F}^n$ as an input and it is not possible to process real numbers as they naturally occur in wireless communication. In 1997, Sudan [Sud97] achieved a major breakthrough when he came up with a polynomial time algorithm for list decoding of Reed–Solomon codes. Since that time the technique has been vastly improved and generalized and a broad overview is given in [Gur04] and [KV03]. A good introduction into list decoding is given in [JH04].

Examples:

1. *Algebraic Geometric Codes.* In 1977, Goppa had the idea to vastly generalize the construction techniques of Reed–Solomon codes and BCH codes. Goppa codes became famous in 1982 when Tsfasman, Vladut, and Zink [TVZ82] constructed an infinite family of codes that exceeds the Gilbert Varshamov bound. (For further details, the reader is referred to the extensive literature on this subject [Gop81], [Gop88], [LG88], [TV91], and [Wal00].

   Consider the *projective plane* $\mathbb{P}^2_{\mathbb{F}}$ and let $V \subset \mathbb{P}^2_{\mathbb{F}}$ be a *smooth curve* of degree θ. This means there is an irreducible homogeneous polynomial $\varphi(x, y, z) \in \mathbb{F}[x, y, z]$ of degree θ with

$$V = \{(\alpha, \beta, \gamma) \in \mathbb{P}^2_{\mathbb{F}} \mid \varphi(\alpha, \beta, \gamma) = 0\}.$$

   The smoothness is characterized by the fact that there is no point on the curve where the partial derivatives vanish simultaneously. $\Gamma(V) := \mathbb{F}[x, y, z]/ < \varphi >$ is called the homogeneous coordinate ring. As $\Gamma(V)$ is a domain, there is a well-defined quotient field $k(V)$, which is called the *homogeneous function field.* (See, e.g., [Ful89, p.91].)

   If $f \in k(V)$, then f has an *associated divisor*

$$(f) := \sum_{P \in V} \mathrm{ord}_P(f) P,$$

   where $\mathrm{ord}_P(f)$ is m if f has a pole of order m at P and $-m$ if f has a zero of order m at P.

   Let $D = P_1 + \cdots + P_n$ be a divisor on V of degree n. Define the vector space

$$L(D) := \{f \in k(V)^* \mid (f) + D \geq 0\} \cup \{0\}.$$

   Let G be a divisor on V having support disjoint from D. Consider the linear map:

$$\begin{array}{rccc} ev: & L(G) & \longrightarrow & \mathbb{F}^n \\ & f & \longmapsto & (f(P_1), \ldots, f(P_n)). \end{array}$$

   The image $\mathcal{C}(D, G)$ of the linear evaluation map ev is called an *algebraic geometric Goppa (AG) code.* Note that $\mathbb{F}[x; k-1]$ is a linear space of the form $L(G)$ and in this way Reed–Solomon codes are AG codes.

   Let $\mathcal{C}(D, G)$ be an algebraic geometric Goppa code defined from a curve of degree θ. If $\deg G < n$, then

$$\dim C(D, G) = \dim L(G) - \dim L(G - D) \geq \deg G + 1 - \frac{1}{2}(\theta - 1)(\theta - 2)$$

   and for the distance one has the lower bound

$$d(\mathcal{C}(D, G)) \geq n - \deg G.$$

Note that $\frac{1}{2}(\theta-1)(\theta-2)$ is the genus of the curve. One way to construct AG codes with good distance parameters is, therefore, to construct curves of low genus having many $\mathbb{F}_q$ rational points.

2. *Low density parity check codes.* A class of linear codes of tremendous practical importance was introduced by Gallager in his dissertation [Gal63]. These binary linear codes were called *low density parity check (LDPC) codes* by the author and are characterized by the property that the code can be written as the kernel of a very sparse matrix. For example, Gallager studied codes whose parity check matrix had three 1s in every column and six 1s in every row randomly chosen.

   LDPC codes come with the remarkable property that efficient decoding algorithms exist whose complexity increases linearly with the code length [RU01]. One of simplest algorithms is the *bit flipping algorithm.* For this, assume that H is a sparse parity check matrix, a code word $\mathbf{v}$ was sent, and a vector $\mathbf{y}=\mathbf{v}+\mathbf{e}$ was received. The algorithm then checks bit-by-bit if the weight of the syndrome vector $\mathbf{y}H^T$ increases or decreases if the bit under consideration is flipped. The bit flipping algorithm is one of the most simple types of message passing algorithms.

   LDPC codes were later generalized by Tanner [Tan81] who defined linear codes defined through graphs. It has been shown that LDPC codes [RSU01] can approach Shannon capacity. A good overview to this active area of research can be found in [MR01]. The class of LDPC codes and codes on graphs became prominent again after the discovery of Turbo codes [BGT93].

73.6 Convolutional Codes

Aside from linear block codes, the codes most used in engineering practice are convolutional codes. For this, consider the situation where a large amount of data has to be encoded by a linear block code. Let $\mathbf{m_0},\dots,\mathbf{m}_\tau\in\mathbb{F}^k$ be $\tau+1$ blocks of messages to be transmitted and assume G is the generator matrix of a linear $[n,k]$ code. The encoding scheme:

$$\mathbf{m_i}\longmapsto\mathbf{m_i}G=\mathbf{x_i},\quad i=0,\dots,\tau$$

can be compactly written in the form

$$\mathbf{m}(z)\longmapsto\mathbf{m}(z)G=\mathbf{x}(z),$$

where

$$\mathbf{m}(z):=\sum_{i=0}^{\tau}\mathbf{m_i}z^i\in\mathbb{F}^k[z]\qquad\text{and}\qquad\mathbf{x}(z):=\sum_{i=0}^{\tau}\mathbf{x_i}z^i\in\mathbb{F}^n[z].$$

Elias [Eli55] had the original idea to replace in this encoding scheme the generator matrix G with a $k\times n$ matrix $G(z)$ whose entries are elements of the polynomial ring $\mathbb{F}[z]$.

Definitions:

Consider the polynomial ring $R:=\mathbb{F}[z]$. A submodule $\mathcal{C}\subseteq R^n$ is called a **convolutional code**. The **rank** of the code $\mathcal{C}$ is the rank, k, of $\mathcal{C}$ considered as an R-module. $\mathcal{C}$ is an $[n,k]$-convolutional code. The **rate** of $\mathcal{C}$ is k/n.

A **generator matrix** for the rate k/n convolutional code $\mathcal{C}$ is a $k\times n$ polynomial matrix G with entries in R such that

$$\mathcal{C}=\{\mathbf{m}G=\mathbf{x}\mid\mathbf{m}\in R^k,\ \mathbf{x}\in R^n\}.$$

The **degree** of the convolutional code $\mathcal{C}$ with generator matrix G is defined to be the largest degree of any $k\times k$ minor of G.

Let $\mathbf{x}(z) = \sum_{i=0}^{\tau} \mathbf{x_i} z^i \in R^n$ be a code vector. Define the **weight of** $\mathbf{x}(z)$ by

$$\mathrm{wt}(\mathbf{x}(z)) := \sum_{i=0}^{\tau} \mathrm{wt}(\mathbf{x_i}).$$

The **free distance** of the convolutional code $\mathcal{C}$ is defined as

$$d_{\text{free}}(\mathcal{C}) := \min\{\mathrm{wt}(\mathbf{x}(z)) \mid \mathbf{0} \neq \mathbf{x}(z) \in \mathcal{C}\}. \tag{73.1}$$

Facts:

1. [Hun74] R is a principal ideal domain and $\mathcal{C}$ is, therefore, a free R-module. As such, $\mathcal{C}$ has a well-defined rank k, and a $k \times n$ generator matrix G with entries in R, such that
$$\mathcal{C} = \{\mathbf{m}G = \mathbf{x} \mid \mathbf{m} \in R^k,\ \mathbf{x} \in R^n\}.$$
2. If G_1 and G_2 are both $k \times n$ generator matrices of the same convolutional code $\mathcal{C}$, then there exists a unimodular matrix $U \in Gl_k(R)$ such that $G_2 = UG_1$.
3. The degree of a convolutional code is well-defined (i.e., it does not depend on the particular generator matrix chosen). In the literature the degree is sometimes also called the *total memory* [LC83] or the *overall constraint length* [JZ99] or the *complexity* [Pir88].
4. The free distance of a convolutional code measures the smallest distance between any two different code words.
5. A major design problem in the area of convolutional codes is the construction of $[n, k]$ codes of degree δ whose free distance is maximal or near maximal. This question constitutes the generalization of the *main linear coding problem.*
6. If $\mathcal{C}$ is an $[n, k]$ convolutional code having $G(z)$ as a generator matrix, then there exists an $(n - k) \times n$ parity check matrix $H(z)$ with entries in R. $H(z)$ is characterized by the property that $G(z)H(z)^T = \mathbf{0}_{k\times k}$.
7. Convolutional codes of degree zero correspond to linear block codes.
8. Convolutional codes of small degree can be efficiently decoded using the Viterbi decoding algorithm [LC83, Chap. 11]. This algorithm has the distinct advantage that soft decision can be processed and due to this fact convolutional codes became the codes of choice for many wireless applications.
9. The free distance of an $[n, k]$ convolutional code of degree δ must satisfy the *generalized Singleton bound* [RS99]:
$$d_{\text{free}}(\mathcal{C}) \leq (n - k)\Big(\Big[\frac{\delta}{k}\Big] + 1\Big) + \delta + 1.$$
10. Convolutional codes achieving the generalized Singleton bound are called *MDS convolutional codes.* Such codes exist as soon as the field size is large enough [RS99].
11. The literature on convolutional codes is not consistent in terms of terminology and definitions. Classical articles are [MS67] and [For70]. The articles [McE98] and [Ros01] provide surveys on recent developments and further connections. Generalizations to multidimensional convolutional codes were considered and the reader will find further reading and references in [GRW00].

In contrast to the theory of linear block codes, there are not so many algebraic construction techniques of convolutional codes with a good designed distance and even fewer constructions of codes that can be efficiently decoded. The reader will find algebraic constructions of convolutional codes in [GS04], [Jus75], [Pir88], [RSY96], [SGL$^+$01], and in the bibliographies of these articles.

12. As one can see convolutional codes as a generalization of linear block codes, it is also true that nearest-neighbor decoding (with respect to the Hamming distance and over the symmetric channel) is an NP-hard problem [BMT78]. Over the *erasure channel* decoding of linear block codes and decoding of convolutional codes are concrete linear algebra problems. The decoding capability of convolutional codes over the erasure channel was investigated in [TRS12].

Examples:

1. Consider the finite field $\mathbb{F}_5$. The generator matrix $G(z) = (z, z+1, z+2, z+3)$ defines an $[n,k] = [4,1]$ convolutional code $\mathcal{C}$ of degree $\delta = 1$ and distance $d_{\text{free}}(\mathcal{C}) = 7$. The generalized Singleton bound for these parameters n, k, and δ is 8 and the defined code is, therefore, not an MDS convolutional code.
2. [RS99, Ex. 2.13]. Consider the finite field $\mathbb{F}_7$ and the generator matrix

$$G(z) = \begin{bmatrix} (z^2+1) & (3z^2+1) & (5z^2+1) \\ (z-1) & (z-2) & (2z-3) \end{bmatrix}.$$

   Then $G(z)$ defines an $[n,k] = [3,2]$ convolutional code $\mathcal{C}$ of degree $\delta = 3$ and distance $d_{\text{free}}(\mathcal{C}) = 6$. The generalized Singleton bound for these parameters n, k, and δ is 6 and the defined code is therefore an MDS convolutional code.

73.7 Random Linear Network Codes

For the situation of communication networks which involve possibly many senders, many receivers, and many intermediate nodes during transmission, new classes of codes called random linear network codes [HMK$^+$06] have been introduced.

Koetter and Kschischang [KK08] introduced a mathematical framework where a code word is a subspace of the vector space $\mathbb{F}_q^n$.

Denote by $\mathcal{P}(q,n)$ the set of all linear subspaces of $\mathbb{F}_q^n$. Let $U, V \in \mathcal{P}(q,n)$ be two subspaces of $\mathbb{F}_q^n$. The **subspace distance** is defined through:

$$\begin{aligned} d_S(U,V) &= \dim(U+V) - \dim(U \cap V) \\ &= \dim(U) + \dim(V) - 2\dim(U \cap V) \end{aligned}$$

and defines a metric on $\mathcal{P}(q,n)$. Denote by $\text{Grass}_q(k,n)$ the **Grassmannian** consisting of all k-dimensional subspaces of $\mathbb{F}_q^n$. A subset $\mathcal{C}$ of $\text{Grass}_q(k,n)$ is called a **constant dimension subspace code** or simply **subspace code**. The subspace distance d_S induces on the code $\mathcal{C}$ the distance

$$d_S(\mathcal{C}) = \min\{d_S(U,V) \mid U, V \in \mathcal{C} \text{ and } U \neq V\}.$$

As in the classical situation it is a major research goal to come up for all parameters k, n, q, d with constructions of codes $\mathcal{C} \subset \text{Grass}_q(k,n)$ whose distance $d_S(\mathcal{C}) = d$ and whose cardinality is maximal. Constructions of subspace codes and bounds on the possible cardinalities of subspace codes are given in [EV11], [KK08], and [SE11].

Facts:

1. Subspace codes are closely related to *rank matrix codes* introduced and studied by Gabidulin [Gab85]. A rank matrix code is a subset of the space $\mathbb{F}_q^{k\times m}$ consisting of $k \times m$ matrices with entries in $\mathbb{F}_q$. If $A, B \in \mathbb{F}_q^{k\times m}$ one defines the distance $d(A,B) :=$

rank$(A - B)$. This is a metric on $\mathbb{F}_q^{k\times m}$ and rank matrix codes therefore have a well-defined distance. When $\mathcal{C} \subset \mathbb{F}_q^{k\times m}$ has distance d, then the subspace code:

$$\{\text{rowspace}[I_k\ A] \mid A \in \mathcal{C}\}$$

has distance $2d$.

Examples:

1. The distance of a constant dimension subspace code $\mathcal{C} \subset \text{Grass}_q(k, n)$ attains its maximal value $d_S(\mathcal{C}) = 2k$ if and only if $\dim(U \cap V) = 0$ for any two different code words $U, V \in \mathcal{C}$. A code $\mathcal{C} \subset \text{Grass}_q(k, n)$ whose distance is $2k$ and which has the property that for any $0 \neq v \in \mathbb{F}_q^n$ there exists necessarily a unique $U \in \mathcal{C}$ such that $v \in U$ is called a *spread code*. Spread codes are spreads in the sense of finite projective geometry [Hir98] and they exist if and only if $k \mid n$. An efficient decoding algorithm for spread codes can be found in [GMR12].

Modern computer science emerged when the eminent British mathematician Alan Turing invented the concept of Turing machine (TM) in 1936. Though very simple and primitive, TM serves as the universal model for all known physical computation devices. The principles of quantum mechanics, another revolutionary scientific discovery of the 20th century, had never been incorporated in the theory of computation until the early 1980s. Benioff first coined the concept of quantum Turing machine (QTM). Motivated by the problem that classical computers cannot simulate quantum systems efficiently, Feynman posed the quantum computer as the solution. The field of quantum computation was born.

Quantum computation mainly studies the construction and analysis of quantum algorithms that outperform the classical counterparts. In terms of computability, quantum computers and classical computers possess exactly the same computational power. But in terms of computational complexity, which measures the efficiency of computation, there are many examples confirming that quantum computers do solve certain problems faster. The two most significant ones are Shor's factorization algorithm and Grover's search algorithm, among other examples such as the Deutsch–Jozsa problem, the Bernstein–Vazirani problem, and Simon's problem.

Quantum computers share many common features of the classical computers. In a classical computer, information is encoded in binary states (for example, 0 denotes the low voltage state and 1 denotes the high voltage state), and processed by various logic gates. In a quantum computer, information is represented by the states of the microscopic quantum systems, called qubits, and manipulated by various quantum gates. A qubit could be a two-level atom in the excited/ground states, a photon with horizontal/vertical polarizations, or a spin-$\frac{1}{2}$ particle with up/down spins. The state of a qubit can be controlled via physical devices such as laser and microwave. The distinctions between quantum and classical computers originate from the special characteristic of quantum mechanics. In contrast to a classical system, a quantum system can exist in different states at the same time, an interesting phenomenon called *superposition*. Superposition enables quantum computers to process data in parallel. That is why a quantum computer can solve certain problems faster than a classical computer. But, when we measure a quantum system, it randomly collapses to one of the basis states. This indeterministic nature makes the design of efficient quantum algorithms highly nontrivial. Another distinctive feature of the quantum computer is that the operations performed by quantum gates must be unitary. This is the natural consequence of the unobserved quantum systems evolving according to the Schrödinger equation.

Throughout this chapter, we will use Dirac's bra-ket notation (see Section 65.4 for more information). In quantum mechanics, the state of a quantum system is described by a unit vector in a complex Hilbert space (a complete inner product vector space). Under Dirac's bra-ket notation, we use $|\psi\rangle$ ("ket") to denote a vector in the Hilbert space and $\langle\psi|$ ("bra") for its dual. The inner product of two vectors $|\psi\rangle$ and $|\phi\rangle$ is denoted $\langle\psi|\phi\rangle$. We also use $|\psi\rangle|\phi\rangle$ and $|\psi\phi\rangle$ interchangeably with the notation for the tensor product $|\psi\rangle \otimes |\phi\rangle$.

74.1 Basic Concepts

Definitions:

A **(classical) Turing machine** (TM) is an abstract computing device consisting of a finite control, a two-way infinite tape, and a read/write head that moves to the left or right on the tape. It can be described by a 6-tuple $(Q, A, B, \delta, q_0, q_a)$, where Q is a finite set of control states, A a finite alphabet, $B \in A$ the blank symbol, q_0, $q_a \in Q$ the initial and accepting states, and δ the transition function

$$\delta : Q \times A \to Q \times A \times \{L, R\}.$$

L and R stand for moving left and right, respectively.

A **quantum Turing machine** (QTM) is an abstract computing device consisting of a finite control, a two-way infinite tape, and a read/write head that moves to the left or right of the tape. It can be described by a 6-tuple $(Q, A, B, \delta, q_0, q_a)$, where Q is a finite set of control states, A a finite alphabet, $B \in A$ the blank symbol, q_0, $q_a \in Q$ the initial and accepting states, and δ the transition amplitude function

$$\delta : Q \times A \times Q \times A \times \{L, R\} \to \mathbb{C}.$$

The transition amplitude function satisfies

$$\sum_{(q_2, a_2, d) \in Q \times A \times \{L,R\}} |\delta(q_1, a_1, q_2, a_2, d)|^2 = 1,$$

for any $(q_1, a_1) \in Q \times A$. L and R stand for moving left and right, respectively.

A **quantum bit** (qubit) is a two-level quantum system, modeled by the two-dimensional Hilbert space H_2, with basis $\{|0\rangle, |1\rangle\}$. For example, for a spin-$\frac{1}{2}$ particle, $|0\rangle$ and $|1\rangle$ denote the spin-down and spin-up states, respectively. They can be mapped to the standard basis for H_2 as $|0\rangle = [1 \quad 0]^T$ and $|1\rangle = [0 \quad 1]^T$.

A **quantum register** of length n is an ordered system of n qubits, modeled by the 2^n-dimensional Hilbert space $H_{2^n} = H_2 \otimes H_2 \otimes \ldots \otimes H_2$ with basis $\{|00\ldots00\rangle, |00\ldots01\rangle, |00\ldots10\rangle, |00\ldots11\rangle, \ldots, |11\ldots11\rangle\}$. The basis states are ordered in lexicographic order. We may also write each basis state as $|i\rangle$ for $0 \leq i < 2^n$, interpreting the n-bit string of 0s and 1s as the binary representation of i.

An **one-bit quantum gate** is a unitary map $U : H_2 \to H_2$.

An **n-bit quantum gate** is a unitary map $U : H_2 \otimes H_2 \otimes \ldots \otimes H_2 \to H_2 \otimes H_2 \otimes \ldots \otimes H_2$.

A **quantum circuit** on n bits is a unitary map on H_{2^n}, which can be represented by a concatenation of a finite number of quantum gates.

Facts:

1. [BV93] Any function which is computable by a TM is computable by a QTM.
2. [Fey82] Any function that is computable by a QTM is computable by a TM.
3. [NC00, p. 13] A general state of a qubit is a unit vector $a|0\rangle + b|1\rangle$, where $a, b \in \mathbb{C}$ and $|a|^2 + |b|^2 = 1$. a and b are the probability amplitudes of $|0\rangle$ and $|1\rangle$, respectively. A measurement of a qubit yields either $|0\rangle$ or $|1\rangle$, with probability $|a|^2$ or $|b|^2$, respectively.
4. [BB02] A general state of n-bit quantum register is a unit vector

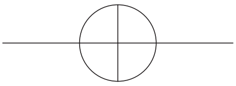
$$\sum_{x=00\ldots 0}^{11\ldots 1} \psi_x |x\rangle,$$

where $\psi_x \in \mathbb{C}$ and $\sum_{x=00\ldots 0}^{11\ldots 1} |\psi_x|^2 = 1$. ψ_x is the probability amplitude of $|x\rangle$. A measurement of a quantum register yields $|x\rangle \in \{|00\ldots 0\rangle, |00\ldots 1\rangle, \ldots, |11\ldots 1\rangle\}$, with probability $|\psi_x|^2$.

Examples:

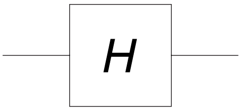
This section contains a list of quantum gates that are frequently used. We provide the description of their effects on the basis states, matrix representations, and circuit diagrams. In the circuit diagrams, the horizontal lines stand for the qubits. When there is no gate on the line, no operation is done, which can be interpreted as the identity operation. When the diagram of a gate shows up on a horizontal line/lines, the corresponding gate operation is applied to the qubit/qubits, with the input coming from the left and the output (result) going out to the right. The entire circuit diagram is read from left to right.

1. NOT gate Λ_0: $\Lambda_0|0\rangle = |1\rangle$, $\Lambda_0|1\rangle = |0\rangle$, or $\Lambda_0 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$.



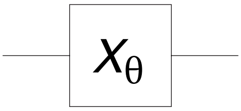
2. The Walsh–Hadamard gate H: $H|0\rangle = \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle)$, $H|1\rangle = \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle)$, or

$$H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}.$$



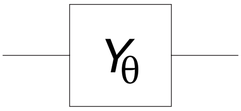
3. The x-rotation gate X_θ: $X_\theta|0\rangle = \cos\frac{\theta}{2}|0\rangle - i\sin\frac{\theta}{2}|1\rangle$, $X_\theta|1\rangle = -i\sin\frac{\theta}{2}|0\rangle + \cos\frac{\theta}{2}|1\rangle$, or

$$X_\theta = \begin{bmatrix} \cos\frac{\theta}{2} & -i\sin\frac{\theta}{2} \\ -i\sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{bmatrix}.$$



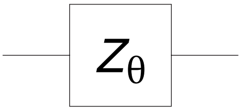
4. The y-rotation gate Y_θ: $Y_\theta|0\rangle = \cos\frac{\theta}{2}|0\rangle + \sin\frac{\theta}{2}|1\rangle$, $Y_\theta|1\rangle = -\sin\frac{\theta}{2}|0\rangle + \cos\frac{\theta}{2}|1\rangle$, or

$$Y_\theta = \begin{bmatrix} \cos\frac{\theta}{2} & -\sin\frac{\theta}{2} \\ \sin\frac{\theta}{2} & \cos\frac{\theta}{2} \end{bmatrix}.$$



5. The z-rotation gate Z_θ: $Z_\theta|0\rangle = e^{-i\theta/2}|0\rangle$, $Z_\theta|1\rangle = e^{i\theta/2}|1\rangle$, or

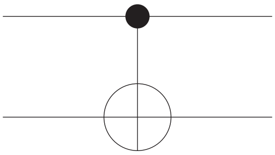
$$Z_\theta = \begin{bmatrix} e^{-i\theta/2} & 0 \\ 0 & e^{i\theta/2} \end{bmatrix}.$$



6. Controlled-NOT gate Λ_1: $\Lambda_1|00\rangle = |00\rangle$, $\Lambda_1|01\rangle = |01\rangle$, $\Lambda_1|10\rangle = |11\rangle$, $\Lambda_1|11\rangle = |10\rangle$, or,

$$\Lambda_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

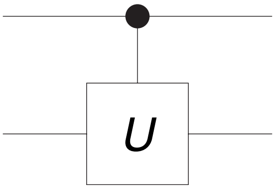
The first qubit acts as the control bit; the operation on the second qubit is controlled by it. If the control bit is $|0\rangle$, no operation is done on the second qubit. If the control bit is $|1\rangle$, the NOT gate is applied to the second qubit. There is no change on the control bit in either case. In the diagram for the Controlled-NOT gate, a black dot denotes the control bit and a vertical line signifies the control action.



7. Two-bit Controlled-U gate $\Lambda_1(U)$, where U is any arbitrary one-bit unitary transform: $\Lambda_1(U)|00\rangle = |00\rangle$, $\Lambda_1(U)|01\rangle = |01\rangle$, $\Lambda_1(U)|10\rangle = |1\rangle U|0\rangle$, $\Lambda_1(U)|11\rangle = |1\rangle U|1\rangle$, or,

$$\Lambda_1(U) = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & & \\ & & & U \\ 0 & 0 & & \end{bmatrix}.$$

The first qubit acts as the control bit; the operation on the second qubit is controlled by it. If the control bit is $|0\rangle$, no operation is done on the second qubit. If the control bit is $|1\rangle$, the one-bit gate U is applied to the second qubit. There is no change on the control bit in either case. In the diagram for the Controlled-U gate, a black dot denotes the control bit and a vertical line signifies the control action.

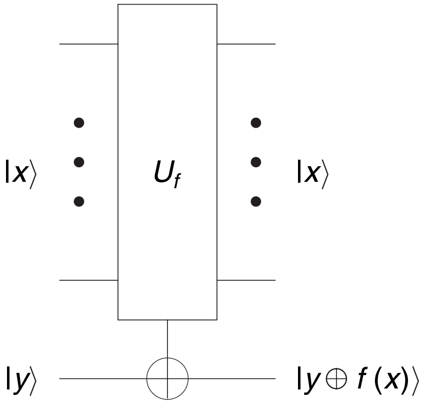


8. Function evaluation operator $U_f : H_{2^n} \otimes H_{2^m} \to H_{2^n} \otimes H_{2^m}$, where $f : \{0,1\}^n \to \{0,1\}^m$, $|x\rangle \in H_{2^n}$, and $|y\rangle \in H_{2^m}$, is given by

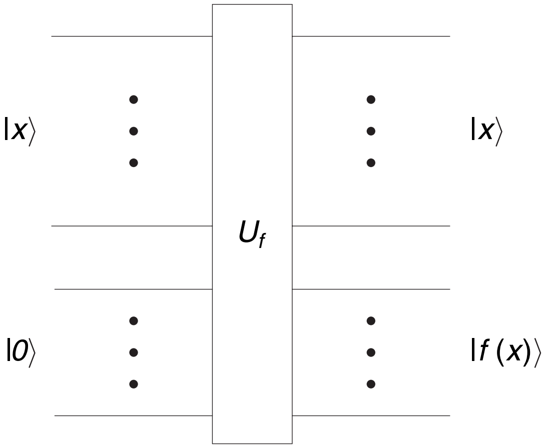
$$|x\rangle|y\rangle \to |x\rangle|y + f(x)\text{mod}2^m\rangle.$$

Two special cases of this operator will be used in the algorithms discussed later.

- $m = 1$, U_f is given by: $|x\rangle|y\rangle \to |x\rangle|y \oplus f(x)\rangle$, where $\oplus$ is the addition mod 2.



- $y = 0$, U_f is given by: $|x\rangle|0\rangle \to |x\rangle|f(x)\rangle$.



9. Quantum Fourier transform (QFT) (n-bit):

$$|x\rangle \to \frac{1}{2^{n-1}} \sum_{y=0}^{2^n-1} e^{2\pi i x y/2^n} |y\rangle,$$
